F. K. Brainard.[5] The authors are to be congratulated on giving such a clear exposition of their method of computing XY curves. However, the writer would like to ask if they can tell approximately how much error is introduced by making the approximations used in the paper. To begin with, Equation [3] is approximate only, and later in the paper the item $\Sigma T_d \frac{d\psi_n}{dt}$ is neglected as the authors state. (See place a few lines below Equation [10].) Also no mention is made of the variation in the synchronizing power of the motor with frequency which Mr. Putman stressed so much in an A.I.E.E. paper in 1926. At that time, the writer felt that this last phenomenon was due to the approximation in Equation [3] just mentioned and submitted an equation and its solution which fitted the case a little better and which seemed to render the idea of the synchronizing power's varying with the frequency unnecessary, although Mr. Putman did not agree with this.[6] In the present paper the authors neglect this point entirely as they make no use either of the method derived in the paper referred to above or the substitute method proposed by the writer. Probably the method used in this paper is sufficiently accurate for all practical purposes and the complication resulting from the other methods is not justified, but the writer would like to have the authors' opinion on this point.

Also there seems to be some discrepancy in the definition of the quantity X (or C as it is sometimes called).

Stevenson's definition of X (and the writer believes it was he who first proposed it) was as follows:[7]

$$X = \frac{0.80\, WR^2 \text{ r.p.m.}^4}{10^6\, P_0 f}$$

This, as stated by him, reduces to

[5] Electrical Engineer, Allis-Chalmers Manufacturing Company, Milwaukee, Wis.

[6] See Trans. A.I.E.E., vol. 45 (1926), p. 1124.

[7] See *Refrigerating Engineering*, vol. 2 (1924), p. 128.

$$X = 10\left(\frac{\text{r.p.m.}}{F}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [a]$$

where F = natural frequency in oscillation per minute
f = frequency of circuit in cycles per second, and
r.p.m. = revolutions per minute.

This seems a very logical definition since resonance with the fundamental occurs at $X = 10$. However, Stevenson's curves published in the same paper were apparently based on

$$X = 9\left(\frac{\text{r.p.m.}}{F}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [b]$$

Now the present authors propose

$$X = 9.25\left(\frac{\text{r.p.m.}}{F}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [c]$$

Hence it would seem quite desirable to standardize on some definition of X and the corresponding "flywheel constant" and not leave it to the individual to select his own definition.

The A.I.E.E. have adopted the following formula for natural frequency:

$$F = \frac{266{,}500}{\text{r.p.m.}}\sqrt{\frac{P_s f}{WR^2}}$$

where P_s = synchronizing power, which is defined as the rate of change of power with respect to the displacement angle expressed in kilowatts per electrical degree. Hence it would seem desirable to use P_s in this work also rather than P_0.

If the above value for F is substituted in Equation [*a*] and the resulting expression solved for WR^2

$$WR^2 = \frac{71.0\ P_s f X}{\left(\frac{\text{r.p.m.}}{100}\right)^4}$$

and the authors' flywheel constant F_c becomes

$$F_c = \frac{71.0\,P_s f}{\left(\frac{\text{r.p.m.}}{100}\right)^4} \quad \ldots\ldots\ldots\ldots\ldots\ldots [d]$$

If Equation (*b*) or (*c*) is used instead to define X, then F_c will become $\dfrac{79.0\ P_s f}{\left(\frac{\text{r.p.m.}}{100}\right)^4}$ or $\dfrac{76.8\ P_s f,}{\left(\frac{\text{r.p.m.}}{100}\right)^4}$ respectively.

Any of the above expressions will do, of course, but some one should be used, and that only.

The writer would also like to ask if there is any advantage in defining the synchronizing power in terms of power measured electrically at the motor terminals, as the authors have defined P_0, rather than mechanically at the motor shaft as P_s is presumably defined by the A.I.E.E. In the first case it results in the efficiency of the motor (or the ratio of the hp. output to kw. input which is proportional to efficiency) entering into the expression for F_c (see Equation [16] of the paper), while in the second case it does not and the expression for F_c is simplified correspondingly. (See Equation [*d*] above.)

M. C. Davison.[8] The writer was in very close touch with Mr. Putman and also with Mr. Stevenson of the General Electric Co. while they were both working very intensively on this flywheel problem. His company, he believes, is the only one making compressors that has gone far enough into the problem to get together sufficient information to solve its own flywheel problems. However, he has reached the conclusion that the present solution of the flywheel problem is entirely practical and dependable.

In cases where the writer's company has changed flywheels on machines which were put out before this problem was solved (there have probably been 25 or 30 of these), it has almost invariably been found that the trouble was due to the incorrect value of P_0 as given by the electrical manufacturers at the time the motor was purchased. It is further interesting to note that, in so far as it has been possible to determine, the new flywheels furnished on these old jobs have in every case remedied the trouble. Furthermore, the writer does not know of a single case of flywheel trouble the company has had since it has been working on the basis outlined in the paper.

There is one point brought out by the authors which the writer is inclined to question: They indicate that the ammonia-compressor manufacturers were the first to use plate valves and operate the reciprocating compressors at the higher speeds. As a matter of fact, the writer believes it will be found that compressor manufacturers had standardized synchronous-motor-driven plate-valve air compressors of the so-called "high speed" type before there was any appreciable movement among the ammonia-compressor builders toward the development of the synchronous-motor-driven direct-connected ammonia compressor.

M. N. Halberg.[9] The authors comment on the fact that their XY curves were plotted through the resonance points of the motor while this was not done by Dr. Stevenson in his original XY curves.

The writer questions the value of plotting these curves through resonance except for cases where the current pulsation is relatively low. The differential equation which is used in obtaining the XY curves is based on the assumption that the synchronous torque of the motor is directly proportional to the angle between the rotor and rotating magnetic field. For ordinary values of current pulsation this approximation is quite close, but if the pulsation is extremely high at resonance, as is the case with many air compressors, the assumption will be far from correct and the results obtained will have little meaning. On the other hand, if the current pulsation is relatively low at points near resonance, it might be of advantage to have the entire curve plotted, since values of X may be chosen quite close to the resonant point. However, in this case it would not be advisable to use an average value of the parameter λ for all the XY curves as was suggested in this paper, since the effect of variations in this parameter is quite large at points near resonance.

In discussing the application of synchronous motors to carbon dioxide compressors, the authors mention that little work has been done in calculating the flywheel requirements of this application. A paper entitled "Some Problems in the Application of Direct-Connected Synchronous Motors to Carbon Dioxide Compressors," by D. W. McLenegan, appeared in the January, 1927, issue of *Refrigerating Engineering*. The author of this paper discussed both the torque and flywheel requirements of synchronous motors direct-connected to a CO_2 compressor. A typical XY curve was shown for each type of compressor in general use. The advantages of 180-deg. cranks over 90-deg. cranks for certain types of CO_2 compressors were also pointed out and explained.

D. W. McLenegan.[10] The authors have presented a very useful paper. It is well to have this method of analysis com-

[8] Compressor Engineering Department, Ingersoll-Rand Co., New York, N. Y.

[9] General Electric Co., Schenectady, N. Y.

[10] Ibid.

pletely described and explained so that it may be applied more widely than it has been. The writer feels that they have made a valuable contribution by their data on compressors, both as to the suggested method of capacity reduction for air compressors, and by the method presented for taking account of the relative weights of high-pressure and low-pressure reciprocating parts.

The XY-curve method is not new but has been in constant commercial use for fully seven years, and has been checked by many oscillograph tests on various compressor installations. After the general solution of the flywheel problems had been worked out and presented to this Society in 1920 (Item 1 of the author's bibliography), the method was applied to a large number of compressors by calculating the current pulsation for various assumed values of WR^2 and plotting the results. However, this method was too slow and laborious for commercial use. It was found that these curves were of remarkably similar shape for all compressors of a given class. By dimensional analysis, Dr. A. R. Stevenson worked out the parameter X, by means of which the peaks of these curves could be superposed; and after correcting for the varying ratios of compressor-horsepower to motor rating, the curves for various compressors of the same class fell very close together. The remaining differences were explained by correcting for variations in weight of reciprocating parts and ratio of connecting-rod length to crank length.

Mr. Putman then redeveloped this same parameter X by the method described in this paper, and added a number of valuable short cuts which have been useful in constructing new XY curves—especially his resonance curves for the amplitude factor C, and the phase-shift curves. His curve tracer has also been very useful, and the original model is still in use at Schenectady.

The authors' suggestion regarding automatic operation of compressors, although apart from the main subject of the paper, is very interesting to the writer. A number of large automatic air compressors with synchronous drive are already operating, and he believes that similar arrangements will be worked out for ammonia compressors. However, he thinks that this will eventually be done by means of automatic bypassing rather than by high-torque motors. Motors of such characteristics would involve greater first cost, and also somewhat greater starting inrush, which would probably not be acceptable to power companies in most cases.

Standardization of a flywheel constant, as proposed by the authors, is very desirable. However, the writer thinks that this should be based on a motor constant such as P_0 or P_s, rather than the inclusive value F_c. P_s (which has been adopted by the A.I.E.E. in connection with the expression for natural frequency of oscillation of a synchronous machine) represents the kilowatts per electrical degree displacement of the rotor.

Either P_0 or P_s will have an approximate relationship to the kilowatt rating of the motor. This relationship is sometimes very useful as a means of estimating the value of P_0 or P_s. If the formula for flywheel effect were made to include X as a compressor factor and P_0 or P_s as a motor factor, then the remaining factors, namely, speed and frequency, could be incorporated in a single constant which could then be tabulated for all standard frequencies and synchronous speeds. The formula for required flywheel effect would then be:

$$WR^2 = X \times P_s \times E$$

where E would be taken directly from the proposed tabulation.

Authors' Closure

Mr. Goss and Mr. Putman. Answering Mr. Brainard's questions, we do not know what approximation is involved in the assumption of a constant value of T_s for a given case of current pulsation. All the oscillographic measurements of current pulsation which have been made have checked so close to the calculated values that we feel that whatever approximation is involved must be negligible. It is true that T_s varies with the frequency, and to get the correct value one must know the frequency of the principal pulsation in the particular case being investigated.

The omission of $\sum T_d \frac{d\psi_n}{dt}$ in calculating the torque pulsation corresponding to ψ_n is not at all necessary. In fact, this term was actually used in making many of our standard XY curves. The effect of damping on the shape of XY curves was clearly shown by Stevenson. (See Bibliographical Reference 3.)

After all, this paper presents nothing new so far as the fundamental theory is concerned. It is only an additional contribution to a well-known problem. It presents for general use the results of many hours of tedious work in applying known methods to the making of a standard set of XY curves.

Mr. M. C. Davison, in his discussion, says, "The writer does not know of a single case of trouble the company has had since it has been working on the basis outlined in this paper." Mr. D. W. McLenegan says in his discussion, "The XY curve method is not new, but has been in constant commercial use for fully seven years and has been checked by many oscillograph tests on various compressor installations." Such testimony should satisfy the most skeptical about the sufficiency of the fundamental solution.

Regarding the definition of "X" there should be no confusion. Dr. Stevenson's Equation [2] (Bibliographical Reference 3) for "X" is identical with the authors' Equation [15]. "X" is defined as 9.25 times the square of the ratio of the r.p.m. divided by the natural frequency in cycles per minute. This is the formula on which Stevenson's curves were based (Bibliographical Reference 3), not nine times as stated by Mr. Brainard. Stevenson's formula $X = \frac{0.80\, WR^2(\text{r.p.m.})^4}{10^8\, P_o f}$ is an approximate form assuming an efficiency of 93 per cent. The other formula $X = 10\left(\frac{\text{r.p.m.}}{F}\right)^2$ is an approximate form in which the efficiency is neglected entirely.

The P_s used in the A.I.E.E. natural frequency formula is supposed to be defined as the rate of change of input power with respect to the displacement expressed in kilowatts per electrical degree. This definition is the same as that of P_s except that displacement is expressed in electrical degrees instead of in electrical radians.

We are glad to have Mr. Davison's correction of our statement regarding the development of the high-speed compressor valves.

We wish to apologize for omitting reference to Mr. McLenegan's excellent paper entitled, "Some Problems in the Application of Direct-Connected Synchronous Motors to Carbon-Dioxide Compressors."

Mr. Putman. Mr. Halberg has questioned the value of plotting XY curves through the resonance points. Both Dr. Stevenson and the writer thought this was desirable, but the problem was to do it and still keep the XY curve a characteristic curve of a compressor type only; that is, keep it independent of the motor speed. It was for this reason that the writer suggested that an average value of $\lambda = 0.1$ be used in plotting the curves. It was recognized, of course, that such curves would not be accurate near the resonance points. When it was necessary to investigate a case of operation near resonance, it was necessary to calculate a curve based on the correct value of λ.

I am glad to hear from Mr. McLenegan that my original curve tracer is still in use in Schenectady. The curve tracer pictured

in the paper is the second one designed, and its mechanical features have been considerably improved. I will be glad to supply further information regarding the construction of this curve tracer to any one desiring to build one.

I like Mr. McLenegan's suggestion for a standard flywheel constant. I have often felt that our F_c had a decided disadvantage in that it bears no simple relation to the horsepower or kilowatt rating of the machine. I always did like P_o, because one could guess its value so easily from the kilowatt rating of the machine. I suggest that Mr. McLenegan place before the N.E.M.A. his suggested tabulation and formula for calculating the WR^2 since this association now has under consideration the adoption of standard values of X for different compressor applications.

APM-51-13

Design of Ellipsoidal Heads for Pressure Vessels

By T. W. GREENE,[1] NEW YORK, N. Y.

This paper, after dealing theoretically with the stresses set up in cylindrical pressure vessels provided with ellipsoidally dished heads, gives results of tests made on a propane storage tank 7 ft. in diameter, 38 ft. 4 in. long, and designed for a working pressure of 200 lb. per sq. in., the heads being ellipsoidal with a 2-to-1 ratio of axes. From these results the author concludes that (1) heads with dish and large knuckle radii proportioned to closely approximate true ellipsoidal shapes with a ratio of axes of 2 to 1, are far superior to the flat dished heads with small knuckle radii commonly used in pressure vessels; (2) that the stress distribution in such heads closely approximates that set forth by theory, and that in consequence the formulas presented in the paper can be safely used for design.

DURING the last few years, advantage has been taken of the construction of a large number of pressure tanks to make an intensive study of the design and stress distribution in pressure vessels with the object of developing correct procedure and methods of construction for oxyacetylene-welded vessels. This has been necessitated by the high test pressure generally specified for welded equipment, which, in accordance with standard practice, is three times the working pressure or a maximum test fiber stress of 24,000 to 27,000 lb. per sq. in. These high test pressures, abnormally high compared to test pressures for other types of construction, have shown that extremely high stresses and excessive straining far out of proportion to those in the shell, exist in certain parts of the heads. High stress concentration has especially been noted around standard nozzle and saddle-reinforced manholes, and at the sharp knuckles of flat-dished heads commonly used in pressure vessels where the heads are dished to a radius equal to the tank diameter. These high stresses have, in fact, been of such magnitude as to cause failure of one manhole head of a large ethylene tank designed for 300 lb. working pressure when tested several times hydrostatically to 1000 lb.[2]

The conditions brought out by this failure and subsequent investigations have led to the adoption of heavily reinforced openings and to the change in head designs from the commonly used flat dished heads to an ellipsoidal shape with an axis ratio of 2 to 1. Theoretically, the stresses in any part of such ellipsoidal heads should not be in excess of those in the shell.[3] Very good results have been obtained with these designs in the construction of over a hundred oxyacetylene-welded pressure vessels of various sizes, typical ones of which have been investigated by taking strain-gage measurements during test. This has led to the adoption of the new-design head as standard for welded construction. Practical considerations in regard to the design and stresses measured in these ellipsoidal heads are presented below, as it is believed they will be of interest to engineers and fabricators, for they permit economical construction of pressure vessels of practically equal strength in all sections and with the same factor of safety throughout.

Stresses in Ellipsoidal Heads—Theoretical Consideration

The stresses in any portion of a pressure vessel, according to the common approximate theory, are of three kinds: (1) transverse or hoop tension, tending to cause rupture along an element of the vessel; (2) radial or longitudinal, tending to cause rupture at right angles to the first; and (3) radial to the center of the tank due to difference of internal and external pressure. The last one is usually considered negligible, since generally it is relatively small.

In a spherical head the stresses and strains are theoretically independent of direction, and the stresses are found from the common formula

$$S = \frac{PR}{2t}$$

where S is the stress, P the pressure, R the radius, and t the thickness of the head. This formula, however, is not correct for heads with the large radius of dish and small knuckle radius commonly used in pressure vessels. Such heads do not act as sections of spheres except at relatively low pressure. Under high pressure, they appear to act more as dished plates supported at the rim. At the knuckle, where there is an abrupt change in curvature and directional change in the forces acting, high bending stresses are set up, the head tending to protrude at the center and flatten or contract at the knuckle. If the elastic limit of the material is exceeded, which occurs at relatively low pressures, the head tends to take a new shape and to assume that of an ellipsoid of revolution. The magnitude of the stresses and strains developed around the knuckle are given in a paper on "Stresses in a Large Welded Tank Subjected to Repeated High Test Pressure," in *Mechanical Engineering*, February, 1927.

Huggenberger,[4] starting with the stress-strain relations in a solid of revolution and assuming that the head is an ellipsoid of revolution and neglecting bending, has developed the following equations for stresses in ellipsoidal heads:

$$T_r = \frac{P}{2t}\left[(Rk)^2 + x^2\,(1 - k^2)\right]^{1/2} \quad \ldots\ldots [1]$$

$$T_t = 2T_r\left(1 - \frac{1}{2}\,\frac{R^2}{R^2 + x^2\left(\frac{1}{k^2} - 1\right)}\right) \quad \ldots\ldots [2]$$

where T_r = radial tension
T_t = hoop tension
$R = a$ = radius of cylindrical shell ($^1/_2$ the major axis)
b = semi-minor axis
k = ratio of major to minor axis ($= a/b$)
x = distance from minor axis to any point (abscissa)

[4] *Zeitschrift des Vereines deutscher Ingenieure*, vol. 69, no. 6, Feb. 7, 1925, pp. 159–162. For review in English, see "Design of Dished and Flanged Pressure Vessel Heads," by A. B. Kinzel, *Mechanical Engineering*, June, 1927, p. 625.

P = internal pressure, and
t = thickness of plate.

It can be shown from the foregoing formulas that if the depth of the dish is one-quarter the diameter of the tank or the ratio of the major to the minor axis is 2 ($k = a/b = 2$), the stresses in the head at any point will not exceed those in the shell of a vessel with the same plate thickness. This ellipsoidal shape having a depth one-quarter the diameter of the tank is a practical design

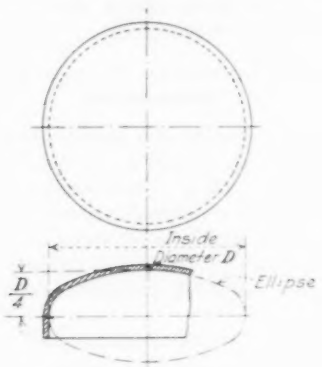

FIG. 1 ELLIPSOIDAL HEAD IN COMMERCIAL PRODUCTION

and is the one which we now use. The stress distribution in such a head, as can be shown from the foregoing formulas, is given in the following formulas:

$$T_r = \frac{P}{2t}\sqrt{4R^2 - 3x^2} \quad \ldots\ldots [3]$$

$$T_c = T_r\left(2 - \frac{4R^2}{4R^2 - 3x^2}\right) \quad \ldots\ldots [4]$$

where T_r = radial stress at any point, and
T_c = hoop stress at any point.

A concrete illustration will show the theoretical stress distribution in such a head. Consider a tank 7 ft. in diameter, for 200 lb. working pressure, plate thickness 1 in. These are the dimensions of the tank investigated for the data in this paper.

Theoretically, from [3] and [4] the maximum radial stress occurs at the center of the crown where $x = 0$. The stress is tension and is 8400 lb. per sq. in. at 200 lb. design working pressure. The radial stress gradually decreases from the center to one-half its value or 4200 lb. per sq. in. tension at the boundary of the knuckle and cylindrical shell. The hoop stresses, theoretically, are of the same magnitude as the radial stresses at the center of the head, and decrease to zero and change to compression around the knuckle. The maximum compressive stress occurs at the boundary where $x = R = 42$ in. and has the same magnitude as the maximum tensile stress, or 8400 lb. per sq. in. under design working pressure. The point where the hoop stress is zero is where $x = \sqrt{2/3}\,R$ or about 0.8 the distance from the center of the tank to the shell. The theoretical radial and hoop-stress distributions in ellipsoidal heads are shown in Fig. 7.

PRACTICAL DESIGN OF ELLIPSOIDAL HEADS

Ellipsoidally shaped heads having a depth of dish one-quarter of the tank diameter are now commercially produced. At least one large fabricator can supply these heads at very little additional cost over other heads, the cost of the dies having been absorbed by the company. This company's general drawing for this shaped head is shown in Fig. 1.

TABLE 1 HEAD DESIGN TO APPROXIMATE ELLIPSOIDAL SHAPE HAVING DEPTH OF DISH ONE-QUARTER THE DIAMETER OF TANK[5]

Diameter of tank, in.	Radius of dish, in.	Knuckle radius, in.	Straight flange length, in. (recommended for welding)
36	30	5.65	4
48	42	8.0	5
60	54	10.3	5
72	60	11.25	5
84	72	13.65	5

A close approximation to the ellipsoidal design can be obtained in a very practical way with a basket-shaped head formed by the combination of two radii, namely, the radius of dish of the head and that of the knuckle. This can be checked on any large-scale drawing. Table 1 gives data for use in designing ellipsoidal heads with a depth of dish equal to one-quarter the diameter of the tank for commonly used sizes. These heads have been quite generally used and can be supplied by several fabricators at practically the same cost as the old-type heads.

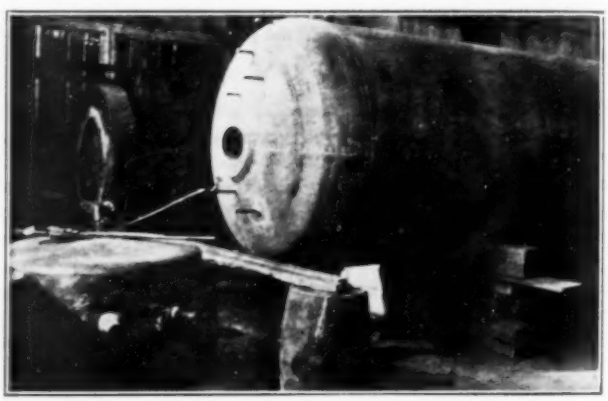

FIG. 2 7 FT. × 38-FT. TANK WITH ELLIPSOIDAL HEAD DESIGNED FOR 200 LB. AND TESTED TO 600 LB. PER SQ. IN.
(The short white lines show locations of 2-in. strain-gage lines for measuring the strains throughout the head.)

DESCRIPTION OF VESSEL TESTED

The experimental data concerning ellipsoidal heads presented in this paper were obtained from a typical test of one of a number of large tanks used for the storage of propane, on which complete strain investigations were made. Test and strain measurements on other pressure tanks of various sizes showed equally satisfactory results.

These propane storage tanks were 7 ft. in internal diameter by 38 ft., 4 in. long, designed for 200 lb. working pressure. The shell thickness was $^{15}/_{16}$ in. and the design fiber stress 9000 lb. per sq. in. Fig. 3 shows the general design of the vessels. The shell was designed and constructed according to the usual practices. Ellipsoidal heads were used with ratio of axes 2 to 1, that is, the depth of dish was one-fourth the diameter of the tank. The radius of dish of the head was 6 ft. and the radius of knuckle $13^3/_4$ in., which gives a very close approximation to the true ellipsoid having a 2-to-1 ratio. The heads were 1 in. thick, or $^1/_{16}$ in. thicker than the shell plate, in order to take care of any possible decrease in thickness due to flanging. No thickness was added to the manhole head for the manhole opening, as the stresses due to the opening were provided for by the manhole design. For the 11-in. × 15-in. opening, a ring-reinforced manhole was welded into the head. The ring was designed to take care of the enormous stresses around the manhole and reduce their intensity to equal that in the shell, the design being based

[5] "Procedure Control in Pressure-Vessel Welding," by H. E. Rockefeller, *Journal American Welding Society*, March, 1928.

upon the theory of a hollow cylinder subjected to an external tensile force equal to the stresses in the head.[6]

The whole tank was annealed after fabrication in order to anneal the weld joining the ring to the head. This weld is of the rigid type, since, unlike a seam weld, its contraction is rigidly resisted by the position and mass of the surrounding metal, so it is necessary to anneal it to relieve any locked-up stresses that may exist.

The Test

The tank was tested hydrostatically to three times the working pressure or to 600 lb. per sq. in. This gave a maximum test fiber stress of 27,000 lb. per sq. in. At 400 lb. pressure all seams were vigorously hammered with a 10-lb. hammer. The strains in the ellipsoidal heads were measured by means of a 2-in. Berry strain gage. For taking the measurements, small holes were drilled 2 in. apart with a No. 56 drill. These holes were drilled just deep enough (slightly less than $^1/_{16}$ in.) for the parts of the strain gage to seat and in no way weakened the plate. A complete set of measurements were taken extending from the end of the major axis of the manhole to the shell. These were taken in both a radial and transverse direction, that is, both the radial and hoop strains were measured. Fig. 2, 5, 6, and 7 show the location of the strain-gage readings. The strains were measured at 0, 200, 400 and 600 lb. test pressure and again at 0, after the pressure was released, to determine the permanent sets. A second test was then made and similar sets of readings were taken to determine the stress distribution after the slight irregularities of shape had been ironed out by the first test. These fabrication irregularities are always present and superimpose local bending strains on the principal pressure strains.

Strain readings were also taken on the inside of the tank before and after the test, at positions opposite to those taken on the outside, to measure the permanent sets. These determinations are important in interpreting and explaining any bending or overstrain that may take place.

[6] For a theory of design of ring-reinforced manholes see "Design of Dished and Flanged Pressure-Vessel Heads," by A. B. Kinzel, *Mechanical Engineering*, June, 1927, p. 621.

Measured Stresses in Ellipsoidal Heads

The results of the 40 strain-gage measurements taken 2 in.

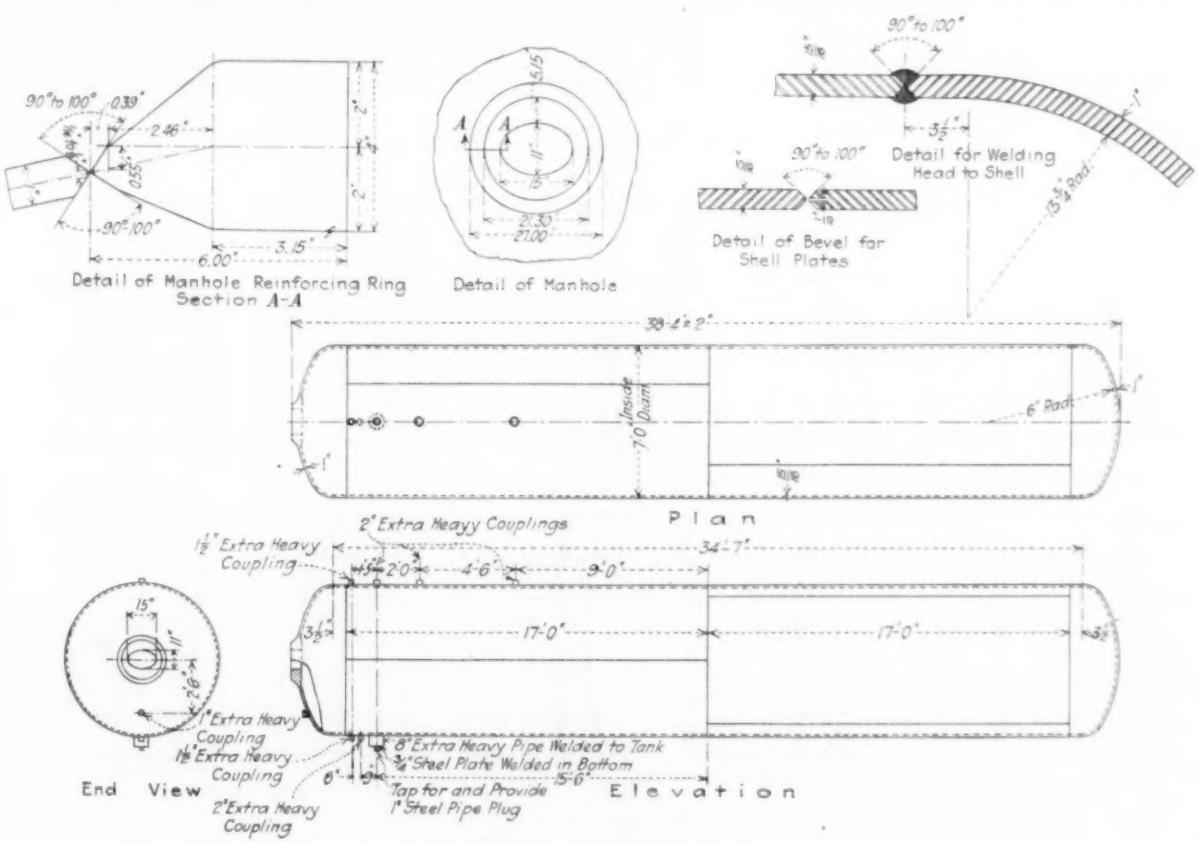

Fig. 3 Showing General Design of Propane Storage Tank Tested

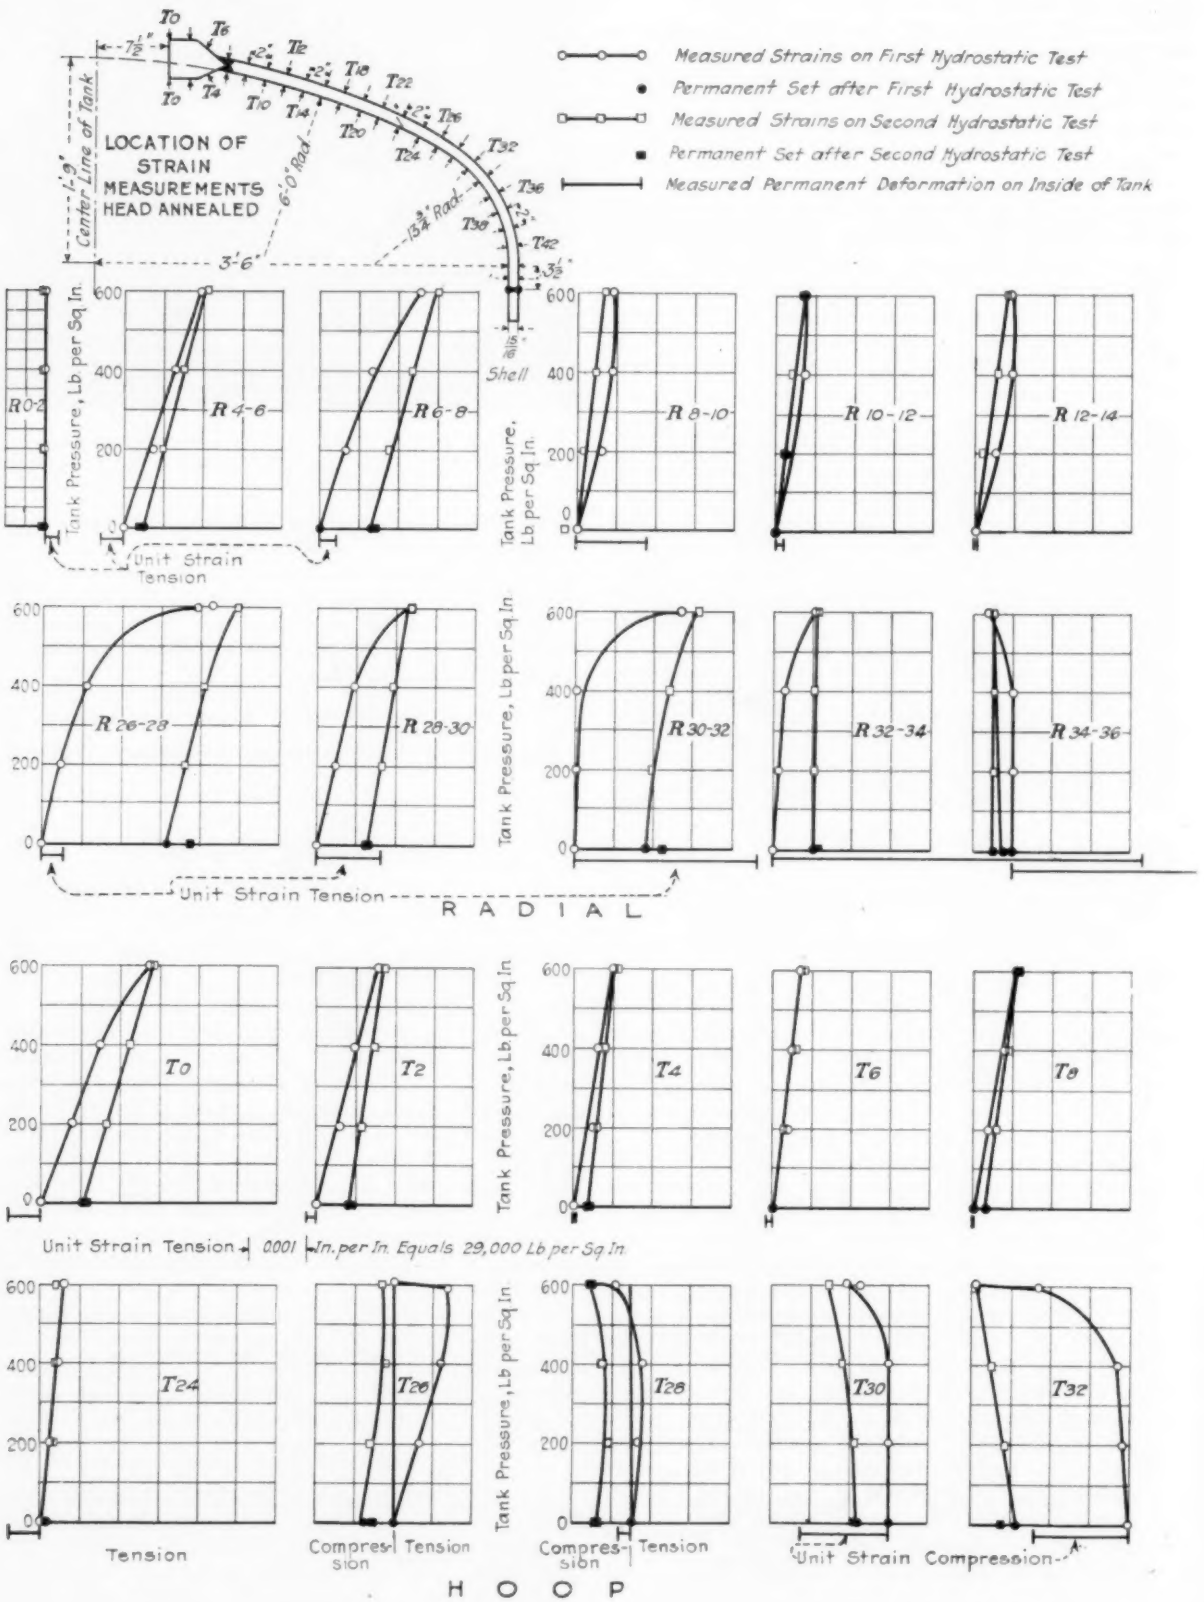

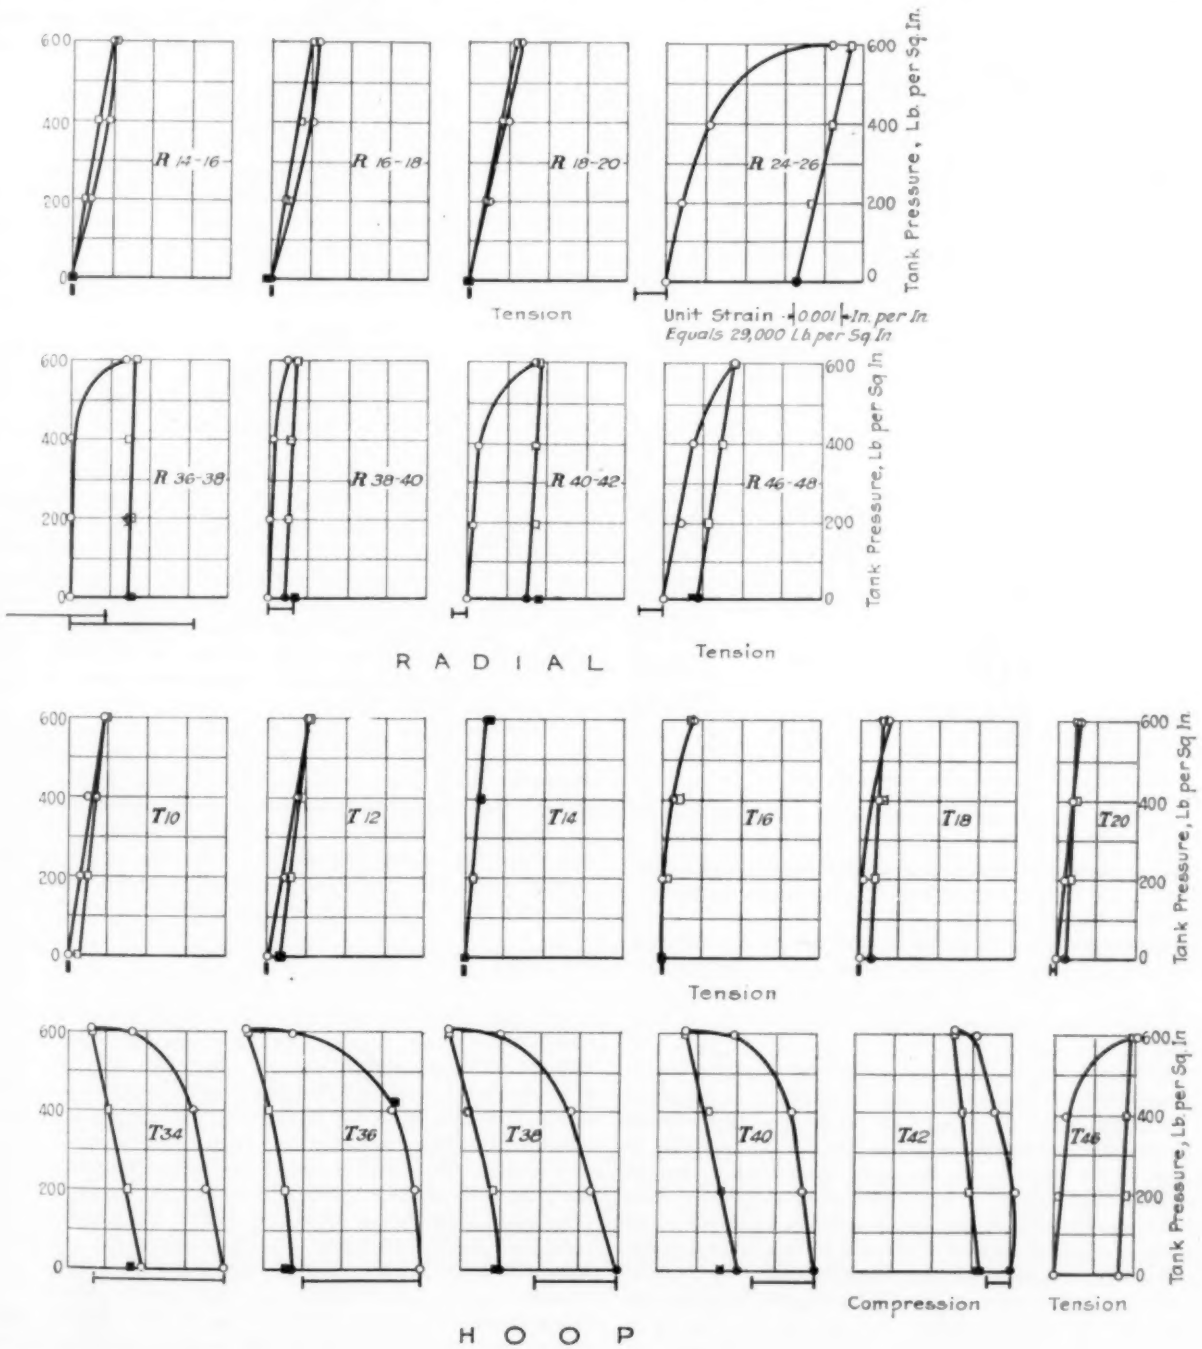

FIG. 5 UNIT STRAINS IN

apart on the ellipsoidal head are shown in Fig. 5, the locations being indicated in the sketch at the top. These curves show the complete distribution of the stresses, both radial and hoop, throughout the head from the edge of the major axis of the manhole to the shell, for both tests. The permanent sets measured on the inside of the tank are shown below the curves.

It will be seen the strains and stresses are practically normal in all parts of the head, and that at no place are they excessive. Due to irregularities in the head, the stresses are slightly higher than they should be at certain points. The head, just inside and next to the knuckle, was somewhat flat and the effect of this irregularity is seen in the stress distribution of the gage lines 24 to 32. The pressure, it was noticed, tended to iron out this flat spot, which superimposed bending strains and increased the total strain at this point. The radial stresses are tension throughout the head, as would be expected. The hoop stresses are tension in the dished section of the head and change to compression at the knuckle, as theoretically they should. The point where the stresses reverse is about gage line 28, which is approximately eight-tenths the distance from the center of the tank to the shell, as indicated by the theory. The permanent sets, measured on both the outside and inside of the tank, were very small, no

Ellipsoidal Head of Tank

permanent set or overstraining occurring at most of the points. The highest overstraining was measured in a radial direction at the knuckle on the inside of the tank where the contraction of the knuckle causes the tension from bending to be added to the normal tension in the head. These strains were not large when it is considered that the tank was tested so near the yield point of the material. In fact, they are negligibly small compared with those measured in heads with sharper knuckle radii and tested at much lower pressures.

The stresses in the second test to 600 lb. were normal and proportional to the pressure, with no increase in the permanent

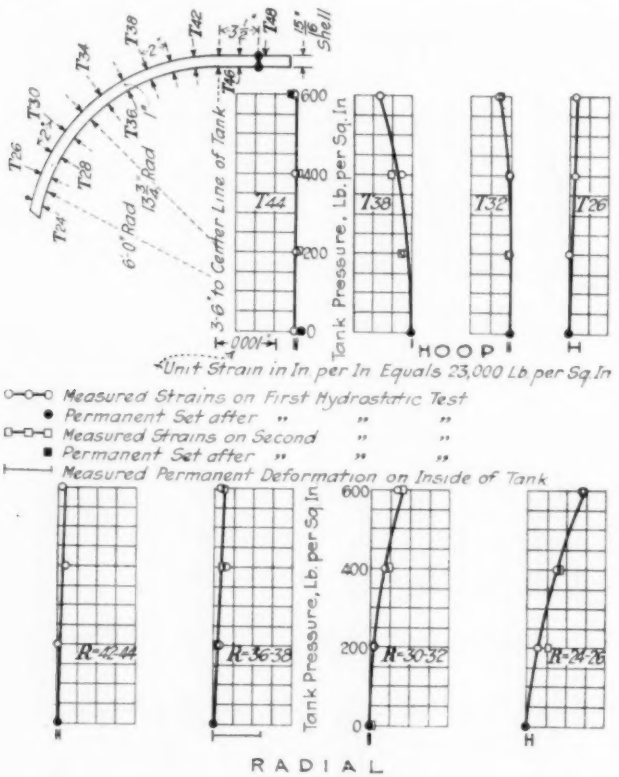

FIG. 6 UNIT STRAINS IN PLAIN HEAD OF ANNEALED TANK

set. The irregularities that had superimposed bending strains and caused the slight overstraining at a few points in the first test had been eliminated.

The stresses measured in the plain head are shown in Fig. 6. These are of the same general character as those in the manhole head but of less intensity. It is remarkable that there was no overstraining around the knuckle, even at three times the working pressure.

The stresses shown in Figs. 5 and 6 are those corresponding to the actual deformations of the material which were measured with the strain gage. These strain stresses are evaluated from the measured unit strains by multiplying by the modulus of elasticity. They are not the design or theoretical stresses in ellipsoidal heads given earlier in the theoretical analysis for these heads, because the strain in any one direction in a material under two or more principal stresses is affected by the lateral deformation caused by the stresses in the other directions. The stresses corresponding to the design or theoretical stresses, however, can be determined from the measured strains. By the theory of elasticity, the following is the relationship between the principal strains and principal stresses:

$$T_r = \frac{mE}{m^2 - 1}(me_r + e_c) \quad [5]$$

$$T_c = \frac{mE}{m^2 - 1}(me_c + e_r) \quad [6]$$

where T_r = radial stress
T_c = hoop stress
e_r = radial strains (measured with strain gage)
e_c = hoop strains (measured with strain gage)
$1/m$ = Poisson's ratio or factor of lateral contraction.

Taking $1/m = 1/3$ as Poisson's ratio, the radial and hoop stresses in ellipsoidal heads in terms of the measured strains are

$$T_r = 3/8\,(3\,e_r + e_c) \quad [7]$$

$$T_c = 3/8\,E\,(3\,e_c + e_r) \quad [8]$$

These measured stresses are shown plotted and compared to design stresses in Fig. 7. These are plotted for 400 lb. test pressure, or twice the design working pressure. For working pressure, they are only one-half as great as those shown. The stresses at three times the pressure were not plotted because, due to irregularities in the heads, the stresses in the first test were slightly above the elastic limit at a few places, and the stress-strain relation, of course, is not proportional. After the irregularities were ironed out, however, the stresses at three times the working pressure in the second test, although not shown, did not pass the elastic limit and were proportional to those plotted at 400 lb. for this test.

This curve, Fig. 7, shows the measured stresses to be in close agreement with both the radial and hoop theoretical stresses. The agreement is not so close on the first test, due to the irregularities in the head. There is a very close check in the second test. The radial stresses are a maximum at the center of the head and decrease to a minimum at the boundary of the head and shell. The hoop stresses are a maximum in tension at the center and change to compression at the knuckle, the maximum value of both the tensile and compressive hoop stresses being the same as the maximum radial stress.

These results show that heads dished to correct curvature and with a large knuckle radius, to approximate an ellipsoidal head with ratio of the axis 2 to 1, are far superior to the flat-dished, sharp-knuckle heads commonly used in pressure vessels, and that for design the stresses can be accurately calculated by the theoretical formulas for ellipsoidal heads. The ring-reinforced manhole, when the whole head is properly annealed, adequately takes care of the enormous stresses around such openings.

COMPARISON OF STRESSES IN ELLIPSOIDAL AND STANDARD DISHED HEADS

The extent to which the stress distribution in heads has been improved by using the elliptical shape, and the superiority of this shaped head over the standard flat-dished head, may be appreciated by comparing the stresses computed from measurements of the two types. A comparison of the maximum stresses measured around the manhole and knuckle of both types is shown in Table 2. The strain measurements in the flat-dished heads are those taken on the ethylene tank and which were published in *Mechanical Engineering*, February, 1927. The heads of this tank were dished to a radius equal to the diameter and had a $4^3/_4$-in. knuckle radius. The two heads are not exactly comparable in size as the ethylene tank was 5 ft. in diameter and $1^1/_8$ in. thick. The test shell fiber stress, however, was the same in both cases, and the relative difference in the stress intensity in the two types is approximately that shown in the table. It can

be seen from the table that the ellipsoidal heads are far superior and that the high stress concentration found in flat-dished heads does not exist with ellipsoidal heads, the stresses in the elliptical-shaped heads being practically normal throughout, even under very high pressure.

CONCLUSION

The results of the foregoing investigation and test of ellipsoidal heads for pressure vessels show that:

1 Heads with dish and large knuckle radii proportioned to closely approximate true ellipsoidal shapes with a ratio of axes of 2 to 1, are far superior to the flat-dished heads with small knuckle radii commonly used in pressure vessels.

2 The stress distribution in such heads closely approximates the theory, and the formulas for ellipsoidal heads reviewed in the paper can be safely used for design.

Discussion

W. M. COATES.[7] The paper contributes to engineering experience additional measurements of the strain in pressure-

[7] Instructor in Engineering Mathematics, University of Michigan, Ann Arbor, Mich.

vessel heads. From the strains (Fig. 5), the stresses are computed on the assumption that there is no resistance to bending; i.e., each element of the head is in equilibrium under normal forces in the directions of the meridians and the parallel circles (formulas [5] and [6]). These stresses are then compared with those computed from formulas [3] and [4], which give the stresses on an element of an ellipsoid which is under uniform internal pressure, and offers no resistance to bending (Fig. 7).

The hypotheses underlying the development of formulas [1] and [2] contain two elements which are not realized. The bending stresses are negligible and the surface has a continuously varying radius of curvature.

The exact solution to the problem, taking full account of both these elements, is not yet in a state in which it can be offered to the engineer.[8] However, approximate solutions of a form sufficiently simple to permit practical application have been developed for full heads.[9] These have been checked experimentally both in the laboratory and in the plant.[10] The qualifications of the desirable full head are those stated in this paper, namely, that the pressure vessel shall be practically of equal strength in all sections.

There is nothing to be said in favor of the flat-dished head with small knuckle radius. It gives a very high stress-concentration factor on the inside surface at the knuckle. The hemispherical head does not represent the most economical use of material, for the head is underworked, and the maximum stress is concentrated in the drum. A sample computation shows stresses in the head from 27 to 50 per cent lower than those in the drum.[11]

It is possible to design full heads of ellipsoidal or quasi-ellipsoidal shape (i.e., with two, three, etc., radii of curvature) in which the stress is approximately the same in the drum, the knuckle, and the crown, if proper care is given to the dimensions of knuckle and crown radii for a given ratio of the depth of the head to its base radius. The true half-ellipsoid of revolution with this ratio equal to $^1/_2$ is not the most favorable form.[12]

The approximate method mentioned can be applied to this last group of heads, to take account of the bending stresses and the geometric discontinuities of the surfaces, such as at the junction of head and drum, or of two sections with different radii of curvature (e.g., near point T_{26} of Fig. 7). At such places, stresses are developed which are not negligible, not only in the head, but also in the drum. Even for the favorable case of an ellipsoidal head with axis ratio $^1/_2$, stresses are set up in the cylinder which are some 13 per cent higher than those computed from the membrane Equations [3] and [4], and as the knuckle radius decreases, the difference exceeds 100 per cent. In the head itself, a hoop shearing stress is developed at the junction of about the same magnitude as the crown stress, and a meridianal bending stress whose maximum is about 60 per cent of that magnitude, at a point about $^1/_{10}$ the distance to the crown, measured along the meridian away from the junction. Such stresses due to discontinuities of the surfaces joined are of periodic character, and are damped out rapidly as the distance from the junction increases. Outside the region of their action, the so-called "membrane" formulas are good, and the design can be based upon a superposition of the two systems of stresses: membrane, and discontinuity.

To check computations, measurements similar to those of this paper have been made, supplemented by measurement of the angular deformation of normals to the head. From the latter the bending stress may be computed, and thus the stresses at the inner surface of the head are obtained.

The introduction of a manhole into the head brings new stresses at its rim. With designs favorable for full heads, these are greatly in excess of the stresses at the inner surface of the knuckle. The problem here is not in the same stage of refinement as that of the full head, and awaits a more thorough investigation of these discontinuity stresses.[13]

The measurements given in this paper are in line with expectations. Referring to Fig. 7, first test, there is a large percentage error in the radial (called meridianal) stress from that predicted by use of the membrane equations, enough to cause a change in character from tension to compression near the junction of head and drum. This is due to the discontinuity in the radii of curvature of the surfaces joined here; i.e., the cylinder and the quasi-ellipsoid. The compressive stress on the outer surface due to bending plays an important role, and since a pressure of 600 lb. per sq. in. should not make much difference in the radii of curvature (for cylinder and $13^3/_4$ in. for head) this stress is not changed greatly. The second test verifies this. The junction of the surface with radius of curvature $13^3/_4$ in. to that of radius of curvature 6 ft., sets up new discontinuity stresses which are large in the first test. As is to be expected, the second test shows a marked decrease in these stresses, since the difference in the radii has been diminished. Similar discussion holds throughout. All of these stresses are of oscillatory character and are damped out as they leave the junction at which they are set up. They can be computed from the data given. However, an experimental check demands the mentioned additional measurements of angular deflection of normals.

These are some points in the paper concerning which, it is felt, elaboration or correction would be advisable. In Fig. 5, the unit strain is not indicated on the axis of abscissas. There are two values indicated in two different places, neither of which coincides with the unlabeled unit used in the graphs. How were the permanent deformations on the inside of the tank measured (with check of the scale here also, in view of the last sentence on the fifth page that they are very small)? What is the maximum error to be expected in the strain measurements? The lettering of the gage points in Figs. 5 and 7 seems to be in error. In Fig. 7 the stress-distribution curves obtained by joining the points are, of course, for the outer surface. They will show a different character for the inner surface.

Furthermore, there are places where revision of expression should be made. The first statement on the second page cannot be demonstrated. The surface constructed from a meridian with two radii of curvature should not be called an "ellipsoid." On the fifth and sixth pages there should be more care in distinguishing "stress" and "strain." On the sixth page under Fig. 6, "the irregularities, etc.," is not borne out in Fig. 7.

In conclusion, it may be stated that greater progress can be expected in the head design of pressure vessels if experimental investigations are planned to get not only the membrane stresses, but also the discontinuity stresses, especially in the neighborhood of manholes and other breaks in the surface. There is reason to expect that the approximate methods of computation may be ap-

plied which hold for favorably shaped full heads, although here it may be necessary to find a new favorable shape.

G. M. Eaton.[14] The advantage of having equal tension and compression is only a matter of words unless it is true that the tank is just as liable to fail in compression as it is in tension. In determining the ratio of minor to major axis on a really reliable basis, it would be essential to test tanks to destruction and find whether or not compression failure is going to occur. In many cases overstress in compression is not feared, but if this head is liable to fail first from collapse then it is essential to adjust the stress so that the section is as nearly balanced as possible.

H. E. Rockefeller.[15] When need was first found for a head having a depth of dish equal to one-quarter of the diameter of the tank, it was learned from the head fabricators that the depth of dish desired could be secured and an approach to a true elliptical head by using a large knuckle radius smaller than standard crown radius. Consequently the design of heads for various diameters was changed so as to include the crown radius and knuckle radius which would give the closest practical approach to the truly ellipsoidal shape.

Within the past year, however, one of the head manufacturers has produced dies for forming true ellipsoidal heads for some of the diameters of the heads which are required. As truly ellipsoidal heads have become available they have been used, and undoubtedly when the ellipsoidal dies for the full range of sizes for heads are available, the writer's company will probably eliminate the deep-dished type of head which it is now using in general.

A. L. Kimball.[16] The curves in Fig. 7 do not take account of the variation of stress on outside and inside radius. Of course, a case of this sort will only arise where there is quite a sharp curvature and Fig. 7 was not intended to represent this case.

In justification of the photoelastic method, the writer disagrees with one speaker that it cannot be used. In this case it would be better not to use the photoelastic method because the variation of stress in the cross-section is so large, but where the contour is gradual, and the thickness of the plate is relatively small, the method of polarized light could be used very well on the assumption that the stress is substantially uniform from one side to the other of the cross-section. A very useful check could thus be obtained by the photoelastic method although it might not be 100 per cent accurate.

G. O. Carter.[17] This work started with extensometer readings on the actual vessels with short-radius knuckles where failure occurred, and Mr. Greene obtained marked differences in compression and tension at very close points. That started a good deal of this investigation, and to obtain confirmation several boiler accidents were investigated.

Some engineers talked about caustic embrittlement and things of that kind as causing failures, but when they checked what had been done on new equipment stressed to three times working pressure, they agreed that there were localized stresses of terrific magnitude. The stresses thus concentrated at one point have probably caused thousands of boiler and pressure-vessel accidents that were attributed to fatigue of metal or caustic embrittlement, assuming that the design of the vessel was correct.

W. Trinks.[18] A question was asked by one of the speakers about the fact that compression exists at the end of the long axis of the ellipse. The writer can fully understand why compression should exist at that point, but in going from there to the immediately adjacent cylindrical part, there should be, at the end of the ellipse, a very large amount of compression, and immediately adjacent to it in the cylindrical part only tension. Now there certainly must be a transition from one to the other. It is unthinkable that at a thousandth of an inch to one side of the imaginary division line 20,000 lb. per sq. in. compression is encountered and a thousandth of an inch to the other side of that line there is 10,000 lb. per sq. in. tension.

That means that at the important line, where the ellipsoidal head becomes a cylinder, the stresses which are given by the author's theory must be departed from and the question comes up whether the ellipsoid is not used solely because the stresses in it can be figured. In other words, certain shapes are used because they allow of analytical solution and engineers think they have solved the problem by using the stresses computed from the simple shape. To the writer it appears that all are being fooled about the applicability of the ellipsoid because something else is going on at the junction and, therefore, the stresses figured from the ellipsoid are seriously modified at that point. All of this brings up the question whether, to the author's knowledge, somebody may have succeeded in using a graphical method of figuring stresses in dished heads of any shape. If that were so the old method of a circular arc for the center of the head with smaller circular arcs joining the cylindrical might be adopted.

B. L. Newkirk.[19] Where a small number of points are involved, as in this case, it is doubtful whether the line which would be indicated by the theory of least-squares is the best representation. For example, if another observation added to the observations we have already would change the position of the line materially, then it is not right to say that even these observations are best represented by the line that the theory of least-squares indicates. The theory of least-squares rests on the supposition that that representation is the best which makes the sum of the squares of the residuals a minimum. There is no proof that this supposition is correct when the number of observations is small.

It is important that observations wherever possible should be represented graphically. The application of the theory of least-squares can mislead very decidedly if observations are discussed by the theory of least-squares to arrive at the values of certain unknowns without making a graphical representation. The least-square treatment often covers up things that would appear from the graphical representation. The equation used in applying the theory of least-squares represents only a few of the phenomena involved in any problem, one or two or three unknowns. The number of unknowns is actually infinite. It is hoped that the unknowns considered are dominant, that the equation represents the dominant phenomena or the dominant phenomenon involved. It may be that other considerations which are overlooked affect the observations. If the observations are represented graphically, they are much more likely to disclose such a situation, but if treated by the theory of least-squares, and without a graphical representation, it practically never would be found out.

In that connection, when a graphical representation is made, one should distinguish carefully between large discrepancies and inaccuracies. The writer includes under large discrepancies departures from the curve that are too large to be accounted for

[18] Professor of Mechanical Engineering, Carnegie Institute of Technology, Pittsburgh, Pa. Mem. A.S.M.E.

[19] Engineer, Research Laboratory, General Electric Co., Schenectady, N. Y. Mem. A.S.M.E.

as inaccuracies. If points occur too far off the line to represent inaccuracies of observation, warning is given that either a mistake has been committed or that something occurs that the theory does not take account of.

RICHARD A. E. DE JONGE.[20] As far as I know, the first experiments with ellipsoidal-shaped heads were made by Mr. Höhn, chief engineer of the Swiss Boiler Inspection Association, and by his assistant, Dr. Huggenberger. The latter has given a complete mathematical analysis of the whole problem which is very interesting. He takes all stresses into consideration. Mr. Höhn has made experiments with dished heads as well as with ellipsoidal-shaped heads. He has developed a simple method of finding the two radii called for in basket-shaped heads.

It is the present custom in Europe to shape boiler drums for high-pressure boilers out of one solid piece, and to dish the heads on directly in preference to riveting or welding. This has been done especially for boilers with steam pressures of 1200 lb. per sq. in. and above, where riveting or welding is simply out of the question, Mr. Höhn has also given information on how to weld boiler shells and heads where this is still practicable so as to avoid additional stresses.

Is it not that designers of heads, who send with their orders their recommendations to the manufacturers, are not educated to the fact that the ellipsoidal head is the best, that they still use a radius at the throat and a radius at the center. It would be best to refer the matter back to the standardization committee, and make it compulsory to use the ellipsoidal head, because that is the logical step in the development from the spherical head which has no bending stresses, and the flat head which has the highest bending stresses. The ellipsoidal head thus represents an intermediate stage.

Barraclough and Gibson in Australia made some interesting investigations on a boiler under actual load conditions. They placed a large number of little mirrors along the meridian line of the boiler, and from actual measurements on these mirrors with an optical instrument they found that the stresses did vary so as to show strong compression in the interior of the head near the throat. They made the experiments on an existing boiler under pressure, and observed how the stresses vary when the boiler is under no load and when the load is applied. They used water pressure instead of steam, but for the purpose of stresses this is immaterial. They have shown the actual stress distribution. The stress distribution indicated uniform tensile stress in the cylindrical part of the boiler, and in the head, a sharp decrease to almost zero at the joint. From there on there is a very strong compressive stress started which reaches its maximum at the point of least radius of curvature at the throat. This then drops to zero a short distance from the point of greatest curvature, and becomes a tensile stress again which increases to a maximum at the crown of the head. This refers to the outer elements of the head. The inner ones showed exactly the opposite stresses. Since this investigation was on a working model, the three-dimensional process has been taken care of.

L. H. BURKHART.[21] Nearly all manufacturers making dished and flanged heads have a large quantity of forms or dies on hand, probably an investment of thousands of dollars, and they are generally made for spherical-dished heads, and they do not always suit the diameter of the dished head required. The dishing blocks may be smaller than the diameter of the head, yet it is always possible to dish a head much larger than the diameter of the block, if it is spherical, because the head can always be shifted so that every part of the head covers the die, and as the radius of the curvature in a spherical head is the same, a smoothly dished head will result. It is not possible to do that with an ellipsoidal head because the radius of curvature changes in the different proportions of the head so the die must cover the entire surface of the head if it is to be dished to the ellipsoidal shape.

Again, the ellipsoidal head, when the ratio of one to two is used, is about twice the depth of dish of the spherical head where a radius equal to the diameter of the head is used. On thin plate it becomes impossible to dish the plate to that depth without buckling the plate. It is possible in thicker plates to make a deep dish. But manufacturers have occasion to use heads $^1/_4$ in. and up, and the thinner the heads the more difficult to dish without buckling.

The problem seems to work out best by taking the standard spherical-radius die, and turning a larger fillet radius on the male die so that it will approximate the ellipsoidal head. The strains are much less in the knuckle of a large radius than they would be if a shorter radius were used, as has generally been the practice. The ellipsoidal head has advantages of uniform stress over the spherical head, but the users of vessels employing dished heads ought to go guardedly against specifying ellipsoidal heads until manufacturers are equipped and means have been worked out for producing these heads.

The company the writer represents is a large user of dished heads and has recently requested quotations from several mills that are provided with spinning machines for producing these heads. They come back with prices of equipment which seem exorbitant and cannot be charged into the cost of the job. In some cases some mills refuse to quote as they are not equipped to produce ellipsoidal heads. These are the difficulties that a manufacturer encounters.

AUTHOR'S CLOSURE

In Fig. 7, the dotted line, which is outside the inside surface at the crown, but on the inside of the surface near the knuckle, is the true ellipsoid of revolution in which the major axis is twice the minor axis. The basket-shaped head, with the radius of 6 ft. and a knuckle radius of $13^3/_4$ in., deviates from the true ellipsoidal shape as shown in the curve, which is drawn to scale. The deviation is not more than $^1/_2$ in. to $^3/_4$ in., going outside of the true ellipsoidal shape at the knuckle and slightly inside near the crown. It is about the closest approximation that can be obtained to the true ellipsoidal shape with any two combinations of radii.

The question has been raised as to why a true elliptical head has not been recommended in place of one with two radii as used for the head investigation reported in this paper. I do not want to give the impression that this head is recommended in preference to the true elliptical one or vice versa. Practical considerations will govern the type of heads eventually used. It was brought out in the discussion that one company, as head fabricators, preferred to have the true ellipsoidal shape. One fundamental reason for this is that it is possible to approximate the true ellipsoidal shape by a basket-shape design using slightly varying radius of dish and slightly different knuckle radius. Some purchasers, for instance, might specify a 68-in. radius of dish and 12-in. knuckle radius instead of the 72-in. and $13^1/_4$-in. radii used for the heads investigated in this paper, which, incidentally, would fairly approximate a true ellipsoidal shape. It can readily be appreciated from a fabrication standpoint that if they were to be required to have numerous dies of different sizes, the cost of fabricating these heads would become prohibitive. On the other hand, several fabricators are standardizing on certain combination of radii, so that the basket-shape heads are becoming more or less stock sizes.

[20] Designer, New York Edison Co., New York, N. Y. Mem. A.S.M.E.

[21] Chief Engineer, Struthers-Wells Co., Warren, Pa. Mem. A.S.M.E.

As time goes on, there probably will result a condition in which the basket-shape heads will be standard with some fabricators, while with others the true ellipsoidal heads will be standard. The difference between the two is small, and is more a practical consideration of fabrication.

The data given in this paper are not intended to present a brief for either head, but are intended to show the advantage of the ellipsoidal head, either true or approximate, over the older types of heads, and to present the theory and engineering data of stress distribution for such heads.

The question has been raised regarding the stresses in the head and cylinder at the junction of the head with the shell of the tank, as to whether it is possible to have compression in the head and tension in the adjacent metal of the cylindrical shell. At this point the condition of boundary limits governs and the exact theory breaks down. This upset of theory at the boundary condition is best illustrated in a tank with true semi-spherical heads. The stresses in a semi-spherical head are one-half the stresses in the cylindrical shell of equal plate thickness. Thus we have a condition at the junction of the semi-spherical head and shell where the stresses in the head by theory are one-half the stresses in the adjacent cylindrical shell. The theory, therefore, breaks down at this boundary condition. What actually happens is that the stresses change gradually in their intensity with no sudden demarkation. Likewise, with an ellipsoidal head there will be found a gradual change from the hoop compression stresses in the head to the cylindrical tensile stresses. It is possible to notice with the older type heads, where the hoop compression stresses are very intense at the knuckle, that the forces will deform the cylindrical shell inward for a distance of 6 to 12 in. if the pressure is carried up to or slightly in excess of the yield point of the tank material. Huggenberger's theoretical analysis of the ellipsoidal head neglects both bending and the forces of the attached cylinder which he assumes to be comparatively small.

The subject of a true ellipsoidal head versus the basket-shaped head has been discussed so extensively that it seems advisable to add a few comments in regard to this subject.

The question as to which is the better type of head or the one that should be specified, as pointed out before, is purely a matter of practical fabrication. The situation is in the process of evolution. As these heads are more extensively adapted, and more manufacturers specify their use, a greater number of fabricators will fall into line to make them. Some of these have already gone to true ellipsoidal shape. Others, as has been pointed out, have had to compromise with the basket-shape design, using a combination of two radii.

A little discussion of Huggenberger's formula may throw some light upon this subject. Huggenberger's formula, which is reviewed in the paper, is based on an ellipsoid revolution, and is applicable to ellipsoidal shapes other than the one in which the major axis is twice the minor axis.

With an elliptical shape, in which the depth of the dish is less than one-quarter that of the tank diameter, the stress distribution is somewhat different from that indicated in the paper. The radial tensile stresses are maximum at the crown and decrease slightly toward the knuckle. The hoop stresses, on the other hand, are of maximum tension at the crown, but change to very high-compression stresses at the knuckle, the intensity of these stresses depending upon the shape of the ellipse. With increased depth of the dish, the stresses decrease in intensity until a shape is reached in which the ratio of the axis is one; in other words, a semi-spherical head. In this latter case, the stresses are theoretically and actually at a minimum, their intensity being one-half the stresses in the shell.

The ellipsoidal shape, in which the depth of the dish is one-quarter that of the tank diameter or the ratio of the axis two to one, presents a compromise between shape and cost of fabrication. With this shape, according to Huggenberger's theory, the maximum stresses will not exceed those in the shell; in other words, a design of equal strength.

In the use of such heads, as the stresses are very much reduced below the older standard heads, a decrease in thickness is permitted, which of course is an item of economy. Opposed to that is the increase of forming due to die costs. This is a new type of head and as such demands special dies. In the evolution attending its use, as the heads are more extensively adopted, the cost of forming will naturally decrease and the tendency in the meantime will be to use, in one case, a basket shape and in another case a true ellipsoidal shape, and it will be up to the boiler code to more or less standardize type of head and its design. With standardization, the cost of forming will not be the important item that it is today.

The Boiler Code Committee is considering specifying the use of either the true ellipsoidal shape or the basket shape, provided the latter does not materially deviate from the first.

Mr. Huggenberger in his theoretical analysis and derivation of formulas for the stress distribution in ellipsoidal heads has neglected bending. The analysis becomes extremely complicated if this is taken into consideration. In the investigation an attempt was made to evaluate the bending, if such occurred, by taking strain-gage measurements on the inside as well as outside. It was, of course, impossible to measure the strains on the inside under load. Strain measurements, however, were taken inside the tank prior to putting in water, and after the test was completed, which of course determined only the permanent set but from which the nature of the bending could possibly be evaluated.

Unquestionably there is some bending imposed in an ellipsoidal head which somewhat affects stress distribution. The agreement of the measurements taken during the first test was not as close as those obtained in the second test, due, no doubt, to slightly reshaping the head to give a better stress distribution. The disagreement, however, between actual measurements and theory seems to be of little importance when compared to the improvement of stress distribution with these heads over the older type, and it is questionable whether a more accurate theoretical analysis would add any practical advantages over the approximate analysis of Huggenberger.

APM-51-14

Analysis of the Uniform-Rise and Uniform-Pressure-Angle Cam Curves

A Method of Designing Cams by Means of Prepared Charts

By R. F. MALLINA,[1] CAMDEN, N. J.

The practical design of cams sometimes requires a thorough investigation of the practical limits to which a designer may go without greatly changing the leverage ratio from cam shaft to cam-lever shaft and without putting unnecessary strain on the follower stud.

It is the purpose of this paper to point out methods of obtaining such limits and to provide tables and charts which will enable the draftsman to determine certain cam curves with a minimum of effort.

The results of this investigation are as laid down in two appended charts.

DISREGARDING cams with uniform acceleration which are ordinarily used when cams revolve with great velocity, two of the principal cam curves are the uniform-rise curve and the uniform-pressure-angle curve. The graphical method of laying out the uniform-rise curve is simple, accurate, and direct. The graphical method for the uniform-pressure-angle curve, however, is of a complicated nature, inaccurate, and indirect. Engineering handbooks and textbooks do not mention it, and this is probably the reason few design engineers are acquainted with it.

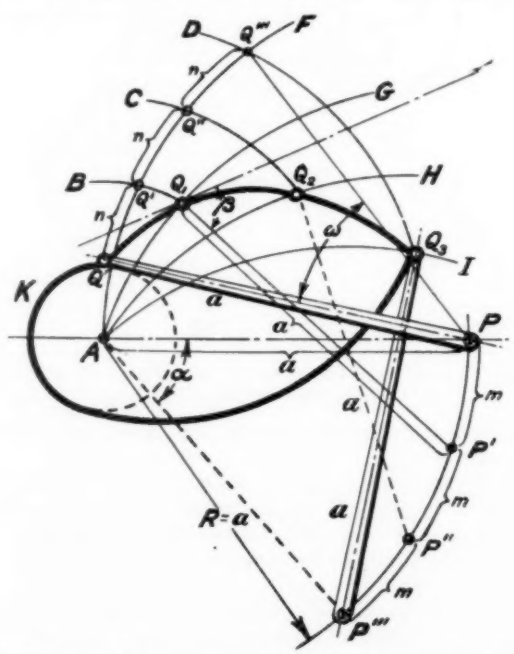

FIG. 1 GRAPHICAL METHOD FOR LAYING OUT UNIFORM-RISE CURVE

The mathematical method of determining the uniform-pressure curve is of course correct, but it is not simple. The equation of the curve is a logarithmic function, rather long and expressed in parametric form.

The only practical way to make use of the uniform-pressure-angle curve is to develop a family of curves for a series of pressure angles, plot them in a chart, and designate the leverage at certain intervals. The designer has then but to copy the particular curve in which he is interested and reduce or enlarge the scale to suit his given conditions.

In what follows the author will describe graphical methods of determining the cam curves, giving the equations employed and also explaining the use of the charts derived.

THE UNIFORM-RISE CURVE

From the standpoint of maintaining the torque or the leverage between the cam shaft and cam-lever shaft constant, the uniform-rise cam is ideal. Such a cam mechanism acts similarly to a pair of circular gears, and the angular-displacement ratio or leverage $L = \alpha/\omega$ is constant.

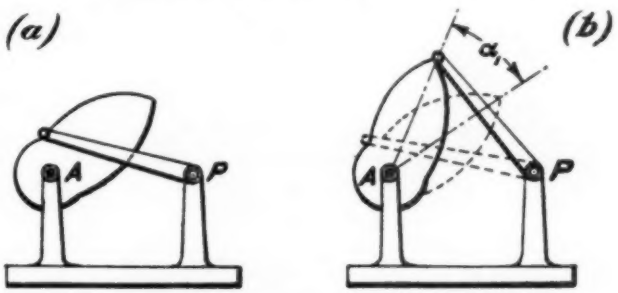

FIG. 2 PHYSICAL CONCEPTION OF A CAM SYSTEM
(Cam A is rotating and cam lever pivot P is stationary.)

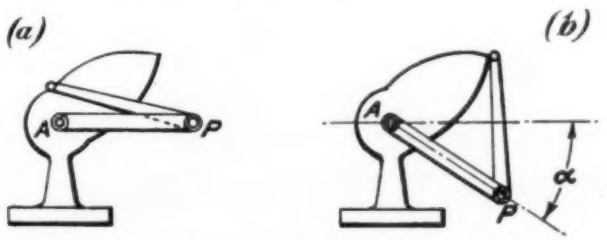

FIG. 3 MATHEMATICAL CONCEPTION OF A CAM SYSTEM
(Cam A is stationary and cam lever pivot P is rotating around cam axis.)

Fig. 1 illustrates the graphical method in general use. Assuming the base circle K, the maximum-lift circle D, and the cam-displacement angle α as given, the curve may be laid out in the following manner: Using the follower axis P as a center, strike arc F with the cam-lever length $a = PA$ as radius. A is the axis of the cam. Arc F intersects circle K at point Q, and circle D at Q'''. Angle QPQ''' is the cam-lever displacement angle ω. With A as center, strike arc PP''' and make angle PAP''' equal to α. Divide arc QQ''' into equal parts: $QQ' = Q'Q'' = Q''Q''' = n$ and arc $P'P'''$ in the same number of equal parts: $PP' = P'P'' = P''P''' = m$. Strike arc B through Q' and arc C through Q'' with A as center. With P', P'', and P''' as centers, strike arcs AG, AH, and AI with radii a, which intersect arcs B, C, and D at points Q_1, Q_2, and Q_3. The points Q, Q_1, Q_2, and Q_3 then represent the uniform-rise

[1] Head, Apparatus Development Division, Victor Talking Machine Co. Mem. A.S.M.E.

curve. The method is extremely simple and direct because the curve is not obtained by a trial-and-error method.

Uniform-rise cams can be used only within certain limits. The nearer the origin Q is to the cam center A, the more the pressure angle β approaches 90 deg., causing a friction moment greater than the cam lifting moment, with a consequent binding of the mechanism.

The Uniform-Pressure-Angle Curve

The logical method to avoid binding action is to design a cam curve with a uniform pressure characteristic; that is, a curve such that the angle between the lever and the tangent to the cam curve is constant and less than 90 degrees.

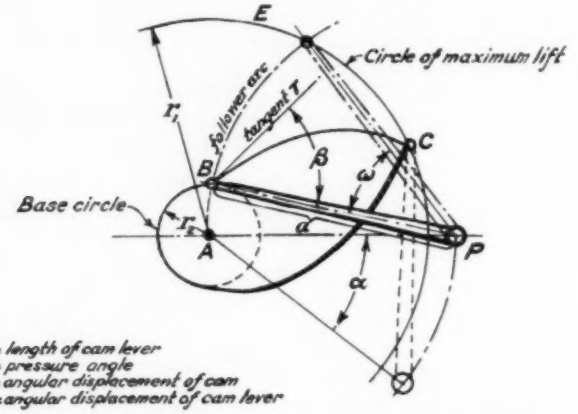

Fig. 4 Graphical Method for Laying Out Uniform-Pressure-Angle Cam Curve

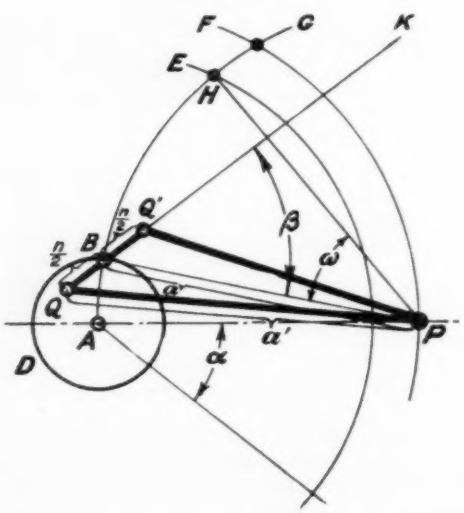

Fig. 5 Characteristic Triangle Used for Graphical Layout of Uniform-Pressure-Angle Cam Curve

The graphical method for determining the cam curve is illustrated in Figs. 2 to 6, inclusive.

Fig. 2 shows the general arrangement of cams. The cam pivot A and the cam-lever pivot P are parts of the frame. The angle α_1 is the displacement angle of the cam or the angle through which it must move to cause the follower to rise from the base circle of the cam to its extreme outer point.

For the graphical as well as for the mathematical treatment, it is more convenient to consider the cam stationary and let the cam-lever pivot P rotate around the cam pivot A as in Fig. 3.

For the same rise of the follower the angle α_1 or α is called the displacement angle or the angular displacement of the cam.

Fig. 4 shows the relationship between the angular displacement α of cam and the angular displacement ω of the cam lever.

The given values in a cam problem are as a rule the angle α the cam-lever length a, and the radii r_1 and r_2. In automatic machines α is part of a cycle within which a certain operation has to be performed.

From Fig. 4 it is obvious that the angle ω and the points B and C are determined by the values mentioned. The angle β is called the pressure angle and is the angle formed by the tangent T to the curve and the cam lever PB (see Fig. 12). If β is 90 deg. the cam cannot revolve, and if $\beta = 0$ deg., the follower cannot be lifted from the base circle. In order to keep the friction in the various elements constant, the curve between B and C must be such that β remains constant.

The graphical method of laying out the constant-pressure-angle cam curve as illustrated in Figs. 5 and 6 is a trial-and-error method.

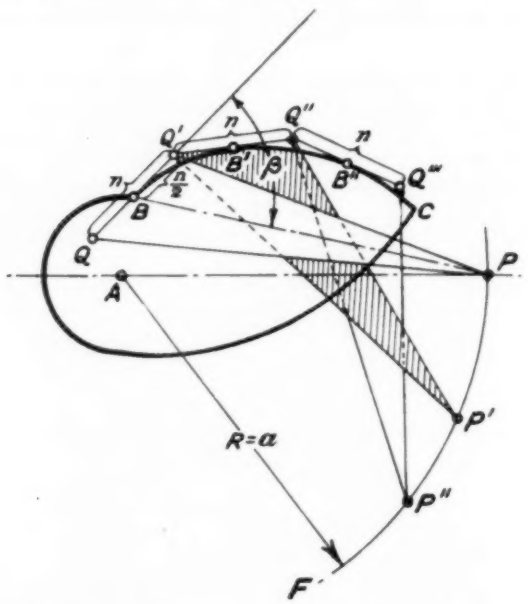

Fig. 6 Consecutive Positions of Characteristic Triangle for Laying Out Uniform-Pressure-Angle Cam Curve

A pressure angle β must be assumed and the curve laid out section by section. If the cam angle α proves to be too small or too large for a given cam-lever displacement angle ω, the pressure angle β must be changed until α approaches the required magnitude.

The curve is laid out as follows: Referring to Fig. 5, draw base circle D, circle of maximum lift E, and cam-lever-fulcrum circle F around center A. Then with P as a center, strike follower arc AG. Follower arc AG intersects the base circle D at point B. Assume a pressure angle $\beta = PBK$, and on the side BK of this angle locate points Q and Q' equidistant from point B. Distance BQ is chosen arbitrarily. Point B is to become a point of tangency in the layout of the first section of the cam curve. With points P, Q, and Q' established, the characteristic triangle PQQ' of the cam curve is obtained.

Keeping point P on the arc F (Fig. 6), rotate the characteristic triangle until point Q falls on point Q'. This gives a new point Q'', as well as a new point of tangency B'. The process should be repeated until the cam curve passes through point C.

The envelope of the elements is the uniform-pressure-angle curve.

The most convenient manner for the draftsman to lay out the uniform-pressure curve is to draw the characteristic triangle on a small piece of transparent paper and add the elements together by marking the points Q, Q', Q'', etc., while rotating P on circle F.

The smaller the lengths n, the more accurate the completed cam curve will be.

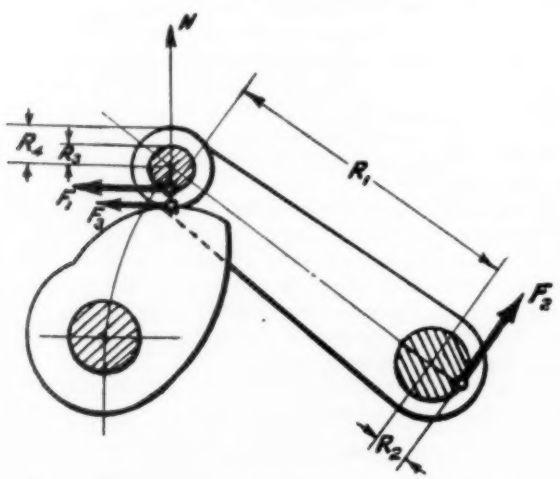

FIG. 11 FRICTIONAL FORCES ACTING ON A CAM SYSTEM

TYPES OF UNIFORM-PRESSURE CAMS

The four types of cams in general use are shown in Figs. 7–10.

Fig. 7 shows a cam with the cam radius and cam lever of infinite length. In this case the cam is both a uniform-pressure cam and a uniform-rise cam.

Fig. 8 shows a cam with an infinite cam radius and a cam lever of finite radius.

Fig. 9 shows a cam with cam-lever radius of infinite length and a cam radius of finite length.

In Fig. 10 both the cam radius and the cam-lever radius have finite dimensions.

DEFINITION OF MAXIMUM PRESSURE ANGLE

The maximum pressure angle or binding angle is the angle at which the follower begins to bind on the cam. The binding takes place when the friction moment, acting on the cam lever, is equal to the lifting moment on the cam lever.

The total friction moment is caused by three component forces (see Fig. 11):

a The sliding friction F_1 of the follower on the stud,
b The sliding friction F_2 of the cam lever shaft in the cam lever bearing, and
c The rolling friction F_3 of the follower on the cam curve.

DETERMINATION OF MAXIMUM PRESSURE ANGLE

To illustrate the influence of each of the three aforementioned forces on the binding angle, four different cases will be calculated

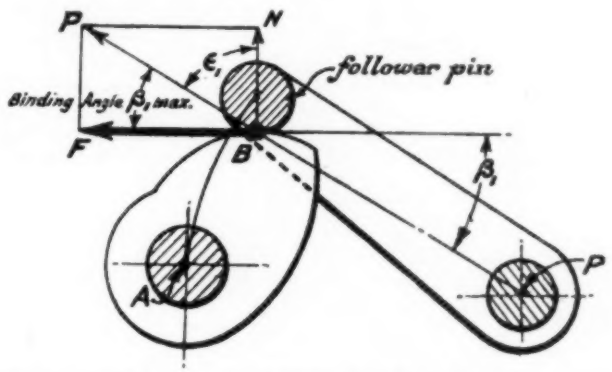

FIG. 12 ILLUSTRATION OF BINDING ANGLE WHERE ONLY THE SLIDING FRICTION BETWEEN FOLLOWER AND CAM SURFACE IS CONSIDERED
(Binding angle $\beta_1 = 78°$.)

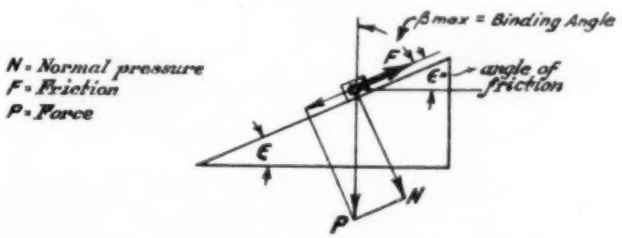

FIG. 13 DIAGRAMMATIC ILLUSTRATION OF BINDING ANGLE

with the following values given (Fig. 11):

Angle of sliding friction, steel on steel (dry),

$$\epsilon = 12°$$

where $\tan \epsilon$ = coefficient of sliding friction,

Angle of rolling friction, steel on steel,

$$\delta = 0.1°$$

where $\tan \delta$ = coefficient of rolling friction,

$R_1 = 2$ in. $R_3 = 1/8$ in.
$R_2 = 3/16$ in. $R_4 = 1/4$ in.

Case 1. The follower is a pin and the sliding friction F acting on the pin is the only friction considered. (See Fig. 12.) The follower binds on the cam when

$$\beta_1 \text{max.} = 90° - \epsilon_1 \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

$$\epsilon_1 = \epsilon = 12°$$

$$\therefore \beta_1 \text{max.} = 78°$$

Equation [1] will be more easily understood by constructing a vector diagram of a force P acting on an inclined plane as shown in Fig. 13.

Case 2. Fig. 14 represents a cam mechanism with a follower roller. The rolling friction F between the follower roller and the follower stud is the only friction under consideration.

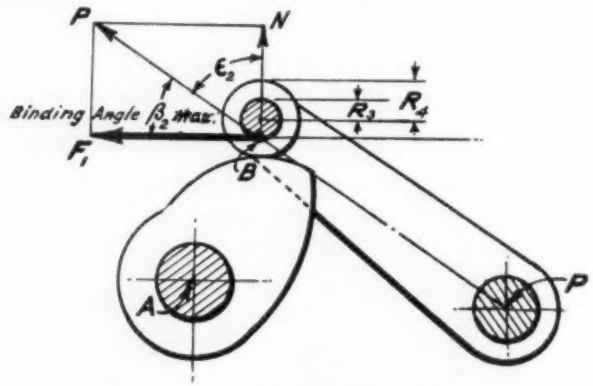

FIG. 14 ILLUSTRATION OF BINDING ANGLE WHERE ONLY THE SLIDING FRICTION BETWEEN FOLLOWER AND FOLLOWER STUD IS CONSIDERED
(Binding angle $\beta_2 = 83° 56'$.)

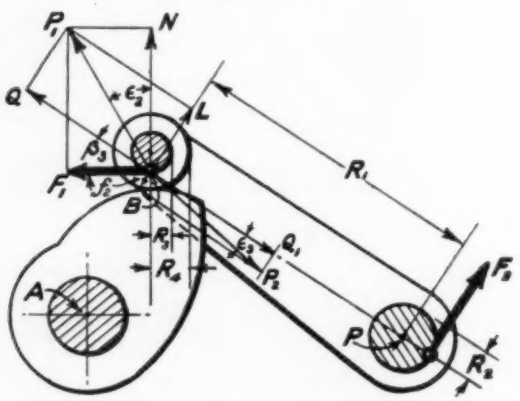

FIG. 15 ILLUSTRATION OF BINDING ANGLE WHERE ONLY FRICTION BETWEEN FOLLOWER AND FOLLOWER STUD AND THE FRICTION IN CAM LEVER BEARING ARE CONSIDERED
(Binding angle $\beta_3 = 82° 47'$.)

The follower binds on the cam when

$$\beta_2 \text{max.} = 90° - \epsilon_2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

$$\tan \epsilon_2 = \frac{R_3}{R_4} \tan \epsilon \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

$$= \frac{1}{2} \tan 12° \text{ or } \epsilon_2 = 6° 4'$$

$$\therefore \beta_2 \text{ max.} = 83° 56'$$

Case 3. Here the friction F_2 of the cam-lever shaft on its bearing in addition to the friction F_1 is considered.

Referring to Fig. 15, the two forces acting on the follower are the normal force N and the friction F_1. N and F_1 are components of P_1. The force P_1 may be divided into the lifting component L and the cam-lever force Q. The reaction Q_1 of the force Q is equal to the latter magnitude and opposite in direction. This force Q_1 produces a friction F_2 which, reduced to a force acting on radius R_1, results in $f_2 = F_2 \frac{R_2}{R_1}$. The two forces Q_1 and f_2 are components of P_2. If P_1 and P_2 lie in the same line and are opposite in direction there will be no lifting force and the follower will bind on the cam.

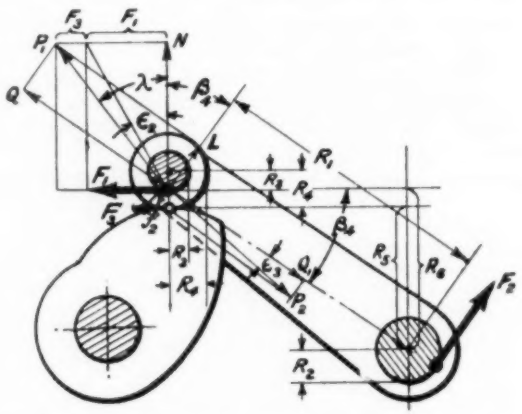

FIG. 16 ILLUSTRATION OF BINDING ANGLE WHERE ALL FRICTIONS (SLIDING AND ROLLING) ACTING ON THE SYSTEM ARE CONSIDERED
(Binding angle $\beta_4 = 82° 41'$.)

The forces P_1 and P_2 are in line when:

$$\beta_3 \text{max.} = 90° - (\epsilon_2 + \epsilon_3) \quad \ldots\ldots\ldots\ldots [4]$$

$$\tan \epsilon_2 = \frac{R_3}{R_4} \tan \epsilon \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

$$\tan \epsilon_3 = \frac{R_2}{R_1} \tan \epsilon \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

Since $\epsilon_2 = 6° 4'$ (see *Case 2*)

$$\tan \epsilon_3 = \frac{3}{16}, \quad \tan 12° \text{ or } \epsilon_3 = 1° 9'$$

$$\therefore \beta_3 \text{max.} = 82° 47'$$

Case 4. This case includes all friction forces acting on the cam lever (Fig. 16).

The three forces acting on the follower are the normal pressure N, the sliding friction F_1, and the rolling friction F_2. The rolling friction F_3 is very small compared with F_1, and the difference between R_5 and R_6 is also very small. For practical purposes F_3 may therefore be assumed to be in line with F_1. The force P_1 is determined by the normal pressure N and the sum of the friction forces $F_1 + F_2$.

The follower binds when P_1 is in line with P_2 and when P_1 and P_2 act in opposite directions, or when

$$\beta_4 \text{max.} + \lambda + \epsilon_2 = 90°$$

$$\tan \lambda = \frac{F_1 + F_2}{N} = \frac{N \tan \epsilon_2 + N \tan \delta}{N} = \tan \epsilon_2 + \tan \delta$$

$$\tan \epsilon_2 = \frac{R_3}{R_4} \tan \epsilon \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

$$\tan \lambda = \frac{R_3}{R_4} \tan \epsilon + \tan \delta \quad \ldots\ldots\ldots [7]$$

$$\tan \lambda = {}^1/_2 \tan 12° + 0.1 \text{ or } \lambda = 6° 10'$$

$$\tan \epsilon_3 = \frac{R_3}{R_4} \tan \epsilon \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

$$\tan \epsilon_3 = \frac{3}{16} \times \frac{1}{2} \tan 12° \text{ or } \epsilon_3 = 1° 9'$$

$$\therefore \beta_4 \text{max.} = 82° 41'$$

Summarizing, the binding angles in the four cases are as follows:

Case 1, $\beta_1$max. = 78° Case 3, $\beta_3$max. = 82° 47′
Case 2, $\beta_2$max. = 83° 56′ Case 4, $\beta_4$max. = 82° 41′

As will be noted, the rolling friction is practically negligible, the difference between the binding angle in Case 3 and Case 4

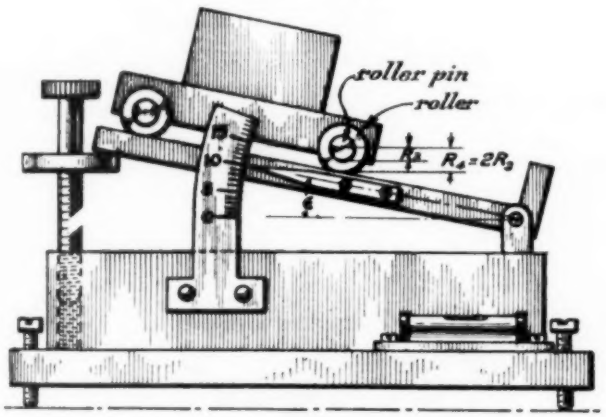

FIG. 17 APPARATUS TO DETERMINE EXPERIMENTALLY THE BINDING ANGLE OF CAMS USING DIFFERENT METALS AND LUBRICANTS

being very small. The effect of the friction in the cam-shaft bearing which is represented by the difference of Case 2 and Case 3 is also negligible for practical purposes.

For all practical purposes, where a follower roller is used, Case 2 will give results sufficiently accurate. In order to have a correction and safety factor, however, it is advisable to increase the friction angle ϵ_2 by 25 per cent. In the examples given this safety factor would cause the binding angle in Case 2 to closely approach the real conditions as given in Case 4.

Taking Case 2 with the corrected angle of friction

$$\epsilon_0 = \epsilon + 0.25\epsilon = 1.25\,\epsilon$$

and substituting ϵ_0 for ϵ in Equation [3],

$$\tan \epsilon_2 = \frac{R_3}{R_4} \tan \epsilon_0$$

$$\tan \epsilon_2 = \frac{R_3}{R_4} \tan 1.25\,\epsilon \quad \ldots\ldots\ldots\ldots [8]$$

The determination of the maximum-pressure angle or binding angle β max. by Equations [2] and [8] will serve for all engineering purposes.

EXPERIMENTAL DETERMINATION OF MAXIMUM-PRESSURE ANGLE

To check the computed binding angle βmax., a carriage on interchangeable rollers with adjustable friction angle was used (Fig. 17). The values obtained are given in Table 1.

DETERMINATION OF A PRACTICAL PRESSURE ANGLE

The maximum-pressure angle cannot be used as a practical pressure angle since no power can be transmitted. Assuming

TABLE 1 VALUES OF β MAXIMUM

Material of			Bearing of roller on pin	Lubricated or dry	Composite friction angle ϵ	Binding angle βmax.
Roller pin (stud)	Roller (follower)	Sliding surface (cam)				
Steel	Steel (locked to skid)	Steel	Locked to skid	Dry	11½°	78½°

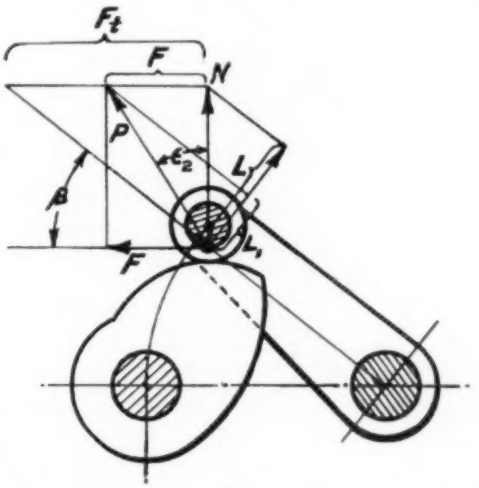

FIG. 18 ILLUSTRATION TO DEFINE FRICTIONAL LOSS OF A CAM

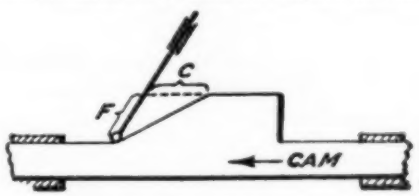

FIG. 19 ILLUSTRATION TO DEFINE LEVERAGE OF A STRAIGHT-MOTION CAM

or allowing a certain percentage of frictional loss in the cam mechanism, the pressure angle can be computed. It is simpler, however, to assume a pressure angle, see whether it is sufficiently large or small to do a certain work in a certain time, and then figure the frictional loss.

Example:

$R_3 = \frac{1}{8}$ in. $\epsilon = 12°$
$R_4 = \frac{1}{4}$ in. βmax. = 82° 22′ (by [8] and [2])

Assume that the practical pressure angle $\beta = 60°$.

The frictional loss η is the ratio $(L - L_1)/L = F/F_t$. (See Fig. 18.)

At $\beta = 82° 22'$ the friction $F = F_t$ and $\eta = F/F_t = 1$, or the frictional loss = 100 per cent.

At $\beta = 60°$ the ratio

$$\eta = \frac{F}{F_t} = \frac{N \tan \epsilon_2}{N \cot \beta} = \frac{\tan \epsilon_2}{\cot \beta}$$

By Equation [8] $\tan \epsilon_2 = \frac{R_3}{R_4} \tan (1.25\epsilon)$

$$\eta = \frac{\tan (1.25\,\epsilon)}{\cot \beta} \times \frac{R_3}{R_4} \quad \ldots\ldots\ldots\ldots\ldots\ldots [9]$$

or

$$\eta = \frac{\tan(1.25 \times 12°)}{\cot 60°} \times \frac{1}{2} = 0.232$$

or the frictional loss $\eta = 23$ per cent.

The Leverage on the Uniform-Pressure-Angle Curve

On the uniform-pressure-angle curve the leverage or the ratio of the angular velocities or displacements of the cam and the cam lever is not constant. Since the lifting power is dependent upon this ratio, it is important to determine it for different points of the curve.

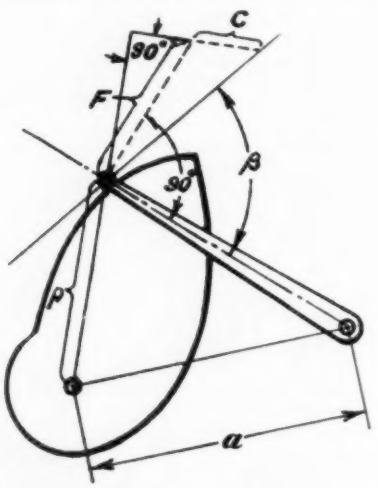

Fig. 20 Illustration to Define Leverage of a Circular Cam

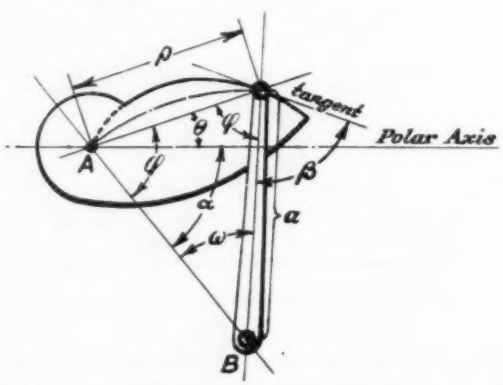

Fig. 21 Illustration to Define Symbols Used in the Equations of the Uniform-Rise Curve

Fig. 19 shows the displacement of cam and follower on a straight-line-motion cam mechanism.

When the cam is displaced by the distance C and the follower displacement is F, the leverage L is the displacement ratio C/F.

On a circular-arc cam small angular displacements have to be taken into consideration. Referring to Fig. 20, the angular displacement of the cam is $d\alpha = dC/\rho$ and the angular displacement of the follower is $d\omega = dF/a$.

$$\text{The leverage } L = \frac{d\alpha}{d\omega} = \frac{dC}{dF} \times \frac{a}{\rho} = \frac{C}{F} \times \frac{a}{\rho}$$

The quotient C/F is determined graphically and then multiplied by a/ρ.

The Uniform-Rise-Curve Equation

As previously mentioned, the uniform-rise-curve cam transmits motion like a pair of gears with a constant ratio or constant leverage L. The variable in such a cam is the pressure angle β.

When the polar axis is so chosen that $\omega = 0$ for $\alpha = 0$, the mathematical expressions are (Fig. 21):

$$L = \frac{\alpha}{\omega} = \text{leverage} = \text{constant}$$

$$\begin{cases} \theta = (1 - 2\,L)\,\varphi + K \\ \rho = 2a \cos \varphi \end{cases}$$

$$\tan \beta = \frac{\cot \dfrac{\alpha}{2L} + (1 - 2L)\tan \dfrac{\alpha}{2L}}{2L}$$

where the integration constant $K = L \times 180°$.

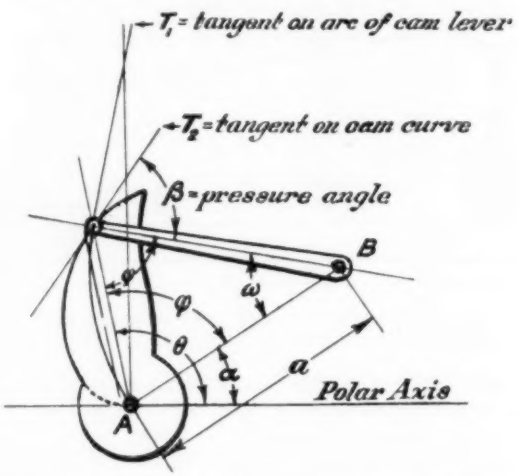

Fig. 22 Illustration to Define Symbols Used in the Equations of the Uniform-Pressure-Angle Curve

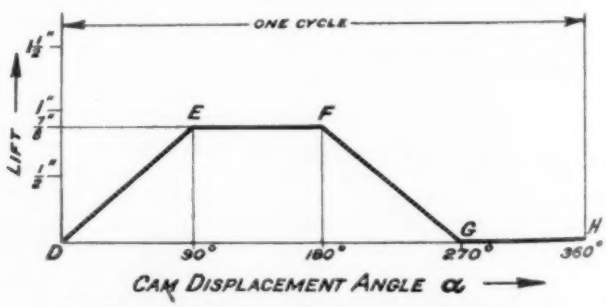

Fig. 23 Cycle Diagram of Cam as Shown in Fig. 24

The Uniform-Pressure-Curve Equations

This cam curve transmits motion at a constant pressure angle β and a variable leverage L.

The mathematical expressions for an arbitrarily chosen polar axis are (Fig. 22):

$$\begin{cases} \beta = \text{pressure angle} = \text{constant} \\ \theta = \varphi \mp \cot \beta \log_e (\tan \beta \tan \varphi \pm 1) + K \\ \rho = 2\,a \cos \varphi \end{cases}$$

$$L = \frac{d\alpha}{d\omega} = \frac{[e^{\mp \tan \beta(\alpha - K)} \mp 1]^2 + \tan^2 \beta}{\mp 2 \tan^2 \beta e^{\mp \tan \beta(\alpha - K)}}$$

The leverage L may be more simply computed as a hyperbolic function.

$$L = \frac{1}{-2}\{\cosh[\tan\beta(\alpha - K)] \mp \sinh[\tan\beta(\alpha - K)]\} + \cot^2\beta\{1 \mp \cosh[\tan\beta(\alpha - K)]\}$$

where K is an integration constant and e the base of the Napierian logarithmic system. The upper signs refer to cam and cam lever when rotating in the same direction. The lower signs refer to cam and cam lever when rotating in opposite directions.

Use of the Charts

As previously mentioned, the uniform-rise curve can be accurately laid out and it may not be necessary to copy the curve from Chart I. However, it provides a convenient means of selecting a suitable curve from a region where the pressure angles are such as not to cause excessive frictional loss.

The uniform-pressure-angle curve cannot be laid out directly to suit a given cam displacement angle, and in most cases it will be desirable to copy it from Chart II.

An example will illustrate the manner of laying out the cam curve from this chart.

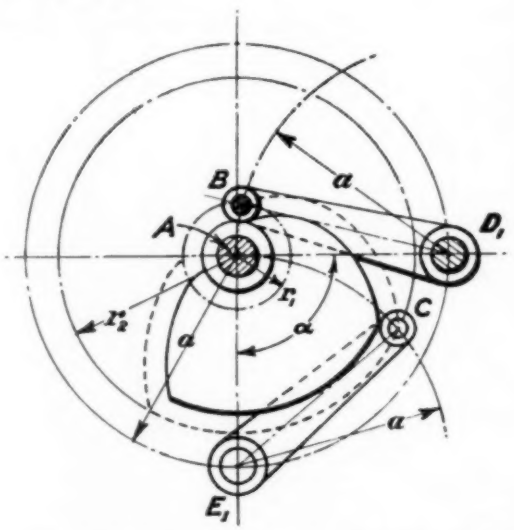

Fig. 24 Uniform-Pressure-Angle Cam, Showing the Use of Chart II and Made According to Cycle Diagram Fig. 23

Given: the diagram as shown in Fig. 23.
Assumed: (See Fig. 24).

Length of cam lever	$a = 1^1/_2$ in.
Radius of base circle	$r_1 = {}^3/_8$ in.
Radius of circle of maximum lift	$r_2 = 1^1/_4$ in.
Follower lift	$r_2 - r_1 = {}^7/_8$ in.
Radius of follower stud	$R_1 = {}^1/_{16}$ in.
Radius of follower roller	$R_2 = {}^1/_8$ in.

To find the uniform-pressure-angle curve suited for the diagram, proceed as follows:

The line *DE* in Fig. 23 represents the rise of the follower, and for simplicity is shown as a straight line. For a uniform-pressure-angle cam curve it would in reality be a curve.

The graphs of the uniform-pressure-angle curve on the chart are laid out for a cam-lever length of $a = 1^1/_2$ in. On the assumption that $a = 1^1/_2$ in. the enlargement ratio of the cam curve on the chart to the actual cam curve 1:1, that is to say, the coordinates (polar or rectangular) must be multiplied by 1. If the enlargement or reduction ratio is other than unity, the curve must be correspondingly enlarged or reduced.

In order to copy the curve conveniently, the layout is made on transparent paper to the scale of the chart. The procedure illustrated in Fig. 24 is as follows:

1 Describe circles with radii $r_1 = {}^3/_8$ in., $r_2 = 1^1/_4$ in., and $a = 1^1/_2$ in.

2 Choose point D_1 on the circle whose radius is a which corresponds to point D on diagram (Fig. 23) and determines the zero value for the cam displacement angle α.

3 Determine point E_1 90 deg. from point D_1 and describe arc AB with center D_1 and arc AC with center E_1. The intersection points B and C are two points on the cam curve.

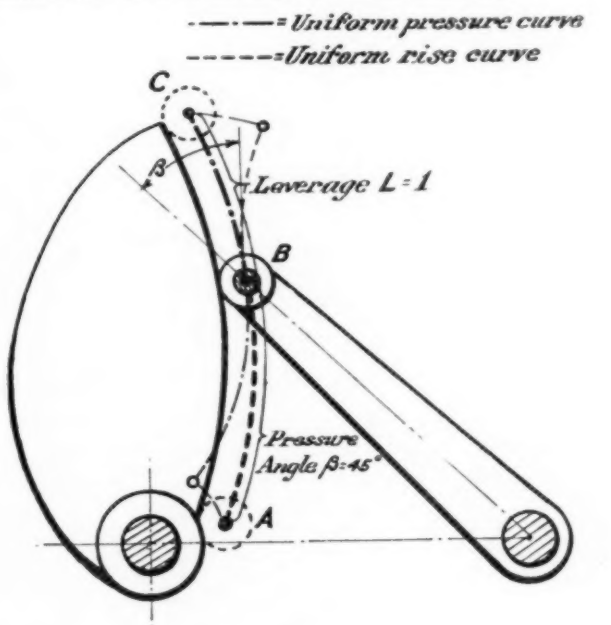

Fig. 25 Combined Uniform-Pressure-Angle and Uniform Rise Cam, Showing the Use of Chart I and Chart II

4 Place this layout on Chart II so that center A coincides with A_1 on the chart and rotate the layout around A_1 until a curve is found which passes through B and approaches C.

In this way it will be found that the pressure angle of the curve in the example is 50 deg.

The frictional loss of the cam mechanism corresponding to this pressure angle, is, according to Equation [9],

$$\eta = \frac{\tan\ (1.25\epsilon)}{\cot\ \beta} \times \frac{R_2}{R_1} = 0.16$$

or frictional loss $\eta = 16$ per cent.

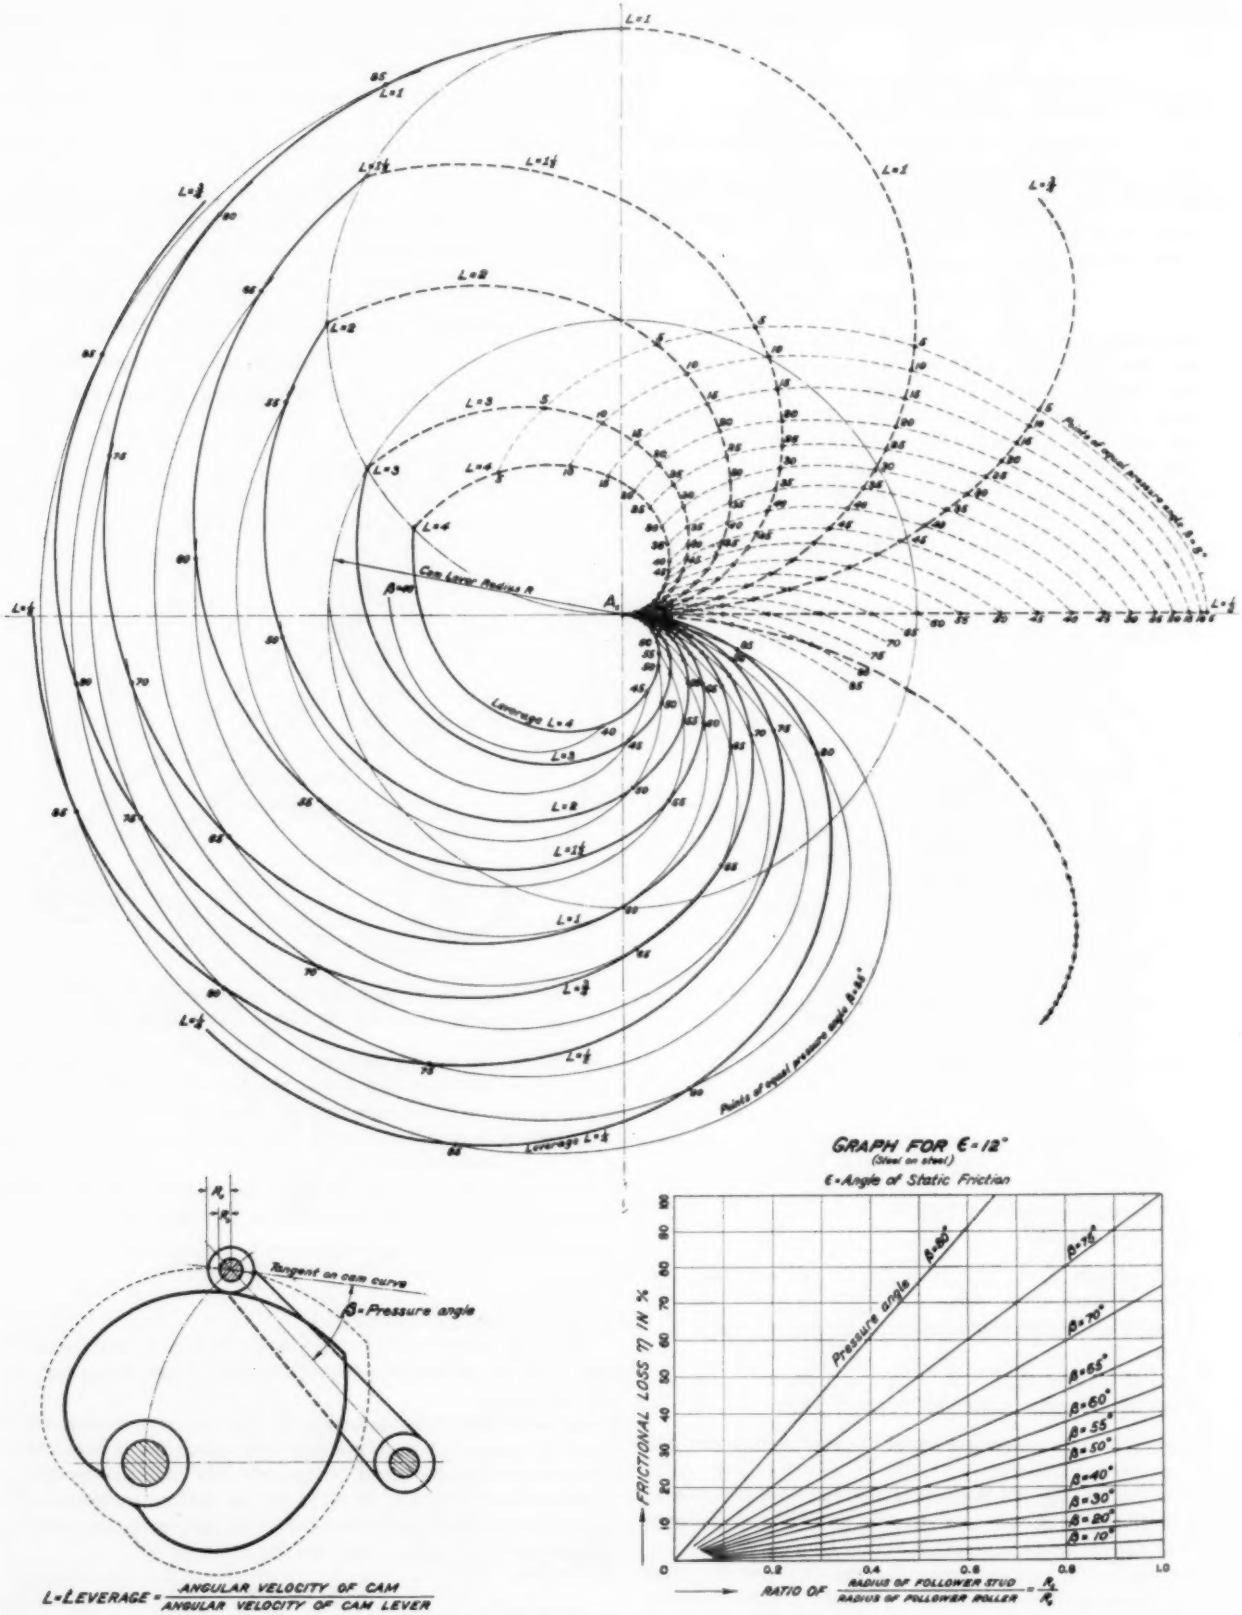
Assuming that $\epsilon = 12°$ (for steel on steel), the frictional loss η may be plotted in terms of R_2/R_1 as shown at the bottom of both charts.

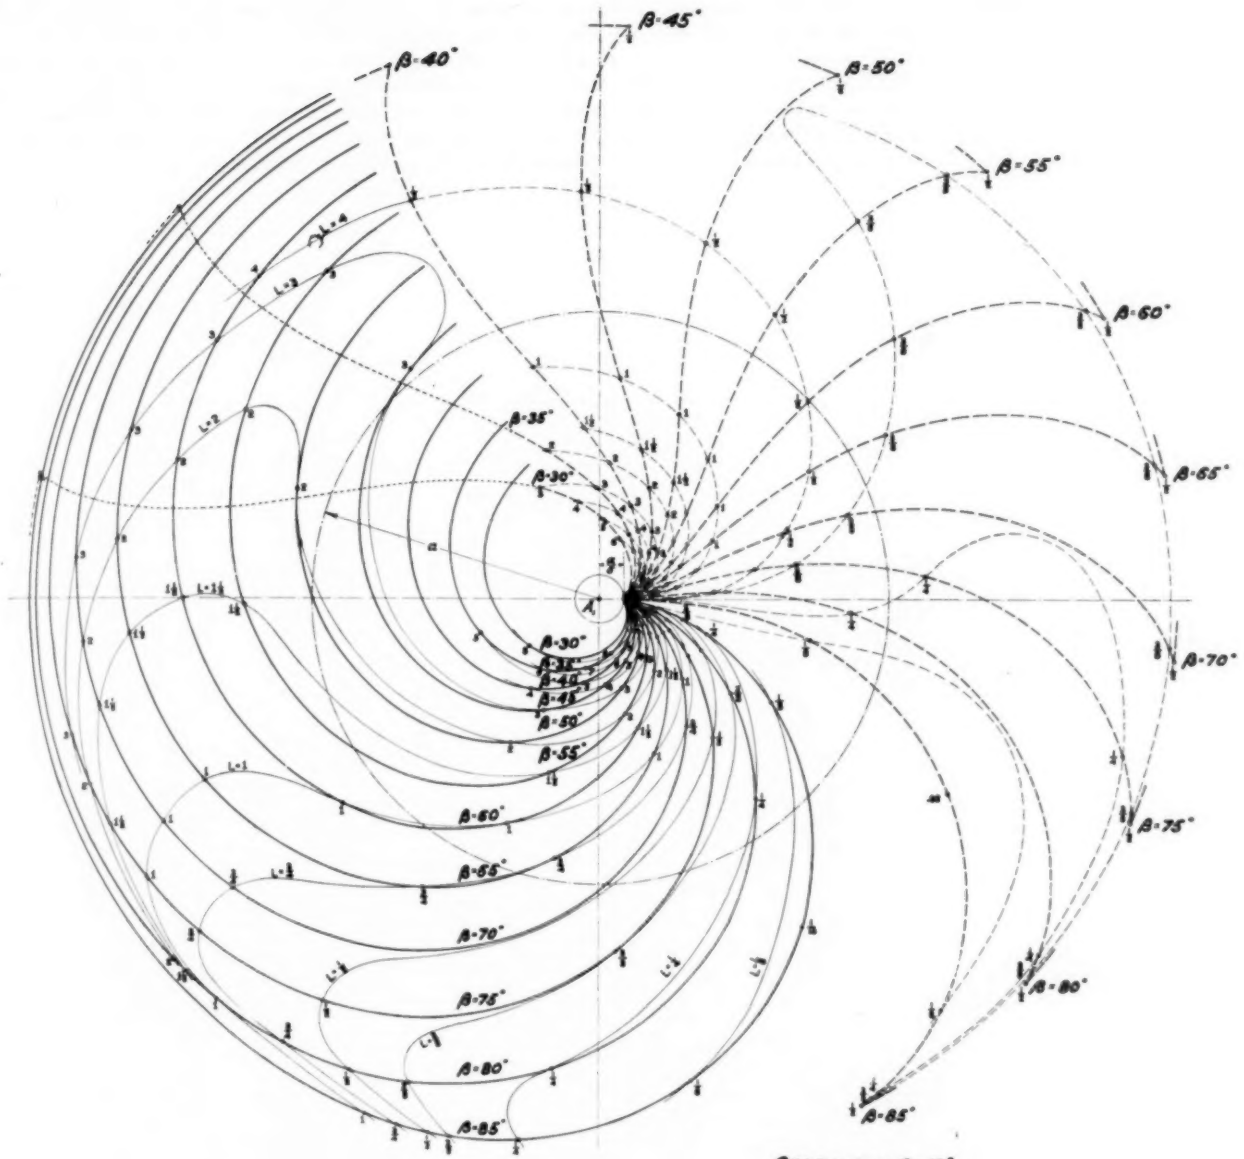
In cases where the leverage on the uniform-pressure-angle curve decreases undesirably, it is sometimes advisable to combine the uniform-pressure-angle curve with the uniform-rise curve.

Referring to Fig. 25, at point B, the uniform-pressure-angle curve AB reaches a leverage of $L = 1$, and from this point to the point C the curve is a uniform-rise curve.

Conclusion

Cams with uniform-pressure angles have been built in accordance with the foregoing methods and employed in light automatic machines with very satisfactory results. They have proved





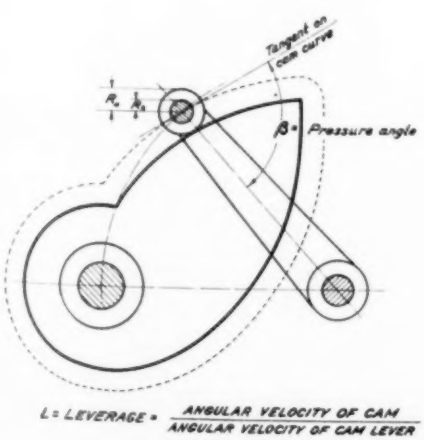


CHART I—UNIFORM-RISE CAM CURVE

NOTE: For cam and cam lever rotating in *same direction*, the heavy dash-lines are the cam curves; the fine dash-lines indicate points of equal pressure angle.

For cam and cam lever rotating in *opposite directions*, the heavy lines are the cam curves; the fine lines indicate points of equal pressure angle.

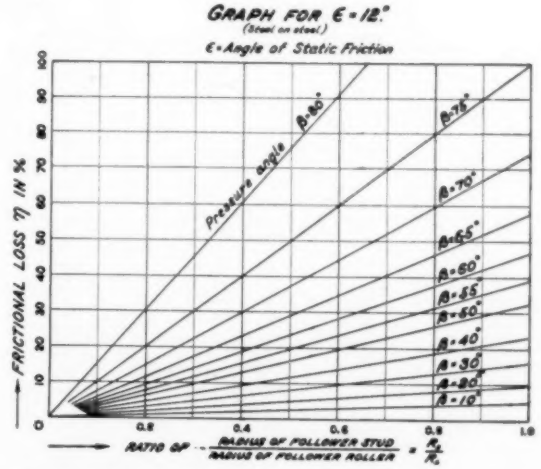

CHART II—UNIFORM-PRESSURE-ANGLE CAM CURVE

NOTE: For cam and cam lever rotating in *same direction*, the heavy dash-lines are the cam curves; the fine dash-lines indicate points of equal leverage.

For cam and cam lever rotating in *opposite directions*, the heavy lines are the cam curves; the fine lines indicate points of equal leverage.

to be of decided advantage where it has been necessary to construct a cam mechanism in a minimum of space and with a maximum of efficiency.

If no limitations of space were dictated in the design of cam structures, it would probably be best to employ the uniform-rise curve and make the cam diameter large enough to obtain a negligible pressure angle. However, in most cases it is necessary to make the parts as small and light as possible. On a small cam the base is always in very close proximity to the cam shaft, and the cam angle is very steep. It is then obvious that best results are obtained by a cam design wherein the cam stud, cam lever, etc., are under uniform stress and uniform wear throughout the cam cycle. A cam curve of such character is necessarily of the uniform-pressure-angle type.

APM-51-15

Friction of Journal Bearings as Influenced by Clearance and Length

By S. A. McKEE[1] and T. R. McKEE,[2] WASHINGTON, D. C.

An investigation at the Bureau of Standards is described, the object of which was to determine the effects upon the frictional resistance of small-bore full-journal bearings of changes in the length-diameter and clearance-diameter ratios. A journal-bearing friction machine provided a method for measuring the frictional resistance when operating under different conditions of load on the bearing, speed of the journal, and viscosity of the lubricant. By a suitable correlation of these factors a measure of the effects of changes of clearance and length with bearings of the same diameter was obtained. The results indicate that changes in the length-diameter ratio as well as in the clearance-diameter ratio have marked effects upon the frictional characteristics of journal bearings in normal operation. Suitable corrections to a theoretical equation for journal friction are derived from these experiments for bearings of all normal clearances and lengths. In the conclusion, further steps toward a more complete understanding of journal-bearing performance are indicated.

THE factors that determine the performance characteristics of journal bearings might conveniently be divided into two classes, operating factors and factors of construction. Among those classed as operating factors (i.e., those that are dependent upon the particular conditions of operation) are the load on the bearing, the speed of the journal, the temperature of operation, and the viscosity, oiliness,[3] and amount of the lubricant. Among the factors of construction (i.e., those that are built into the bearing itself) are (1) the absolute size as represented by the journal diameter; (2) L/D, the ratio of the length of the bearing to the diameter of the journal; (3) C/D, the ratio of the diametral clearance to the diameter of the journal; (4) the condition of the bearing surfaces, which is dependent upon the materials of which the journal and bearing are made, their smoothness, and their deviation from true cylindrical form; and (5) the means for applying or retaining the lubricant, such as oil holes, oil grooves, and relieved spaces.

The object of this study is to determine the effects of changes in two of the most important factors of construction in a normal bearing—namely, the L/D and C/D ratios—in the hope that the results may be of value in the formulation of rational methods for bearing design.

Method for Comparing Bearing Performance

The method chosen for showing the effect of changes in clearance and length was to measure the frictional resistance of a set of bearings having a given length and clearance under a wide range of operating conditions and to repeat the measurements with other sets of bearings having different lengths and clearances, the same journal being used in all the tests.

A convenient graphical method for evaluating the results obtained is to compare the respective coefficient-of-friction curves of bearings having different lengths and clearances, plotting the coefficient of friction f against the generalized operating variable $\mu n/p$ which denotes the product of the viscosity of the lubricant by the number of revolutions per unit time divided by the bearing pressure (load per unit projected area). The justification and advantages of the generalized variable in place of the separate operating factors have been previously discussed. The particular choice of units and notation employed are the same as were used in three previous investigations[4] and consist in expressing the viscosity in centipoises, the speed in revolutions per minute, and the bearing pressure in pounds per square inch, and in denoting the respective quantities by Z, N, and P when so expressed. The graphical method of this paper may therefore be very simply described as a comparison of the f-(ZN/P) curves for bearings of the same absolute size having widely different values of L/D and C/D.

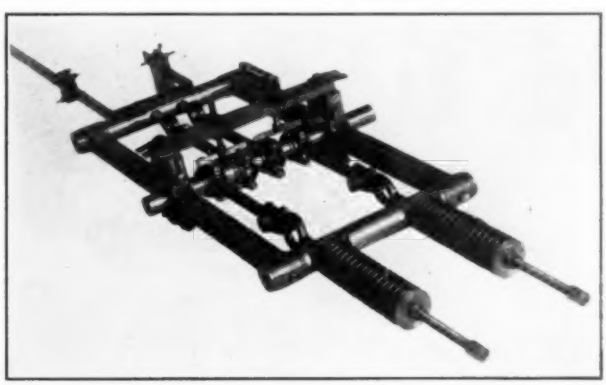

FIG. 1 FRICTION MACHINE, ESSENTIAL PARTS

The Friction Machine and Its Operation[5]

A photograph of the friction machine used in this and preceding work is shown in Fig. 1. The machine was originally designed to use four connecting rods of an automobile engine, with the babbitt-lined "big end" bearings serving as test bearings, mounted on a steel shaft set in a lathe. These rods were used in the tests where the L/D ratio was 1.00, but in all the others solid-bronze babbitt-lined bearings, clamped in special holders of the same general shape as the connecting rods, were used. A photograph of these bearings with a holder is shown in Fig. 2. These

[5] For a more detailed description see papers by S. A. McKee (previously cited), *Journal S.A.E.*, vol. 20 (1927), pp. 3–6, and *Mechanical Engineering*, vol. 49, December, 1927, pp. 1335–1340.

four rods are fastened to a frame by means of eyebolts and clevises in such a manner that they lie in a horizontal plane with the two end bearings on the opposite side of the shaft from the two in the middle. The frame is suspended by two equalizers mounted on a cross-beam fastened to the frame just above the shaft. Load is applied to the bearings by compressing the calibrated coil springs mounted on the sliding eyebolts fitted to the end rods.

Oil is fed to the center of the unloaded sides of the bearings by lines of rubber tubing from a glass bottle. The oil is forced from the bottle by the house air pressure of about 7 cm. of mercury.

The working temperature of the bearings is measured by copper-constantan thermocouples fastened to the loaded sides of the second and fourth bearings. When using the regular automotive connecting rods where the bearing shell was thin, the thermocouples were soldered in the center of the outside of the bearing cap. When using the special bearings, however, con-

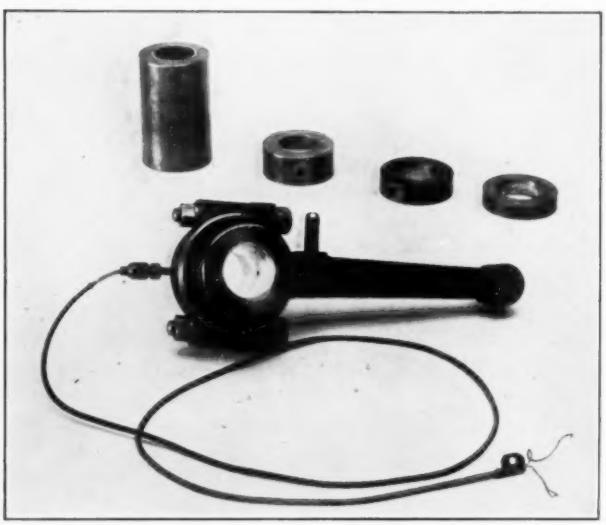

FIG. 2 SPECIAL BEARINGS AND HOLDER, WITH THERMOCOUPLE AND CONNECTOR

nectors were made, which, when screwed in the longitudinal center of the loaded side of the bearing shell, brought the thermo-junction to within about $^1/_{16}$ in. of the babbitt lining. These connectors were found to be advantageous in another respect in that they facilitated the changing of a couple from one bearing to another. It was found advantageous also where frequent bearing changes were necessary, as in these tests, to protect the wires from becoming kinked and broken by winding each couple with spring-steel wire. A couple with its armor and connector is also shown in Fig. 2.

Temperature control is provided by circulating water through the hollow test shaft by means of a small motor-driven gear pump connected to a 20-gal. supply tank.

In making a test run oil is fed to the bearings and the machine brought to steady conditions under a predetermined load and speed to give the desired value of ZN/P.

DESCRIPTION OF THE BEARINGS AND JOURNAL TESTED

In order to conserve both material and labor and yet cover the full range of C/D and L/D ratios desired, the same test shaft was used for all the tests, and but one set of bearings for all the tests with a given L/D ratio. The procedure was to run the tests for a given L/D ratio with successively increasing clearances, starting with the smallest clearance desired and reaming the bearings out to the next larger size after each test was completed.

Tests were made upon bearings having the following L/D and C/D ratios:

L/D = 2.80, with C/D = 0.00075, 0.00100, 0.00200, and 0.00455

L/D = 1.00, with C/D = 0.00046, 0.00065, 0.00100, 0.00200, 0.00400, and 0.01000

L/D = 0.75, with C/D = 0.00043, 0.00093, 0.00200, and 0.00400

L/D = 0.50, with C/D = 0.00048, 0.00100, and 0.00400

L/D = 0.25, with C/D = 0.00038, 0.00091, and 0.00191, and 0.00400.

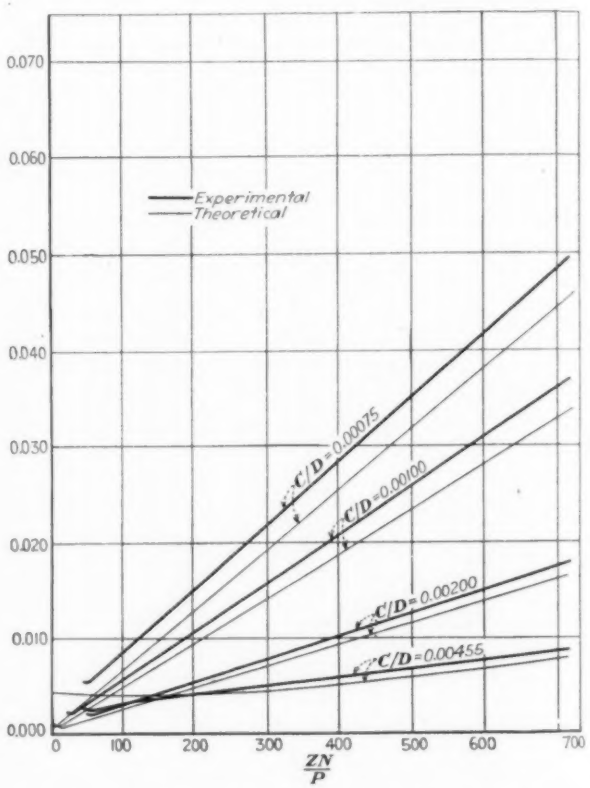

FIG. 3 JOURNAL-FRICTION CURVES FOR VARIOUS C/D RATIOS; L/D = 2.80

For the set with the L/D ratio of 1.00, the automotive connecting rods were used. These were specially prepared with oil grooves omitted and the babbitt lining cast in one piece so that they formed solid bearings. The approximate composition of the babbitt-metal lining was 85 per cent tin, 7.5 per cent copper, and 7.5 per cent antimony. The babbitt-metal lining in the special solid bearings used in all the other tests was of the same composition.

The ends of all the bearings were faced off square and their lengths were correct to within ±0.001 in. to give the required L/D ratio.

The bearing surfaces were finished with a special type of commercial reamer which provided a smooth, accurate bearing surface. The proper diameter for each bearing was based upon the average diameter of that part of the shaft at which it was located, and the diameter of no single bearing was allowed to deviate more than ±0.0002 in. from that required to give the average C/D ratio of the whole set of four. The measurements of diameter were made with a special type of commercial internal micrometer and were accurate to within ±0.0001 in.

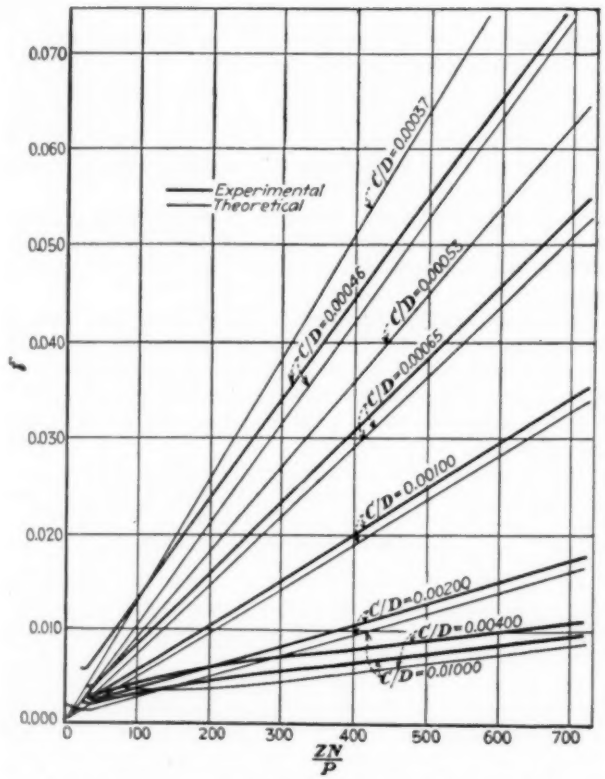

FIG. 4 JOURNAL-FRICTION CURVES FOR VARIOUS C/D RATIOS; $L/D = 1.00$

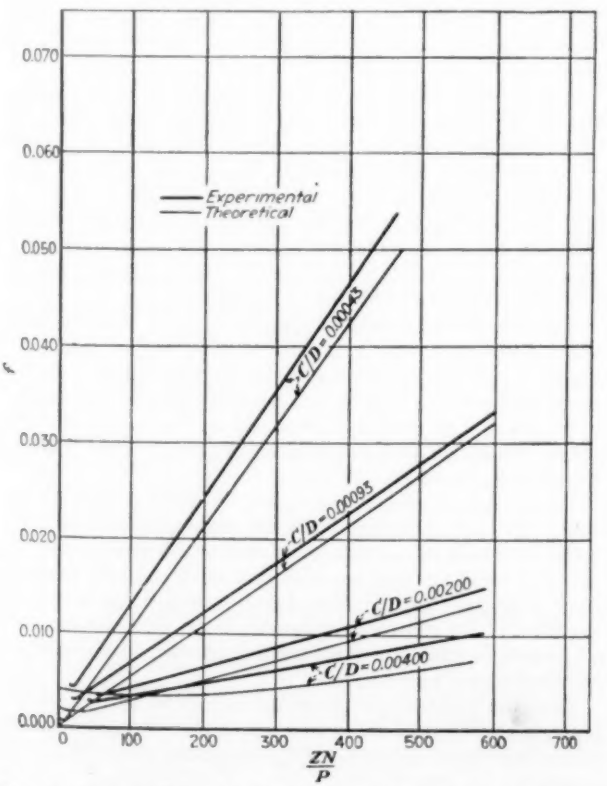

FIG. 5 JOURNAL-FRICTION CURVES FOR VARIOUS C/D RATIOS; $L/D = 0.75$

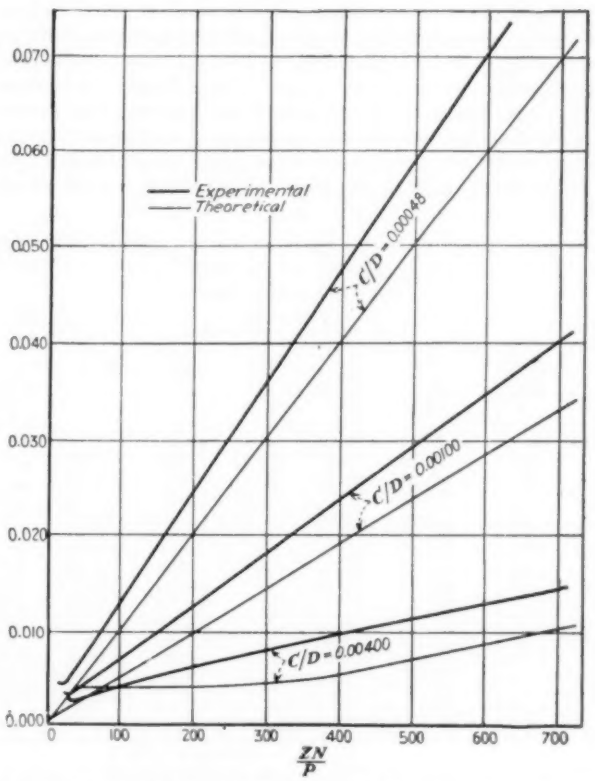

FIG. 6 JOURNAL-FRICTION CURVES FOR VARIOUS C/D RATIOS; $L/D = 0.50$

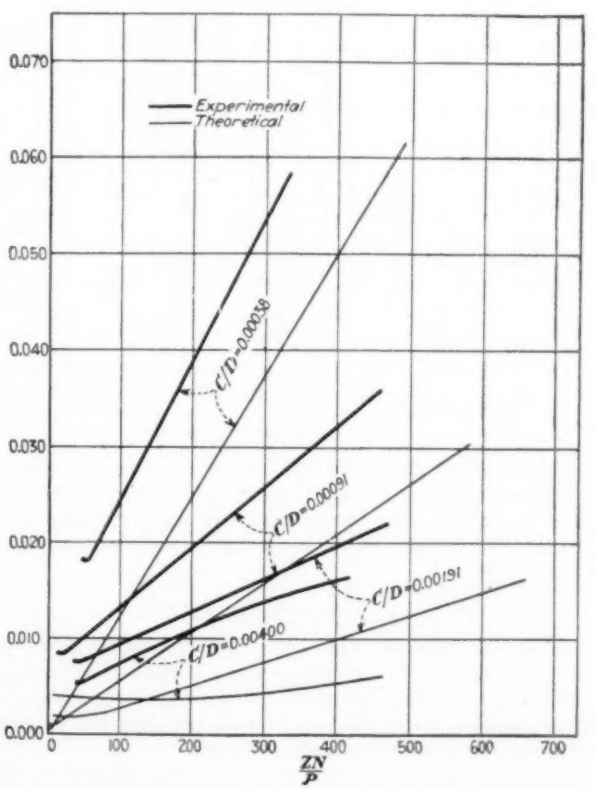

FIG. 7 JOURNAL-FRICTION CURVES FOR VARIOUS C/D RATIOS; $L/D = 0.25$

The test shaft used in these tests was made of a high carbon-tungsten tool steel, its heat treatment being: heated at 1500 deg. fahr., held for 30 min., quenched in oil, reheated at 850 deg. fahr. for 45 min., and air-cooled. It had a Brinell hardness of about 179. After treatment it was ground and lapped. The average diameter at the journals was dependent upon the location and length of the bearings, the maximum value being 1.25054 in. and the minimum 1.25043 in., these values being correct within ±0.00005 in.

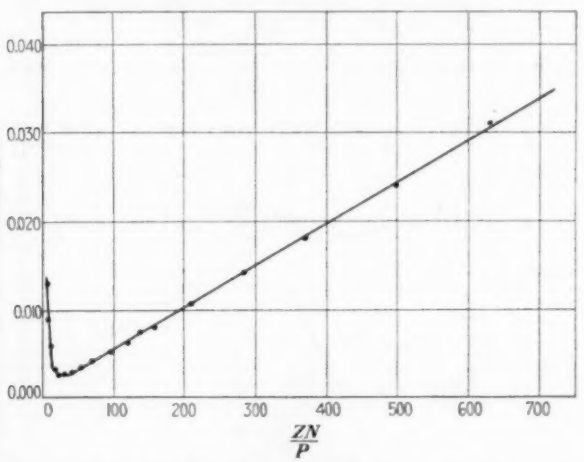

FIG. 8 TYPICAL PLOT OF JOURNAL-FRICTION OBSERVATIONS; L/D = 1.00, C/D = 0.00100

THE LUBRICANT USED

The lubricant used in all the tests was a mineral spindle oil having a viscosity of 126 sec. Saybolt Universal at 100 deg. fahr. The average running temperature was about 77 deg. fahr., the absolute viscosity of the oil at this temperature being about 42 centipoises.

PROCEDURE IN TESTING

All of the bearings were tested without being run in. The runs were made in the decreasing order of ZN/P. The first point of a run was obtained by using a light load combined with a high speed, and the succeeding points were obtained either by decreasing the speed or increasing the load.

The total load per bearing ranged from 25 to 200 lb., and the speed range was from 15 to 700 r.p.m. A typical data sheet is shown in Table 1.

GRAPHICAL PRESENTATION OF RESULTS

The results of these tests plotted in the form of f-(ZN/P) curves are shown by the heavy lines in Figs. 3, 4, 5, 6, and 7. Each figure contains curves for bearings of the same length, but with different clearances. Curves obtained from theoretical equations,[6] in which longitudinal oil flow and end effects are neglected, for the corresponding C/D ratios are shown by the light lines in these figures.

Intercomparison of the curves on a single figure indicates the effect of changes in the C/D ratio and shows the amount that the practical bearing deviates from the theoretical for any given change.

Intercomparison of the figures for different L/D ratios with special attention to the curves having comparable C/D ratios indicates the degree of departure of the experimental from the theoretical values of f which results from different values of L/D; i.e., from differences in the longitudinal oil flow which depends upon this ratio.

Fig. 8 is given as a typical example showing the magnitude of the deviations of the observed points from a smooth curve.

GENERAL DISCUSSION OF RESULTS

(*a*) *Effects at High Values of* ZN/P. As a matter of convenience, the discussion of the effects shown by the curves is divided into two parts, the first being a consideration of the results at the high values of ZN/P.

It will be noted immediately that, in general, the experimental curves for all the tests are more comparable to their corresponding theoretical curves at the higher values of ZN/P than they are at the lower values. This is consistent with the fact that at the higher values of ZN/P the journal runs more nearly concentric with the bearings. Thus there is a greater likelihood that under these conditions the friction of a given journal and bearing is dependent entirely upon the viscous shear of the lubricant, which is a condition upon which the theoretical equations depend.

In considering the effect of the various C/D ratios, it is seen that in general the experimental curves are higher than the theoretical curves for the corresponding C/D ratio, the amount of the deviation being dependent upon both C/D and L/D. The one exception, the curve for C/D = 0.01000 with L/D = 1.00, shown in Fig. 4, can be attributed to the possibility that this clearance was so large that the lubricant did not entirely fill the space between journal and bearing and the resulting action was like that of a partial rather than a full bearing.

When the effect of length is considered, it will be noted, where direct comparison with a given C/D ratio can be made, that except in a few cases there is a general tendency for a progressive departure from the theoretical curves as the length of the bearing is decreased. An obvious explanation for this is that the effect of end-leakage becomes proportionately greater as the length of the bearing decreases.

The exceptions are the two curves for bearings with L/D = 2.80 and C/D = 0.00075 and 0.00100, respectively. Effects that might have had some influence in causing this departure of the performance of the long bearings with small clearance from the general trend are that the effect of shaft deflection may be greater, the effect of the relative irregularities of the surfaces taken as a whole may be greater, and the relative accuracy of the measurements of diameter may be less.

That the effect of the irregularities of the surfaces of the journals and bearings taken as a whole may be greater for the longer bearings is brought out by comparing the C/D ratio of

[6] Sommerfeld, A., "Zur Hydrodynamischen Theorie der Schmiermittelreibung," *Zeit. für Math. u. Phys.*, vol. 50 (1904), pp. 97–155.

the upper curve in Fig. 3 to that of the upper curve in Fig. 7. These C/D ratios represent approximately the condition of smallest clearance with which the bearings of these respective lengths could operate without having an initial binding effect due to the rubbing together of the high spots on the journals and bearings. In other words, at clearances smaller than are represented approximately by these C/D ratios, the friction of the bearings of these respective L/D ratios at high values of ZN/P is not dependent upon the viscous shear of the lubricant alone, but also upon the rubbing together of the high spots.

Too much weight should not be given the curves for the bearings with very small clearances, since the effect of a given error in measuring the diameters becomes proportionately greater as the clearance is decreased. As an illustration of this effect, the theoretical curves for bearings with C/D ratios of 0.00037 and 0.00053 are plotted in Fig. 4, these being the approximate C/D ratios for bearings having clearances only 0.0001 in. less and 0.0001 in. greater than those with the C/D ratio of 0.00046.

(*b*) *Effects at Low Values of* ZN/P. At the lower values of ZN/P the important question to consider is the effect of changes in the C/D and L/D ratios upon the location of the point of minimum friction, since this point can be considered as a basis for the determination of the factor of safety[7] under which a bearing is operating.

It will be seen that the locations of the points of minimum friction in the experimental curves do not have the same definite relation to the value of C/D as is shown by the minimum points of the theoretical curves. In fact, the experimental points of minimum friction lie so much at random that about all that can be determined concerning them is that they lie at or below $ZN/P = 50$ and that for a given L/D ratio the minimum coefficient of friction is highest for bearings with the smallest clearance.

The large deviation between the experimental and theoretical curves near the the point of minimum friction is emphasized in the Appendix, wherein the curves for some of the bearings are plotted on a chart suggested by Howarth.[8]

That there should be no very definite correlation between the experimental and theoretical curves near the point of minimum friction is easily understood when it is considered that the theoretical curves are based upon the assumption that the friction of the bearing depends on the viscous shear of the lubricant alone and that there are no end effects. In the actual bearings, especially at the larger clearances, it is reasonable to expect that the lubricant does not entirely fill the clearance space, and previous experiments[9] have shown that the location of the point of minimum friction is dependent also upon other factors such as oiliness and the condition of the bearing surfaces.

An Equation Representing the Friction of Small-Bore Journal Bearings

The results at the higher values of ZN/P are so consistent that it appears worth while to represent them by a simple equation whereby the frictional torque of a given bearing may be estimated for most normal operating conditions.

The results shown by Fig. 4 indicate that for bearings having an L/D ratio of 1 or thereabouts, the Sommerfeld[10] or Harrison[11] equations will give results accurate enough for practical purposes where the value of ZN/P is greater than 100 and where the coefficient of friction is greater than 0.01. Thus the charts based upon Harrison's equation for bearings of various nominal C/D ratios in Howarth's graphical analysis[12] are suitable for bearings of this type. These equations, however, do not take end effects into account and thus can be considered fair approximations only where L/D is greater than about 0.75.

In developing corrections for various L/D ratios Petroff's[13] equation, owing to its simplicity, appears to be most suitable to use as a basis. While this equation is based upon the assumption that the journal is at all times concentric with the bearing, the deviations between it and the more rigorous Sommerfeld or Harrison equations are negligible at values of ZN/P above 100 and values of f above 0.01.

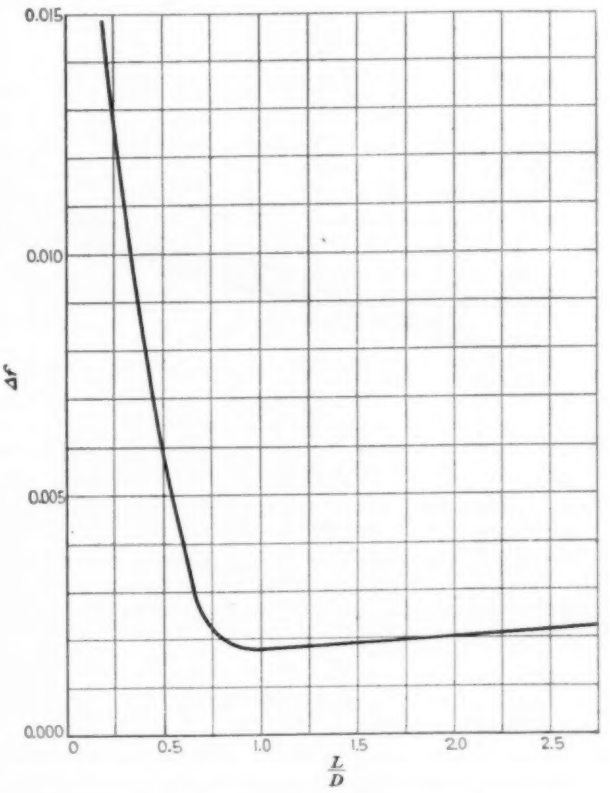

Fig. 9 Correction to Petroff's Equation for Various L/D Ratios

This equation when expressed in the units employed in this paper becomes

$$f_P = 473\left(\frac{ZN}{P}\right)\left(\frac{D}{C}\right)10^{-10} \quad \ldots\ldots\ldots\ldots [1]$$

[12] Howarth, H. A. S., "A Graphical Study of Journal Lubrication," Trans. A.S.M.E., vol. 45 (1923), pp. 421–448; Part II, vol. 46 (1924), pp. 809–832; Part III, vol. 47 (1925), pp. 109–114; reprinted by The American Society of Mechanical Engineers, 29 West 39th St., New York, N. Y.

[13] "Neue Theorie der Reibung," St. Petersb. Acad., 1883; German trans., Hamburg, L. Voss, 1887; French Trans., Rev. de Mécanique, vol. 7 (1900), pp. 571–602.

From the nature of the equation it will be seen that the f_P versus (ZN/P) curves for various C/D ratios are straight lines passing through the origin and that the slope of the line depends upon the C/D ratio.

The equation chosen to correct for the L/D ratio is

$$f = f_P + \Delta f \quad \ldots\ldots [2]$$

where f = coefficient of journal friction for an actual bearing
f_P = coefficient of friction as determined by Petroff's equation
Δf = L/D correction.

This assumes that all the experimental curves for a given L/D ratio are parallel to and equidistant from the Petroff curves for the same C/D ratios. This of course is not exact, but the values obtained are a fair approximation throughout the whole range covered.

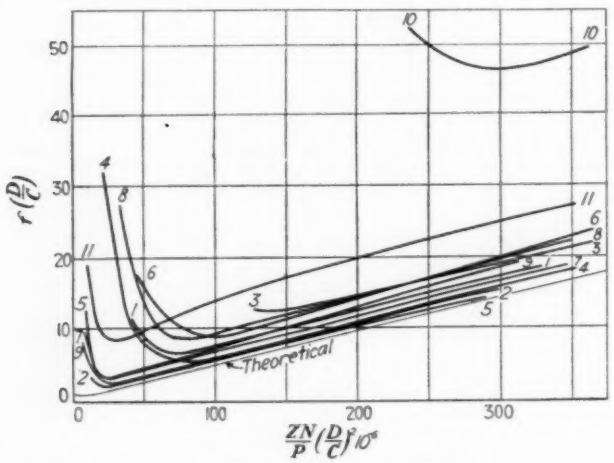

FIG. 10 FRICTION CURVES PLOTTED ON HOWARTH'S CHART; ALL L/D RATIOS; SMALL C/D RATIOS

The curve in Fig. 9 shows the average value of Δf for the various L/D ratios. The maximum error in using this method is about 16 per cent, the average being about 4 per cent. Thus the equation

$$f = 473\left(\frac{ZN}{P}\right)\left(\frac{D}{C}\right)10^{-10} + \Delta f \quad \ldots\ldots [3]$$

should be reasonably accurate for the practical determination of friction losses in small-bore full journal bearings provided ZN/P is greater than 100 and f greater than 0.01. It is of course understood that the speed and load are fairly constant and that an adequate supply of oil is maintained at a relatively low pressure and that there are no oil grooves in such a location on the bearing surface as to materially affect the pressure distribution in the film.

CONCLUSION

The limit of the scope of this investigation is to provide a reasonably accurate experimental indication of the behavior of small-bore full-journal bearings of various clearances and lengths, under normal working conditions.

While the results of the tests at the higher values of ZN/P are fairly consistent with theoretical equations based upon the viscous shear of the lubricant, it would not be justifiable to predict that these results would be a reliable indication of the characteristics of large bearings operating at high speeds and high loads, since it is reasonable to expect that under the latter conditions the effects of such factors as journal deflection, distortion caused by uneven heating, and changes in viscosity due to temperature gradients in the oil film may be of considerable magnitude.

The inconsistencies shown by the results at the lower values of ZN/P are an indication that considerable caution should be used if the carrying capacity of a particular bearing is determined by any method based upon the theoretical value of the minimum thickness of the oil film.

Further steps toward a better understanding of the performance of full-journal bearings suggested by these tests are (1) to make similar tests of the effect of changes of clearance and length using larger diameter bearings under heavier loads and at higher speeds and (2) to determine the carrying capacity of bearings by a study of the effect of changes in bearing metal, lubricant, and over-all dimensions upon the point of minimum friction of bearings finished by the usual commercial methods.

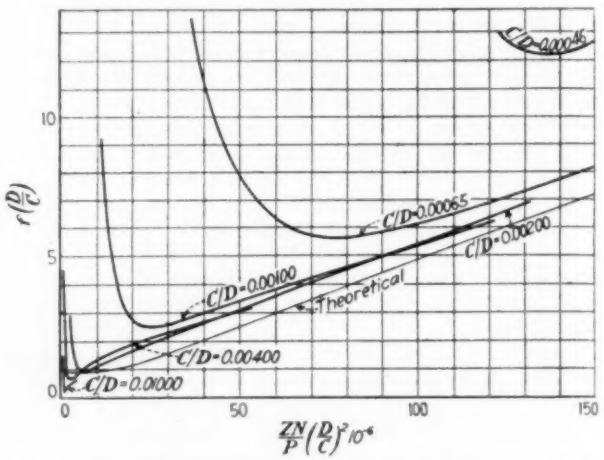

FIG. 11 FRICTION CURVES PLOTTED ON HOWARTH'S CHART; L/D = 1.00; ALL C/D RATIOS

APPENDIX—CURVES PLOTTED ON HOWARTH'S CHART

By Howarth's method of plotting, which uses $f\,(D/C)$ as ordinates and $(ZN/P)\,(D/C)^2$ as abscissas, a single theoretical curve can be drawn to represent bearings of all C/D ratios. In Fig. 10 this theoretical curve is represented by the light line, while the heavy lines numbered from 1 to 11 are the curves for bearings with L/D = 2.80, C/D = 0.00075 and 0.00100; L/D = 1.00, C/D = 0.00046, 0.00065, and 0.00100; L/D = 0.75, C/D = 0.00043 and 0.00093; L/D = 0.50, C/D = 0.00048 and 0.00100; and L/D = 0.25, C/D = 0.00038 and 0.00091, respectively. To avoid crowding the diagram the curves for the bearings with large clearances have been omitted, since all are closely bunched near the origin. Intercomparison of curves having the same L/D ratio but different C/D values (i.e., curves 1 and 2; 3, 4, and 5; 6 and 7; 8 and 9; 10 and 11) shows that there is a tendency for the curves to move progressively upward and to the right as the clearance is decreased. This is shown in Fig. 11, where the curves for the various C/D ratios with L/D = 1.00 are plotted. Upon intercomparison of curves having approximately the same C/D ratio but with different L/D values (i.e., curves 2, 5, 7, 9, and 11) a less pronounced tendency is shown for the curves for the shorter bearings to move upward. These effects indicate that some of the factors treated as negligible in the theoretical equation are having a pronounced influence upon the friction of the bearings.

Discussion

H. WEISS.[14] I should like to ask two questions which an examination of the results suggested to me: (1) In examining the curves representing the results of experiments one is impressed

[14] Assistant Director, L'Ecole Nationale Superieure du Petrole, University of Strassbourg, Strassbourg, Germany.

at seeing that the gross values of ZN/P in the theoretical and experimental curves are two straight lines coming less closer together as the ratio L/D decreases. In particular for L/D = 0.25, these straight lines are nearly parallel, as if there were a systematic wear, a constant friction which has to be added to the friction predetermined by the theory. Do the authors believe that this form of wear is due to disturbances brought by the edges of the bearings which become gradually preponderant, in view of the fact that the formula is derived for a bearing of infinite magnitude, or do they, on the contrary, believe that with errors of the geometric order, such as the size of the bearing, the centering becomes more and more important?

(2) Modern theories on lubrication seem to gain more and more in precision through a separation of two distinct sets of conditions: (*a*) Perfect lubrication, which is of dominating influence at high speeds and at low pressures. The viscosity or the internal properties of the liquid play a preponderant part. The equations of Petroff and the more exact ones of Sommerfeld are applicable to bearings of large size. (*b*) The so-called improved lubrication which is preponderant at low speeds and high pressures. The surface phenomena at the surface of separation between the lubrication of the metal (oiliness) are then of primary importance.

The preceding formulas are no more applicable. We ar edealing here with the friction of solid against solid and it is the Coulomb laws that govern. There is naturally a gradual passage from one process of lubrication to the other as the speed decreases and the pressure increases. I see that in the experiments of Mr. McKee the speed of the shaft was decreased to 15 r.p.m. for a load of 100 lb. I notice that it is in the case of small values of ZN/P that the most important relative deviations are found. In that case, are we not then working within the region of improved lubrication? Experiments of that kind would be suitable to discover under what conditions the influence of surface phenomena shows itself in an appreciable manner.

A. R. Roberts,[15] L. R. McCurdy.[16] The value of this paper would be increased greatly if space could be found for a more complete tabulation of results. In most of the diagrams, an important part of the field, containing probably a majority of the observations, is crowded into a corner where the relative accuracy of scaling is low. With tabulated data, other means of presenting the results than those adopted in the paper are open to any one interested.

If, for example, the data in Table 1 are plotted to a larger scale or to log scales, it will be found that while the points may be fitted fairly well by a single curve they may be fitted much better by two distinct curves, one for each test load, suggesting a "load effect." This feature is noted merely as an example of the possibilities of further analysis of the results afforded by tabulated data.

The factor Δf is found to be independent of C/D; that is, as shown by Fig. 11, the departure of the experimental curves from the reference curve is greatest with the fine clearance. This result is probably not due to end-leakage so much as it is to other factors such as relative smoothness of the surfaces. When "run-in," the friction curves will be modified not only near the point of minimum friction but throughout most of the range.

H. Bateman.[17] These researches go a long way toward the elucidation of a subject in which further mathematical progress is difficult. Even when the question of the effect of the L/D and C/D ratios is treated from the simple viewpoint of Petroff, in which the journal and bearing are regarded as concentric, it presents great difficulties.

Some idea of the effect of a variation of the C/L ratio may be obtained by neglecting curvature. The problem is then equivalent to that of an infinite strip of breadth L, moving with constant velocity V, parallel to a stationary infinite plane at distance C from it. This problem, however, is equivalent to the electrostatic problem of a parallel plate condenser in which the plates are at a distance $2C$ apart, are of finite breadth L, but of infinite length. This problem has been solved by Michell, Bromwich and Love with the aid of elliptic functions.[18]

The charge on one plate of the condenser, which corresponds to the viscous drag of the hydrodynamical problem, is proportional, when C/L is small, to the quantity $VL(1 + \epsilon)/C$ where

$$\epsilon = \frac{2C}{\pi L}\left(1 + \log \frac{\pi L}{C}\right)$$

and is thus greater than the value VL/C obtained by neglecting the end effect. When L/C = 200 the quantity ϵ is of magnitude 0.0237. In the experiments made by the authors of this paper L/C has values between 62.5 and 1867. Some idea of the effect of curvature might, perhaps, be obtained by finding the electrostatic capacity for different values of the ratios L/D and C/D of a condenser whose plates consist of the journal and bearing. Though there is no true analogy between the electrical problem and the hydrodynamical problem, the end effect will probably be of the same order of magnitude in the two cases.

E. O. Waters.[19] It seems that three outstanding conclusions may be drawn from this paper. First, and most obvious, is the fact that decreasing L/D ratios give higher coefficients of friction, as would naturally be the case on account of end leakage. But apparently this is only true for L/D between 1 and 0. The increase in f for values of L/D greater than 1 does not seem logical, and certainly does not tally with Michell's theoretical results for flat bearings, in which f increases continuously from a low value for an infinitely wide bearing to a value more than twice as great for a square bearing and a value about twenty-seven times as great for a bearing of width equal to one-third the length.

The writer agrees with the authors that this peculiar behavior is probably due to shaft deflection, surface irregularities that eluded measurement, etc.—in other words, causes that are in the nature of experimental errors rather than the consequence of high L/D per se. Such being the case, the question may be raised as to whether this phenomenon can be legitimately recognized, when establishing values for Δf. There is danger that the curve in Fig. 9, or at least the upward-sloping part of it, may be valid only for bearings of the same size and tested under exactly the same conditions as those upon which the authors experimented.

In the second place, it is noteworthy that the experimental and theoretical lines agree very closely, in the range from L/D = 0.75 to L/D = 1.00. Moreover, as stated by the authors, Petroff's equation is applicable except in the region of minimum friction, and gives a simple basis for computing the friction of a bearing of infinite length, for any values of Z, N, P, and D/C. For bearings of finite length, the additive correction indicated in Equation [2] would seem to be accurate enough, although it has no analytical background. Exactly the same result is ob-

tainable graphically on Howarth's chart of generalized coordinates, Fig. 11, in which $X = ZN/P(D/C)^2\ 10^{-6}$ and $Y = f(D/C)$, and the basic relation between X and Y can be approximated very closely by a straight line, namely, the asymptote to the theoretical curve.[20] The difference between $f(D/C)$ given by the asymptote and the curve is less than 6 per cent for all values of $ZN/P(D/C)^2\ 10^{-6}$ greater than 5.

As soon as Howarth's coordinates are related by a straight line passing through the origin, D/C may be cancelled out of both X and Y, giving what would seem to be the most simple and practical means for determining f for general design and operating purposes.

Thirdly, it is clear that the experimental results are at variance with the hydrodynamic theory under two distinct conditions: very small values of (ZN/P) (D/C) for all values of C/D tested, and small values of C/D for all values of (ZN/P) (D/C). In both cases, the tests show a marked increase in f above that computed by theory, just as was apparent from S. A. McKee's investigation of the effect of running in on journal bearing performance.[21] The writer believes that this may be explained as follows: In the second case, the minimum film thickness is of the same order of magnitude as the permissible variations and combined errors in measurement of the journal and bearing diameters, and this is true even if the eccentricity is practically zero. The shape of the cross-section of the film space, which when developed is theoretically bounded by a straight line on one side and a cosine curve on the other,[22] determines the relation between $f(D/C)$ and (ZN/P) $(D/C)^2$. When these bounding surfaces are subject to variations in form, that are comparable in magnitude with the average distance between them, the shape of the film space cross-section is profoundly altered and it is to be expected that the theory built up on the simple shape will fail. This explanation does not assume any metal-to-metal contact or breakdown of the oil film.

In the first case, the same effects are manifest, but owing to the high eccentricity of the journal position the cosine curve has a larger relative amplitude and variations in this curve will only affect the running conditions in the short region, where the curve is in close proximity to the developed journal surface. It is therefore to be expected that there will be a much more abrupt transition from the condition of fluid friction to that of solid or semi-solid friction.

It would be interesting if a law could be determined relating ZN/P and D/C with the point of minimum friction, but it is doubtful if this can ever be done, as the relation is of necessity extremely sensitive to conditions of bearing surface that are practically impossible to measure. The present tests show the inadequacy of the hydrodynamic theory in the region of low f, but do not establish anything definite to take its place.

H. A. S. Howarth.[23] This paper represents a very commendable effort to develop rules for taking account of the influence of side leakage on the friction of full bearings. One is apt to be misled, however, by the apparent close agreement between theoretical friction and actual friction. The authors apparently have this thought in mind when they state that errors of 0.00005 in. in the measurement of their diameters would have a large influence upon the position of the theoretical reference curves, shown by light lines in all the figures except Figs. 8 and 9. Such an error would be of more importance for the small clearances than for the large ones.

Although the authors have compared their test friction coefficients with those to be expected in full bearings, they have given us no assurance that their test films were complete. It is quite reasonable to suppose, therefore, that for the high speeds, small clearances, and large L/D ratio, the films might be fairly complete. For small values of L/D, large clearances, and low speeds, it is quite likely that the useful portions of the films, i.e., those in which substantial pressures were present, extended over small angles, possibly not more than 30 deg. If such is the case, it would have been better to have determined the useful length of the bearing in each case and to have plotted the theoretical curve for it instead of assuming that the films were complete 360 deg. in all cases. If this suggested procedure had been followed, it is quite likely that none of the experimental curves would have extended below the theoretical ones, as they do in several of the figures.

In their Fig. 10 the authors have plotted their data using coordinates that make necessary the use of only one theoretical curve. Not all the data is plotted in that chart. There is enough, however, for the present purpose. One wonders perhaps why D/C appears in both coordinates of this chart. One reason for this is the necessity of using the same scale of abscissas with an eccentricity factor scale. It is suggested, therefore, that Fig. 12 of my discussion be placed directly below Fig. 10, making the base scales identical. The theoretical eccentricity of the journal in a full bearing for any abscissa in Fig. 10 may then be found by reading its intersection with the curve in Fig. 12, by means of the eccentricity scale at the left. The figures I have marked on the curve of Fig. 12 indicate the ratio of theoretical friction, per given eccentricity, to the friction when the journal is running concentric. It is therefore evident that when the abscissa value is higher than 50, the friction in the bearing might just about as well be compared with the friction for concentric running, as proposed by Petroff, as with eccentric running as proposed by Sommerfeld.

Another fact we note when referring the curves in Fig. 10 to the eccentricity curve in Fig. 12 is this—the McKee curves Nos. 10, 6, 3, 8, 4, and 1 begin to turn upward at the left when the theoretical eccentricity is less than 10 per cent of the radial clearance. This must mean that the actual eccentricities are considerably greater than the theoretical ones. We would expect the actual eccentricity to be greatest for the very narrow bearing for which $L/D = {}^1/_4$ and when the clearance ratio is greatest, i.e., $C/D = 0.00091$. Curve 10, however, which represents $L/D = {}^1/_4$ and $C/D = 0.00038$, has its lowest point where the abscissa of Fig. 10 is 300. Metallic contact must therefore have taken place when the theoretical eccentricity was approximately 3 per cent. Curve 11, however, which also represents this very short bearing, but which has a greater clearance ($C/D = 0.00091$), does not turn upward until the abscissa is about 30, which corresponds with the theoretical eccentricity of 25 per cent. This is contrary to our expectation. We would expect the closer approach of the surfaces to have been obtained with the bearing having the larger clearance. To this extent the test results appear inconsistent. One explanation for this condition appears to be the lack of uniformity of finish of the bearing surfaces.

A similar eccentricity curve is illustrated in Fig. 13 with the same scale of abscissas as given in the authors' Fig. 11. If Fig. 13 is placed directly below Fig. 11, the theoretical eccentricities corresponding with any points on the curves on Fig. 11

[20] Taking the parametric equations for X and Y in terms of the eccentricity ratio c, it is easily proven that the asymptote passes through the origin and has a slope of $\pi^2/30$ when the viscosity is expressed in lb. sec. per sq. in. One lb. per sq. in. = 68950 dynes per sq. cm.; hence, changing the units to centipoises and introducing 10^{-6} in the X scale, the slope becomes $(\pi^2/30)(10^4/6{,}895{,}000) = 0.0477$. Cf. the constant in the authors' equations [1] and [3].

[22] Howarth, "A Graphical Study of Journal Lubrication," Part I, Fig. 2.

[23] Vice-Pres. and Genl. Mgr., Kingsbury Mach. Wks., Philadelphia, Pa. Mem. A.S.M.E.

can be determined from Fig. 13. All of the Fig. 11 curves are drawn for $L/D = 1$. We would expect the greatest deviation from the theoretical eccentricity when the running clearance ratio is greatest; that is, we would expect the thinnest theoretical films when the clearance ratio is greatest. When examined with this idea in view, the curves appear inconsistent. The low point indicating metallic contact on the curve for $C/D = 0.00046$ occurs when the abscissa is about 140; that is, when the eccentricity is only 5 per cent. Metallic contact, as indicated by Fig. 11, occurs at progressively greater eccentricities as the clearance ratios increase; for example, 0.05, 0.09, 0.28, 0.80, 0.93, 0.99, respectively. These theoretical eccentricities lead to minimum film thickness as follows: 0.00028, 0.00037, 0.00045, 0.00025, 0.00018, 0.00006. We would expect these minimum film thicknesses to decrease uniformly. Instead, however, there is first an increase and then a decrease. Nevertheless, the minimum film thickness apparently occurs as expected when the running clearance is greatest. The result of this analysis, just as that given in a previous paragraph, leads us to believe that the perfection of finish is not the same for all bearings. This explains inconsistencies in the test results, which might be shown in other ways, but the foregoing examples will suffice.

Following up the idea expressed in a previous paragraph, that the useful portions of the test films in the authors' bearings were in some cases much less than 360 deg., it is desirable to find out how low the coefficient of friction could be expected to fall if the test bearings were assumed to be partial. Perhaps we will find lower theoretical coefficients for partial bearings than McKee found for his test bearings. If so, we can believe that McKee's bearings were partial in some cases at least, and that if he had used for comparison theoretical friction curves for such partial bearings, his test coefficients would always have been higher than the theoretical values.

The viscosity employed by the McKees averaged about 40 centipoises. This corresponds in the English system with about 5.85×10^{-6} reyns (inches-pounds-seconds). The curves in the charts published in my "Graphical Analysis of Journal Bearing Lubrication" were drawn in almost every case only for a viscosity of 3.4×10^{-6} reyns. With this in mind, my charts can be used for the present purpose, as explained below. The low points on the McKee curves are obtained for the most part by lowering the speed, as will be evident from the sample of his data given in Table 1. To obtain values of w/N for use in my charts, we divide 40 by his abscissa, for Figs. 3 to 7. It will be noticed that his low points lie in the region of $ZN/P = 50$ or less. We might therefore assume them to be 40, then $w/N = P/N = 1$. This must be corrected for entering my charts by multiplying it by the viscosity ratio 3.4/5.85. We will therefore assume $w/N = 0.58$, and in every case read to the curve drawn for the viscosity 3.4×10^{-6}.

Referring now to figures in my Graphical Analysis and assuming in every case that the clearance ratio is 0.001, we find from Fig. 3 an eccentricity of 0.17 and a coefficient of journal friction of 0.0021, for the full bearing. For the central partial bearings, whose characteristics are given in Fig. 8, we find eccentricities and coefficients of friction varying with the angle length β of the bearing, as follows:

β	Eccentricity factor	Friction coefficient
180 deg.	0.38	0.00134
160 deg.	0.434	0.00130
140 deg.	0.5	0.00128
120 deg.	0.57	0.00128
100 deg.	0.63	0.00128
80 deg.	0.694	0.00128
60 deg.	0.772	0.00128

For partial bearings of this kind, we find theoretical coefficients of friction less than half the lowest test value obtained by the authors. It therefore appears that, as previously stated, if the authors could have measured the useful length of their films, that is, the length in which appreciable pressure existed, they would have found bearings much less than 360 deg. in length; and if they had used the theoretical curves of such bearings as reference curves, their test coefficients of friction would have lain above such reference curves.

There is some question also whether the viscosity of the oil within the film had the average value assigned to it by the authors. Any error in the determination of this viscosity would have a directly proportional influence upon the plotted abscissa of the point for which the friction was measured. If the actual viscosities were lower than the authors estimated, the difference between the theoretical curves and the actual curves would be greater than the authors show. If the actual viscosities were greater than estimated, the differences between these curves

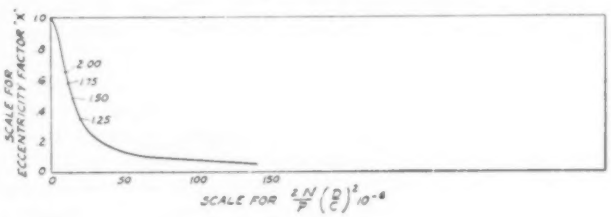

FIG. 12

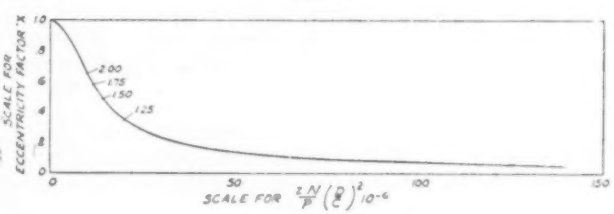

FIG. 13

would have been less. In fact it is quite conceivable that if the authors had determined the actual mean oil viscosity, all their points would have fallen below the theoretical curves for the full bearing. The film temperature was controlled by water-cooling the shaft within the film, and the viscosity was measured in the bearing surrounding the film. Hence it is quite possible that the film was cooler than indicated by the thermocouple.

The net result of this discussion indicates the desirability of extreme care in the design, preparation, and use of apparatus for such experiments; the need for testing larger bearings; the need for higher loads and speeds; and also the necessity for knowledge of the useful length of the films. If the points of nearest approach could be determined also, that would be another long step forward. Many tests by various persons, and with different apparatus, are necessary before authorities can decide how nearly the test results can be expected to compare with our theoretical data. Then only will it be possible to set up dependable factors for determining probable film thicknesses, friction coefficients, and useful proportions of actual bearings. The work of the authors is most commendable, and I hope that they will be able to continue the useful investigations in which they have been engaged for some time past.

G. B. KARELITZ.[24] The paper deals with a series of very important and interesting experiments. Very few systematic

[24] Research Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

tests were made on the question of bearing friction to date, which makes the work published by the authors quite a valuable one.

However, it should be noted that the diameter of the test journal is very small and the machining must be exceedingly accurate if a reliable control of clearances is to be obtained. Under these circumstances it would be advisable to record in the paper all dimensions, as actually measured, of the journals and bearings employed.

The foregoing remark is not intended to cast any doubt on the results obtained. On the contrary, the findings were compared with the available data on friction in large sleeve bearings of the turbo-generator type. The coefficients of friction check quite closely. They also check with measurements made by Lasche in Germany in 1918 on a journal 8 in. in diameter.

It is interesting to note that the coefficient of friction plotted against $\frac{ZN}{P}$ is practically the same for bearings with a ratio of length to diameter from 0.75 to 2.80. This may be taken as an indication that the conditions in the oil film for these lengths of the shell are the same in so far as the influence of end leakage is concerned. For this range of length, commonly employed in bearings, the longitudinal pressure distribution is nearly parabolic. In shorter bearings the end leakage is comparatively worse and the oil film for the same value of P is appreciably thinner, causing higher friction. This means that the running position of a journal in its shell can be conveniently estimated by the standard methods and diagrams for bearings of length equal to the diameter or larger, while for shorter bearings the estimate is more difficult. The running position determines the minimum oil film thickness in the bearing and thus defines the safety of the bearing.

M. D. Hersey.[25] I would like to mention a rather curious confirmation of the McKee paper as regards absolute values. Of course, the paper would be justified if it gave only relative values.

About twenty years ago I undertook an investigation at the Massachusetts Institute of Technology, in the Department of Mechanical Engineering, which was published a few years later in the Journal of the Washington Academy of Sciences, November 19, 1914. This paper gave the experimental results in the form of an empirical equation. I believe these were the first experiments on journal friction in which the results were plotted and interpreted by the dimensional analysis method. This empirical equation gave a line having an intercept on the coefficient of friction axis. The horizontal coordinate is the dimensionless variable, viscosity times speed in revolutions per minute divided by the so-called bearing pressure. The points were rough in these early experiments and scattered, but although three different oils were used, sperm, lard, and mineral oil, there was no systematic difference due to the different oils. There was no doubt at all that they gave this peculiar line standing definitely above a line drawn through the origin and separated from it by a constant amount.

These results have remained under suspicion because of that intercept which, according to Petroff's equation, should not occur.

Now, along comes the McKee paper with an intercept again. Upon converting my empirical equation into the same units the authors of this paper are using, and plotting it on the same chart using appropriate L/D and C/D ratios, a surprisingly good agreement was found. It remains now for some one to explain the physical meaning of the unexpected constant term.

Authors' Closure

Mr. Howarth's interesting analysis of the results obtained tends to emphasize the difficulties involved in obtaining a complete solution to the problem of bearing performance when operating under conditions of low values of ZN/P. He substantiates two points already pointed out in the paper: namely, that in actual bearings, especially at the larger clearances, it is reasonable to expect that the lubricant does not entirely fill the clearance space and that the location of the point of minimum friction is dependent upon the condition of the bearing surfaces. The presence of the latter factor was one of the chief reasons for not attempting to make a definite analysis of the operation of the bearings at low values of ZN/P. The data were obtained without "running in" the bearings, and previous experiments[26] had indicated that even a slight amount of running in would materially affect the point of minimum friction of a given set of bearings.

The question as to the publishing of the complete data for all the bearings, as was suggested by Messrs. Karelitz, Roberts, and McCurdy, was considered at the time of publication, but it seemed preferable to omit all but a sample sheet because of the large amount of space required.

It was realized, as was pointed out by Mr. Karelitz, that errors in measurements of diameter are of greater significance when using a small rather than a large journal. The particular size chosen, however, was most advantageous from the standpoint of the facilities available to carry on the work. It should be noted that a statement is made in the paper limiting the scope of the investigation to small-bore bearings and also that the precision of measurement is probably far greater than usually occurs in commercial practice.

Referring to the question by Mr. Weiss regarding the cause of the increase in deviation between the theoretical and experimental curves as the length of the bearings decreased, it seems probable that the effect of end leakage in changing the lines of flow and pressure distribution in the oil film was the chief factor.

At the small values of ZN/P below the point of minimum friction, such as that mentioned by Mr. Weiss, previous experiments[27] have shown that oiliness has a measurable influence upon bearing friction. This tends to indicate that under these conditions the bearings are operating in the region of boundary or, as he calls it, "improved" lubrication.

Referring to the question of Professor Waters, the large scale for Δf used in Fig. 9 perhaps overemphasized the increase in Δf with an increase in the L/D ratio above $L/D = 1.00$. It should be noted that Equation [3] is limited to cases where f is greater than 0.01, and thus from the practical standpoint of obtaining an estimate of the friction of a given bearing, the upward slope of the curve has little significance. For example, suppose the case of a bearing with $L/D = 2.75$ and $f_P = 0.01$. Then Δf as determined by Fig. 9 would be 0.00225 and f0.01225. Assuming the curve as drawn parallel to the base line, Δf becomes 0.00180 and f becomes 0.01180, the difference between the two results being approximately 4 per cent. Thus even should it be more proper for the curve to have a downward slope, the difference would not be very great.

The authors' basis for drawing the upward slope to the curve was that this curve was at best an empirical approximation based solely upon the results of these tests.

[27] C. P. Barnard, 4th, H. M. Myers, and H. P. Forrest, "The Effect of Oiliness on the Behavior of Journal Bearings," *Ind. & Eng. Chem.*, vol. 16 (1924), pp. 347–350. S. A. McKee, "Effect of Kerosene on Oiliness of Lubricating Oils," *Jl. S.A.E.*, vol. 19 (1926), pp. 356–360.

In considering the conditions during the tests, the test bearings were spaced close together, the loads were comparatively light, and the journals and bearings were probably more nearly true cylinders than is usually found in practice. This would seem to indicate that unless the construction were of great accuracy and rigidity it is not unreasonable to expect that bearings in actual service might show this tendency to a greater extent than was indicated by these tests.

Stress Distribution in Rotating Disks of Ductile Material After the Yield Point Has Been Reached[1]

By A. NADAI,[2] GÖTTINGEN, GERMANY, and L. H. DONNELL,[3] ANN ARBOR, MICH.

This paper covers a study of the distribution of stress in a rotating disk of ductile material (of uniform thickness, with and without a central hole) after the yield point has been passed. Curves are computed showing the growth of the "plastic" region at different speeds, until the whole disk has become plastic. General methods are developed, and applied to examples for finding the complete distribution of stresses and strains in such disks.

While the conditions assumed are seldom exactly realized, the results should throw light on many practical problems as well as form a starting point for a more complete investigation of more complex problems of plastic flow in ductile materials.

WORKERS in many branches of science and engineering are interested in the question of plastic flow of solid bodies. (By plastic deformation in contrast to elastic deformation is meant a permanent and considerable change in the shape of a body which occurs without appreciable weakening of the material.) The various manufacturing processes used to change the shapes of bodies by cold or hot working, such as rolling, drawing, forging, etc., belong to this class of problems in the mechanics of the plastic stage of materials, and several attempts have been made to analyze, with the methods of applied mechanics, the distributions of stresses in such processes.

Another interesting field for study in mechanical engineering is concerned with the improvement of our knowledge of what takes place in various machine elements of ductile material after the yield point has been passed and plastic deformation ha begun to develop. That such problems have practical importance is indicated by the fact that engineers have long found it necessary to specify a high degree of ductility in the materials used for many such machine elements.

This paper is an attempt to make such a study for the comparatively simple case of a disk of uniform thickness stressed by centrifugal forces due to rotation about an axis through its center and perpendicular to its plane. As Stodola mentions in his "Steam and Gas Turbines,"[4] attempts have been made to improve the stress distribution in rotating disks with a central hole by running them during manufacture at a speed such that the inner part of the disk is permanently stretched. This question is also considered by Hencky,[5] by Lasche,[6] and in a report of the Brown-Boveri Co., of Baden.[7] Laszlo[8] has considered an interesting question of some practical importance, namely, that of the stability of the quasi-static equilibrium of a rotating disk stressed above the yield point; i.e., whether there is a certain speed at which a small increment of speed causes the disk to stretch a comparatively large amount, resulting in the destruction of the disk.

Notation

b	= radius of the disk, inches.
r,a,c	= radius of the point considered, of the hole, and of boundary of the plastic region, inches.
ρ,α,γ	= r/b, a/b, c/b, respectively.
S_y	= yield-point stress of material in a simple tensile test, lb. per sq. in.
S_t,S_r	= tangential and radial stresses in the plastic region, lb. per sq. in.
S'_t,S'_r	= same for the elastic region.
$\sigma_t,\sigma_r,\sigma'_t,\sigma'_r$	= S_t/S_y, S_r/S_y, S'_t/S_y, S'_r/S_y, respectively.
S_1,S_2,S_3	= principal stresses in plastic region (= S_t, S_r, 0 in the present discussion).
e_y	= unit strain at yield point in a simple tensile test
e_t,e_r	= tangential and radial unit strains in plastic region.
ϵ_t,ϵ_r	= e_t/e_y, e_r/e_y, respectively.
V	= peripheral speed of disk, ft. per sec.
ν	= Poisson's ratio for the material (= 0.3 for steel).
λ	= density of material, lb. per cu. in. (= 0.282 for steel).
g	= acceleration of gravity, ft. per sec. per sec. (= 32.2).
Φ^2	= $\lambda V^2/gS_y$.

Yielding Under Combined Stress

In recent years a great deal of valuable work has been done to determine the laws of plastic flow in the principal materials of construction, the ductile metals; and before endeavoring to establish the assumptions for finding the stress distributions, it is necessary to consider this.

According to the so-called maximum-shear theory,[9] yielding takes place when the greatest shear stress exceeds a certain value. In a thin rotating disk, where there are no appreciable stresses in the axial direction, the maximum shear stress will depend only on the maximum tensile stress (which is always the tangential normal stress S_t) just the same as in a simple tensile test. Hence, yielding will take place when $S_t = S_y$.

Newer tests seem to indicate that the condition of yielding in the ductile metals under normal temperatures is dependent on the value of all three principal stresses. Simple torsion tests have shown that yielding under simple shear stress takes place, not when the shear stress = 0.5 S_y as it should according to the maximum-shear theory, but when the shear stress is equal to

H. M. Westergaard, in the *Journal of the Franklin Institute*, May, 1920, gives a very comprehensive comparison of the conditions of yielding in ductile metals.

about 0.6 S_y, or a little less than this.[10] This and tests made by W. Lode[11] and later by Eichinger and Ros,[12] seem to indicate that plastic flow takes place when the quantity $(S_1 - S_2)^2 + (S_1 - S_3)^2 + (S_2 - S_3)^2$ reaches a certain value characteristic of the material. This can be interpreted as meaning that a material can absorb elastically a certain amount of energy in being distorted (as distinct from the energy stored up due to change of volume), and will yield only when this is exceeded.

The problem has been analyzed on the basis of both of these theories and it is found that the maximum-shear theory permits, in the special case of the rotating disk considered here, of simpler analysis. The stresses figured on this basis (shown by dotted lines in the figures) differ at most by 16 per cent from those

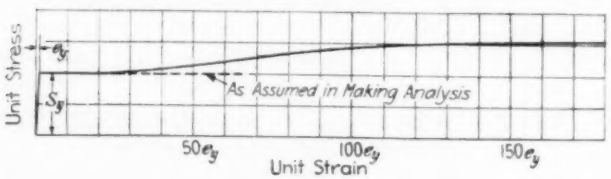

FIG. 1 TYPICAL STRESS-STRAIN DIAGRAM FOR SIMPLE TENSION FOR STEEL

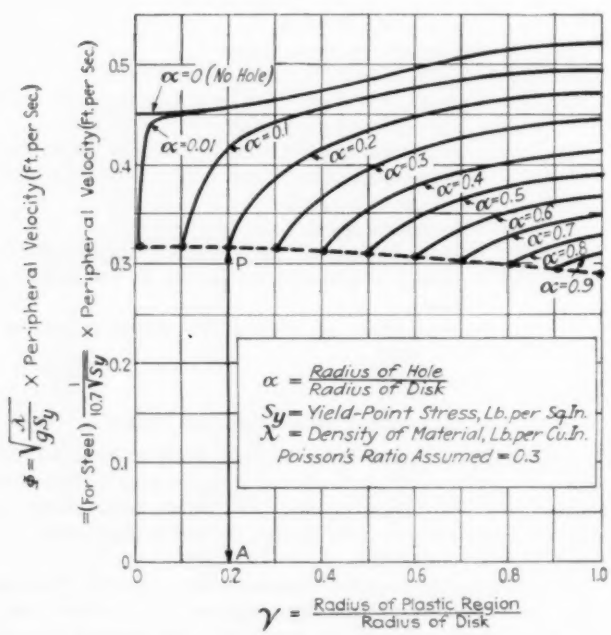

FIG. 2 PROGRESS OF PLASTIC REGION OUTWARD FROM THE CENTER WITH INCREASING SPEED IN A ROTATING DISK ACCORDING TO EXACT THEORY

figured from the more exact theory (shown by full lines), and hence can be considered a good approximation.

ASSUMPTIONS MADE

For the sake of simplicity we shall assume at first:

1 That the disk is of uniform thickness.

2 That the thickness is so small that the stresses do not vary through the thickness. In practice the results can be applied without great error to any disk of constant thickness whose radius is several times the thickness.

We introduce two further assumptions:

3 That the stress-strain curve of the material under simple tension is as shown in Fig. 1, with a sharp corner at the yield point, neglecting the rounded portion of the stress-strain curve which may be detected by very exact measurements of the strains when the plastic deformation starts to develop. In other words, we assume that the material of the disk has a well-defined yield point. In practice, if the material does not have a very well-defined and sharp yield point the stress conditions will not be radically altered, as this will merely affect the abruptness of the transition between the plastic and the elastic regions of the disk (provided that the stress-strain curve is not of the form shown, for example, by soft annealed copper, having a very continuous transition between elastic and plastic deformation).

The last assumption is:

4 That the horizontal portion of this stress-strain curve extends indefinitely to the right as shown by the broken line, Fig. 1. This assumption will be practically correct and is legitimate for most steels, so long as the unit strains do not exceed a few per cent. It is shown later that the maximum strains do *not* exceed such a value until the whole disk has become plastic.

RESULTS

In any rotating disk, conditions are worse nearest the center. As the speed is increased the material at the center will become plastic (i.e., pass the yield point) first, giving a central disk or ring of material in the plastic state surrounded by an outer ring of material still elastic. As the speed is further increased, this plastic region will gradually spread outward, until finally the whole disk is in the plastic state.

SPREAD OF PLASTIC REGION OUTWARD WITH INCREASING SPEED

This is shown by Fig. 2. Here the different curves are for disks with different-sized holes; the abscissas represent the ratio of the radius of the boundary circle of the plastic region to the radius of the disk, and the ordinates are proportional to the peripheral velocity of the disk. The points P on the dotted curve indicate by their ordinates PA the peripheral velocity at which the yield point is reached on the inner boundary of the disk. The corresponding abscissas OA show the ratio of the radius of the hole to the radius of the disk. The curves shown in solid lines may be explained by taking an example. Thus the curve marked "$\alpha = 0.01$" is for a disk with a central hole having a radius of one-hundredth of the radius of the disk, and shows that the material around the hole first passes the yield point at a peripheral speed of about $3.4\sqrt{S_y}$. However, the speed can then be increased, without much more material becoming plastic, until it is equal to the speed at which yielding first takes place in a disk *without* a hole, about $4.8\sqrt{S_y}$. If the speed is increased beyond this the plastic region spreads very rapidly for both the disk with the small hole and for a disk without a hole, the whole disk becoming plastic with an increase in speed of only about 17 per cent, at a speed of about $5.6\sqrt{S_y}$.

This would seem to indicate that while elastic theory shows the stress to be doubled when a small hole is made in the center of a solid disk, actually this is of no great importance when the material is ductile.

DISTRIBUTION OF STRESSES AND RESIDUAL STRESSES

These are shown in Fig. 3 for a solid disk under the following conditions: just before the first yield takes place; when the

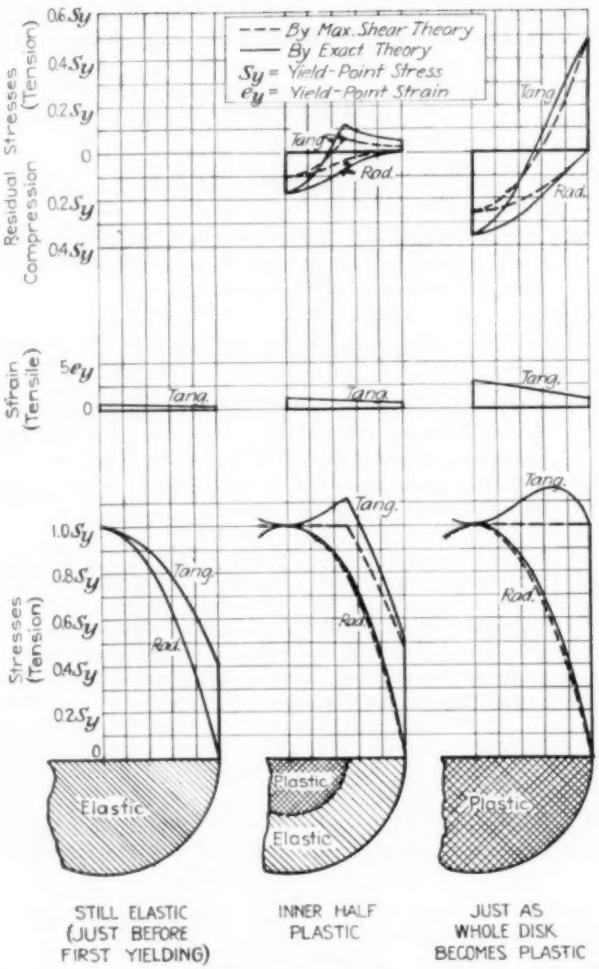

FIG. 3 STRESS DISTRIBUTION, STRAINS, AND RESIDUAL STRESSES IN A SOLID DISK

plastic region is half-way across the disk; and when the plastic region has just reached the outer edge. Fig. 4 shows the distribution for the particular case of a disk with a hole of one-fifth the outer radius. It is worthy of note that the residual stresses at the edge of the hole are just about at the yield point in one case, and well over it in the other.

STRAINS

The unit strains in the plastic region are, like the stresses, greatest in the tangential direction. In a solid disk they are a maximum at the center, but are never greater than three times the unit strain at the yield point (e_y) until after the whole disk has become plastic, as shown in Fig. 3.

The unit strains may be somewhat larger in a disk with a hole, especially at the edge of the hole. Fig. 4 shows how the strains vary along the radius in a typical case, rising to a maximum at the hole. This maximum value is still larger in the case of a very small hole, but never exceeds about 15 e_y until after the whole disk has become plastic. A comparison of this with the unit strains occurring in an ordinary tensile test, Fig. 1, indicates that, for most steels, the assumption that the stress-strain curve remains horizontal after the yield point causes no appreciable error until the whole disk has become plastic.

METHOD FOR FINDING STRESSES

In a given problem the stress at the yield point S_y and the ratio $\alpha = a/b$ of the inner to the outer radius will be known.

On the Basis of the Maximum-Shear Theory the quantity Φ (and hence the peripheral speed V, if desired) can then be determined for any value of $\gamma = c/b$ (c = radius of plastic region, b = radius of the disk) from the following equation:

$$\Phi^2 = \frac{\lambda V^2}{gS_y} = \frac{2 - \alpha(\gamma + 1/\gamma)}{9 + 3\nu - (2 + 6\nu)\gamma^2 + (1 + 3\nu)\gamma^4 - 4\alpha^3(\gamma + 1/\gamma)} \quad \ldots [1]$$

and

$$\Phi^2 = \frac{2}{9 + 3\nu - (2 + 6\nu)\gamma^2 + (1 + 3\nu)\gamma^4} \text{ for a solid disk} \quad \ldots [2]$$

The stresses at any point $\rho = r/b$ in the plastic region are then found from the following:

$$\left.\begin{aligned} \sigma_t &= 1 \\ \sigma_r &= 1 - \frac{\alpha}{\rho} - 4\Phi^2\left(\rho^2 - \frac{\alpha^3}{\rho}\right) \end{aligned}\right\} \quad \ldots [3]$$

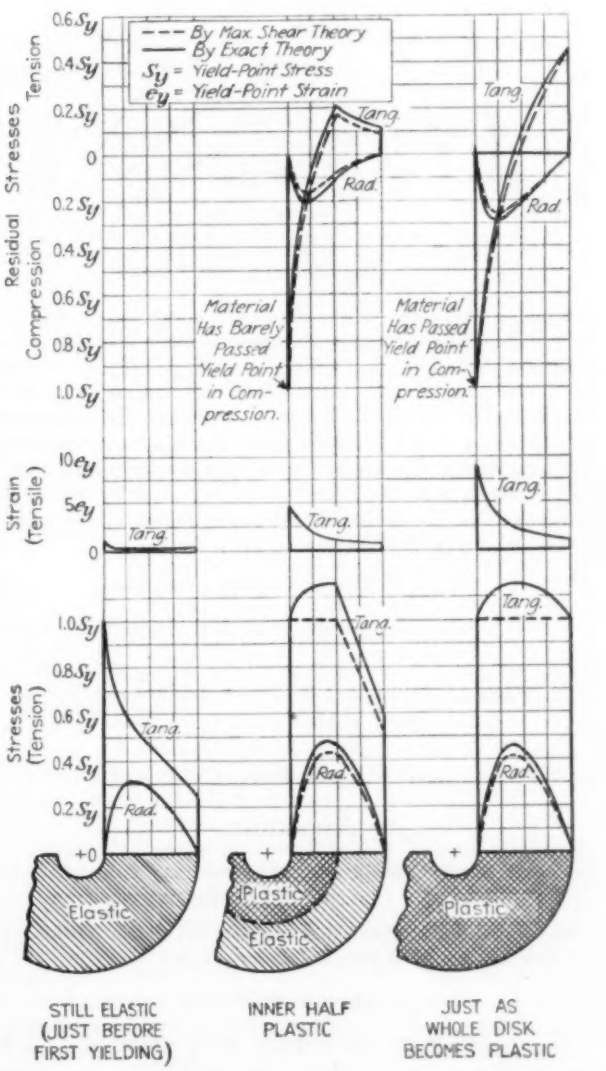

FIG. 4 STRESS DISTRIBUTION, STRAINS, AND RESIDUAL STRESSES IN A DISK WITH A 1-TO-5 HOLE

and

$$\left.\begin{aligned}\sigma_t &= 1\\ \sigma_r &= 1 - 4\Phi^2\rho^2 \text{ for a solid disk}\end{aligned}\right\} \quad \ldots\ldots\ldots [4]$$

On the Basis of the More Exact Theory, Φ is to be determined for any given value of α and γ from Fig. 2, as previously explained. The stresses at any point ρ in the plastic region are then determined from Fig. 5. In this figure the different curves are for disks with different-sized holes. From the known values

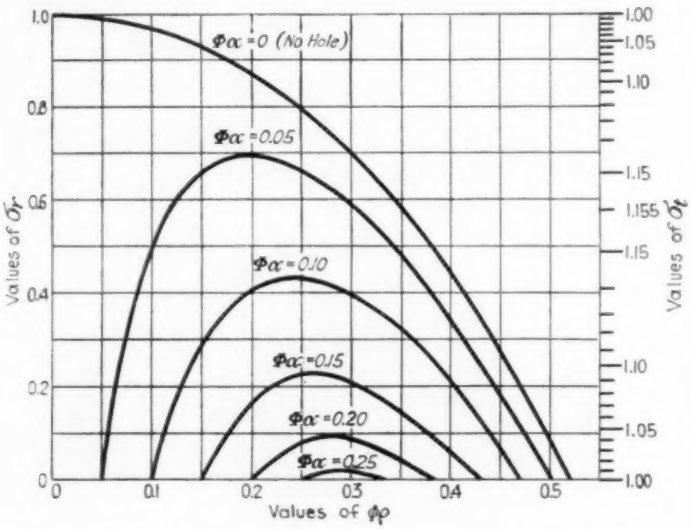

FIG. 5 CHART FOR FINDING STRESS DISTRIBUTION IN PLASTIC REGION ACCORDING TO EXACT THEORY

of Φ and α, and hence of $\Phi\alpha$, the proper curve can be selected. Then if it is desired to know the stress at some point, i.e., some particular value of ρ, it is only necessary to calculate $\Phi\rho$ and locate the point on the curve which has this as its abscissa. The ordinate of this point gives the stress (both radial and tangential, according to the two scales given at the sides of the chart).

Having found the value of σ_t at the boundary of the plastic region (which will be designated by $\sigma_{t(\rho = \gamma)}$) by one of the above methods, the stresses in the elastic region at any point ρ are obtained from the following:

$$\sigma t' = M + N/\rho^2 - 1.5(1 + 3\nu)\Phi^2\rho^2 \ldots\ldots [5]$$

$$\sigma'_r = M - N/\rho^2 - 1.5(3 + \nu)\Phi^2\rho^2 \ldots\ldots [6]$$

where

$$M = [\gamma^2\sigma_{t(\rho = \gamma)} + 1.5\,(1 + 3\nu)\Phi^2\gamma^4 + 1.5\,(3 + \nu)\Phi^2]/(1 + \gamma^2)$$

and

$$N = [\gamma^2\sigma_{t(\rho = \gamma)} + 1.5\,(1 + 3\nu)\Phi^2\gamma^4 - 1.5\,(3 + \nu)\Phi^2\gamma^2]/(1 + \gamma^2)$$

Appendix

THEORY WORKED OUT UNDER THE ASSUMPTION THAT THE YIELD STRESS IS INDEPENDENT OF DEFORMATION

The radial and tangential stresses in the elastic portion of a rotating disk are given from well-known theory by:

$$\sigma'_t = -\tfrac{1}{8}\,(1 + 3\nu)\,\Phi^2\rho^2 + k_1 + k_2/\rho^2 \ldots\ldots [7]$$

$$\sigma'_r = -\tfrac{1}{8}\,(3 + \nu)\,\Phi^2\rho^2 + k_1 - k_2/\rho^2 \ldots\ldots [8]$$

where k_1 and k_2 are integration constants to be determined from boundary conditions.

The yield point will be first reached at a peripheral speed V given by the following equations easily derived from the above:

$$\frac{\lambda V^2}{gS_y} = \frac{1}{3[3 + \nu + (1 - \nu)\alpha^2]} \ldots\ldots [9]$$

and

$$\frac{\lambda V^2}{gS_y} = \frac{2}{3(3 + \nu)} \text{ for a solid disk} \ldots\ldots [10]$$

In the plastic region, Fig. 6 shows the forces on an infinitely small element. The condition of equilibrium of these forces is expressed by the equation:

$$\frac{d}{d\rho}(\rho\sigma_r) - \sigma_t + 12\,\Phi^2\rho^2 = 0 \ldots\ldots [11]$$

(*a*) If σ_t is taken = 1, according to the maximum-shear theory, Equation [11] can be readily integrated and the integration constant determined, giving Equations [3] and [4]. From [4], [7], and [8] and the boundary conditions, one finds for the solid disk:

$$\frac{\lambda V^2}{gS_y} = \frac{24}{9 + 3\nu - (2 + 6\nu)\,\gamma^2 + (1 + 3\nu)\gamma^4} \ldots\ldots [12]$$

Through this the peripheral speed V is obtained for any solid rotating disk, if the radius c of the plastic region (or $\gamma = c/b$) is given. If $\gamma = 1$, that is, if the plastic region just reaches the outer circle:

$$\frac{\lambda V^2}{gS_y} = \frac{1}{4} \ldots\ldots [13]$$

Comparison of [10] and [13] yields a result of practical importance: that is, that in a solid disk the peripheral

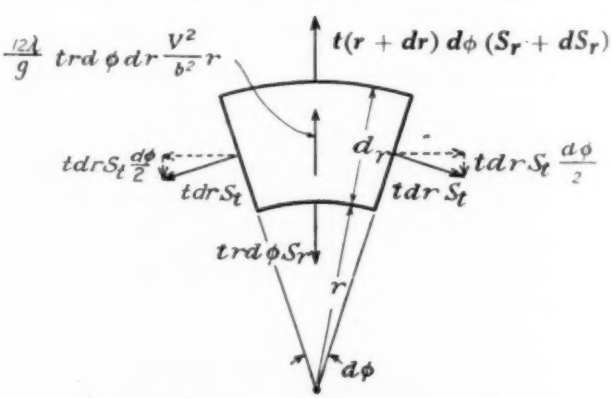

FIG. 6 FORCES ON AN ELEMENT OF DISK

speed V_2 when the disk just begins to stretch permanently on its outer circle is:

$$V_2 = \sqrt{\frac{3(3 + \nu)}{8}}\,V_1 \ldots\ldots [14]$$

or, with $\nu = 0.3$, $V_2 = 1.11V_1$, which is only 11 per cent higher than the speed at which the first yield occurs.

For the *disk with a hole* the expression for the peripheral speed becomes a little more complicated and is:

$$\frac{\lambda V^2}{gS_y} = \frac{2 - \alpha\,(\gamma + 1/\gamma)}{9 + 3\nu - (2 + 6\nu)\gamma^2 + (1 + 3\nu)\gamma^4 - 4\alpha^2\,(\gamma + 1/\gamma)} \quad [15]$$

Yield first occurs now at a speed V given by:

$$\frac{\lambda V^2}{gS_y} = \frac{1}{3[3+\nu+(1-\nu)\alpha^2]} \quad [16]$$

and the plastic region spreads to the outer boundary at a speed given by:

$$\frac{\sigma V^2}{gS_y} = \frac{1}{4(\alpha^2+\alpha+1)} \quad [17]$$

(*b*) According to the more exact theory the quantity

$$(S_1-S_2)^2+(S_1-S_3)^2+(S_2-S_3)^2$$

must always have the same value when yielding takes place. Thus it must have the same value when the material yields under a simple tensile test, in which case it becomes $[(S_y-0)^2+(S_y-0)^2+(0-0)^2] = 2S_y^2$. Hence in a plastic region (before cold working takes place):

$$(S_1-S_2)^2+(S_1-S_3)^2+(S_2-S_3)^2 = 2S_y^2$$

which in our case, as $S_1 = S_t$, $S_2 = S_r$, and $S_3 = 0$, reduces to

$$\sigma_t^2-\sigma_r\sigma_t+\sigma_r^2 = 1 \quad [18]$$

or

$$\left(\frac{\sigma_t+\sigma_r}{2}\right)^2+3\left(\frac{\sigma_t-\sigma_r}{2}\right)^2 = 1 \quad [19]$$

which is now the condition of plasticity. This makes σ_t a variable and when its value is substituted in [11], integration seems to be impossible. To reduce the variables we put

$$\sin\theta = \frac{\sigma_t+\sigma_r}{2} \qquad \cos\theta = \frac{\sigma_t-\sigma_r}{2}\sqrt{3} \quad [20]$$

whence

$$\left.\begin{aligned}\sigma_t &= \sin\theta+\frac{\cos\theta}{\sqrt{3}}\\ \sigma_r &= \sin\theta-\frac{\cos\theta}{\sqrt{3}}\end{aligned}\right\} \quad [21]$$

Substituting [21] in the differential Equation [11] and letting $\Phi^2\rho^2 = w$ we obtain the following:

$$\frac{d\theta}{dw} = \frac{\cos\theta-6\sqrt{3}\,w}{2w\cos(\theta-\pi/6)} \quad [22]$$

where $w = \Phi^2\rho^2$.

One set of values of θ and $\Phi^2\rho^2$ is given by the inner boundary conditions and [21]: $\rho = 0$, $\sigma_r = \sigma_t$, $\Phi^2\rho^2 = 0$, $\theta = \pi/2$ or for a disk with a hole, $\rho = \alpha$, $\sigma_r = 0$, $\Phi^2\rho^2 = \Phi^2\alpha^2$, $\theta = \pi/6$ (from [21]).

Building up from these values by numerical integration we can obtain for any value of $\Phi^2\alpha^2$ (including 0, when there is no hole) a series of values of θ and $\Phi^2\rho^2$ satisfying [22]. From each set of values of $\Phi^2\alpha^2$, $\Phi^2\rho^2$, and θ thus obtained we can calculate the value of $\Phi\alpha$, $\Phi\rho$, and σ_r, σ_t (from θ, using [21]) and these will also satisfy [22]. These values are plotted in Fig. 5.

Each point in Fig. 5 then represents a set of values of $\Phi\alpha$, $\Phi\rho$, σ_r, or, if we wish to so regard it, of $\Phi\alpha$, $\Phi\gamma$ and $\sigma_{r(\rho=\gamma)}$ (the value of σ_r at the boundary of the plastic region) which satisfy conditions in the *plastic* region.

From [7], [8], and [18] and the boundary conditions of the elastic region we can get the following equation:

$$\phi^2\gamma^2 = \frac{(3+\gamma^2)\,\sigma_{r(\rho=\gamma)}+(1-\gamma^2)\sqrt{4-3\sigma_{r(\rho=\gamma)}^2}}{6[(3+\nu)/\gamma^2-(2+2\nu)-(1-\nu)\gamma^2]}$$

from which, if we know ν, we can obtain (by assuming γ and $\sigma_{r(\rho=\gamma)}$ and solving for $\phi\gamma$) sets of values of γ, $\phi\gamma$, and $\sigma_{r(\rho=\gamma)}$ which satisfy conditions at the boundary of the *elastic* region. If we plot from this a new set of curves on Fig. 5, of $\phi\gamma$ plotted against $\sigma_{r(\rho=\gamma)}$ for various values of γ, then every intersection of one of these new curves with one of the old ones will give us a set of values of $\phi\gamma$, $\sigma_{r(\rho=\gamma)}$, $\phi\alpha$, and γ satisfying conditions for both the plastic and elastic regions. For each set of these values we can calculate ϕ, α, and γ. In this way Fig. 2 was plotted, for the particular case of $\nu = 0.3$.

Residual stresses were estimated on the assumption that when the disk is slowed down, stresses are removed according to Hooke's law—i.e., the stresses which would exist at the given speed if the material were perfectly elastic (obtained from [7], [8], and the boundary conditions) were subtracted from those previously obtained. Where the residual stresses reached the yield point in compression, Fig. 4, they were simply cut down to the yield-point value; and as this involved only a very small area, the effect on the remaining stresses was neglected.

(*c*) According to accepted theory, in a plastic region the direction of the principal stresses coincides with the direction of principal strains, and these are related as follows:

$$\frac{2S_2-S_1-S_3}{S_1-S_3} = \frac{2e_2-e_1-e_3}{e_1-e_3} \quad [23]$$

Also, the volume remains practically constant, so

$$e_1+e_2+e_3 = 0 \quad [24]$$

These reduce, in the present case, to

$$e_r/e_t = (2S_r-S_t)/(2S_t-S_r) \quad [25]$$

As in the elastic theory, u being the radial displacement,

$$e_t = u/r,\ e_r = du/dr$$

therefore

$$\frac{de_t}{e_t} = \left(\frac{e_r}{e_t}-1\right)\frac{dr}{r} = \frac{3(\sigma_r-\sigma_t)\,d\rho}{(2\sigma_t-\sigma_r)\rho} \quad [26]$$

whence, using [3] and [4],

$$\frac{d\epsilon_t}{\epsilon_t} = -\frac{3(\alpha+4\Phi^2(\rho^3-\alpha^3))d\rho}{[\rho+\alpha+4\Phi^2(\rho^3-\alpha^3)]\rho} \text{ for a disk with a hole} \quad [27]$$

and

$$\frac{d\epsilon_t}{\epsilon_t} = -\frac{12\Phi^2\rho d\rho}{1+4\Phi^2\rho^2} \text{ for a solid disk} \quad [28]$$

The latter equation is easily integrated:

$$\epsilon_t = k/(1+4\rho^2\Phi^2)^{3/2} \quad [29]$$

and when $\rho = \gamma$, $\epsilon_t = \sigma_t-\nu\sigma_r = k/(1+4\Phi^2\gamma^2)^{3/2}$,

$$\epsilon_t = \sqrt{\left(\frac{1+4\Phi^2\gamma^2}{1+4\Phi^2\rho^2}\right)^3}\times(\sigma_t-\nu\sigma_r)$$

which cannot exceed 3 until the whole disk becomes plastic, as $(\sigma_t-\nu\sigma_r) \lesssim 1$ and the maximum value of $4\Phi^2\gamma^2$ is 1, when the whole disk is plastic (from [13]).

For a disk with a hole Equation [27] can be integrated, but it was found easier to use numerical integration to obtain an approximate solution. The starting point is given as in [29]: $\rho = \gamma$ and $\epsilon_t = \sigma_t-\nu\sigma_r$, which has a value so close to 1.0 under all conditions (as can be seen from Figs. 3 and 4) that this value was assumed. Thus the values of ϵ_t were found over the whole of the plastic region for various values of α and γ, Φ being determined from [1], with the results previously described.

Method for Computing Stress in a Solid Disk Stretched Permanently Under the Assumption That the Yield Stress Depends on the Deformation

Here the authors will finally try to indicate how it seems to be possible to consider the effect of cold work in their calculation. As is well known from an ordinary stress-strain diagram, the stresses within the plastic region depend upon the deformation and increase with the unit elongation. Until now no general law has been known by means of which the effect of cold work *under combined stress* could be expressed. The authors will introduce again certain simple assumptions which are more or less evident, some of them, derived from results of tests, having been previously used in this paper. It will be assumed that when plastic flow takes place in steel:

1 The volume is not changed.

2 Mohr's diagram of the three principal stress circles is a figure geometrically similar to the three principal strain circles.[12]

3 The effect of cold work will be expressed by assuming that the maximum shear stress is a given function of the maximum shearing deformation which we shall take to be a linear function.

4 The change of the dimensions through the plastic deformation remains small when compared with the dimensions of the stressed disk.

Assumption 1 is expressed by the equation:

$$e_r + e_t + e_z = 0 \qquad [30]$$

where e_z denotes the principal extension in the direction perpendicular to the plane of the disk. Assumption 2 is expressed by the proportion:

$$\frac{e_t - e_r}{e_t - e_z} = \frac{S_t - S_r}{S_t - S_z} \qquad [31]$$

Now by using [30] and taking $S_z = 0$, [31] reduces to:

$$\frac{S_r}{S_t} = \frac{e_t + 2e_r}{e_r + 2e_t} \qquad [32]$$

From this proportion we conclude that S_r and S_t can be expressed as follows:

$$\left.\begin{aligned} S_r &= k(e_t + 2e_r) \\ S_t &= k(e_r + 2e_t) \end{aligned}\right\} \qquad [33]$$

where k is an unknown function of the coordinate ρ.

The maximum shearing deformation at an arbitrary point ρ is[14]

$$\gamma_{max} = e_t - e_z = e_r + 2e_t \qquad [34]$$

and the maximum shear stress is $S_t/2$.

Assumption 3 can now be expressed by taking $S_t/2$ to be a linear function of the maximum shearing deformation γ_{max}:

$$S_t = S_0(1 + c\gamma) \qquad [35]$$

where c is a constant and S_0 is a constant stress which is apparently very nearly the stress at which the first yield occurs.

Calling e_0 the tangential unit elongation where the first yield occurs in pure tension, then

$$e_r = e_z = -\frac{e_t}{2} = -\frac{e_0}{2}$$

$$\gamma = \gamma_0 = e_r + 2e_t = -\frac{e_0}{2} + 2e_0 = \frac{3e_0}{2}$$

γ_{max} can never be smaller than $3e_0/2$. By using [33] and [34], Equation [35] takes the form:

$$S_t = \frac{kS_0}{k - cS_0} \qquad [36]$$

It is now necessary to connect these equations with the condition of equilibrium of the disk already given, namely,

$$\frac{d(\rho S_r)}{d\rho} - S_t + S_0\beta\rho^2 = 0, \quad \beta = \frac{\lambda V^2}{gS_0} \qquad [37]$$

and with the condition of compatibility of the strains:

$$\frac{d(\rho e_t)}{d\rho} - e_r = 0 \qquad [38]$$

Equations [33], [36], [37], and [38] are sufficient to determine the stress distribution.

If the constant c, which was introduced in the idealized stress-strain diagram to express cold work (Equation [35]), be taken equal to zero, we obtain the case already worked out in case (*a*) at the beginning of the appendix, and c can only be positive. The actual value of c can be estimated from the stress-strain diagram for pure tension. For example, if in a tensile test the stress S_t should increase by 100 per cent for 10 per cent unit plastic elongation (that is, for $\gamma = 3e/2 = 0.015$), it follows from [35] that

$$c = \frac{S_t - S_0}{S_0\gamma} = \frac{1}{0.15} = \frac{20}{3}$$

It seems impossible to give the exact functions in finite form which would satisfy all the prescribed conditions. But it is possible to find an approximate form of the distribution of the radial and tangential stresses by functions similar to those found for the case where $c = 0$. We indicate the calculation only for the case where the *entire disk is in the plastic stage.*

Assume for the radial stress the function:

$$S_r = CS_0(1 - \rho^2) \qquad [39]$$

where the constant C has to be determined. It is easy to find the corresponding tangential stress to this radial stress distribution which establishes equilibrium, by deriving it from [37]:

$$S_t = S_0[C(1 - 3\rho^2) + \beta\rho^2] \qquad [40]$$

From [33] we now find that

$$\left.\begin{aligned} e_r &= \frac{S_0}{3k}[C(1 + \rho^2) - \beta\rho^2] \\ e_t &= \frac{S_0}{3k}[C(1 - 5\rho^2) + 2\beta\rho^2] \end{aligned}\right\} \qquad [41]$$

and from [36]:

$$k = S_0c\,\frac{C + (\beta - 3l)\rho^2}{C - 1 + (\beta - 3l)\rho^2} \qquad [42]$$

$$\text{For } \rho = 0,\ k = k_0 = S_0c\,\frac{C}{C - 1} \qquad [43]$$

$$\text{for } \rho = 1,\ k = k_1 = S_0c\,\frac{\beta - 2C}{\beta - 2C - 1} \qquad [44]$$

The boundary conditions are: on the outer circle $\rho = 1$, $\sigma_r = 0$; on the boundary of the plastic region $\rho = \gamma$, $\sigma_r = \sigma'_r$, $\sigma_t = \sigma'_t$; and in the middle of the disk $\rho = 0$, $\sigma_r = \sigma_t$ for a solid disk; or for a disk with a hole $r = a$, $\rho = \alpha$, $\sigma_r = 0$.

[12] See "Der bildsame Zustand der Werkstoffe," J. Springer, Berlin, 1927, p. 51.

[14] The letter γ in Equation [34] has another meaning from that used earlier in the paper.

but from [40], for $\rho = 1$, $S_t = S_0(-2C + \beta)$ . . . . . [45]

and from [35], for $\rho = 1$, $S_t = S_0(1 + c\gamma_1)$ . . . . . [46]

The equality of the right-hand members of [45] and [46] gives finally the boundary condition for $\rho = 1$, namely,

$$-2C + \beta = 1 + c\gamma_1 \text{ . . . . . } [47]$$

Until now the condition of compatibility of the strains [38] has not been used. By taking the values of e_r and e_t from

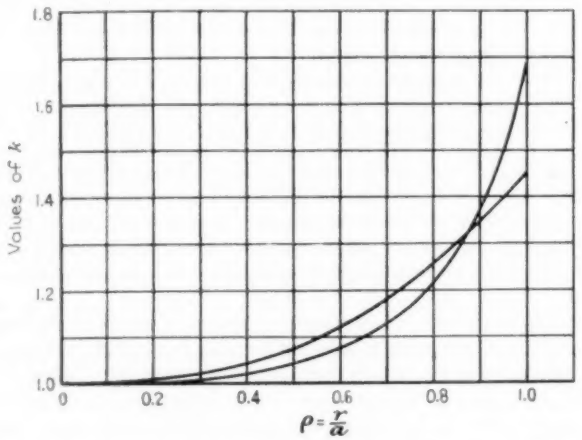

FIG. 7 FUNCTIONS OF k CORRESPONDING TO EQUATIONS [20] AND [25] FOR $\beta = 5.5$

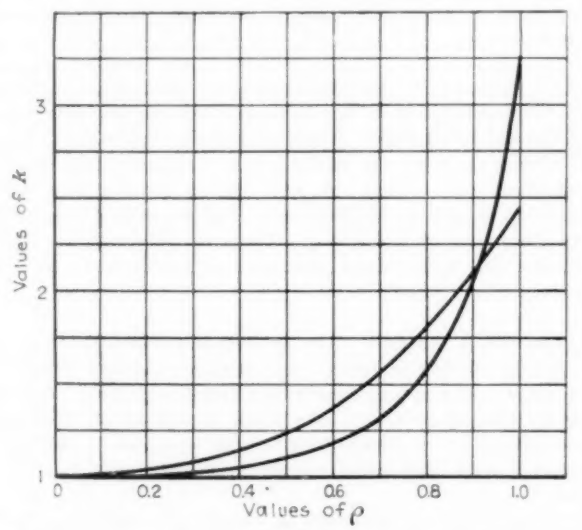

FIG. 9 CURVES OF k CORRESPONDING TO EQUATIONS [20] AND [25] FOR $\beta = 12.5$

[41], one obtains from [38] a differential equation for the function which can be readily integrated. This gives a second expression for the function k, namely,

$$k = k_0(1 + A\rho^2)^m \text{ . . . . . } [48]$$

where

$$m = \frac{8 - \beta + 8c\gamma_1}{5 - \beta + 5c\gamma_1} \qquad A = \frac{5 - \beta + 5c\gamma_1}{\beta - 1 - c\gamma_1} \text{ . . . . . } [49]$$

Had the exact function [39] been chosen for the radial stress S_r, both expressions [42] and [48] for the unknown function k would have been found equal. As this will not be the case, it is now possible for given values of γ and c to find a value of β for which expressions [42] and [48] for k differ the least. It was indeed possible to find such values of β for which the errors seemed to be not too serious, so that the expressions for the radial and tangential stresses S_r and S_t in [33] are exact enough practically to account for the effect of cold work.

It is not necessary to calculate the value of β by the method

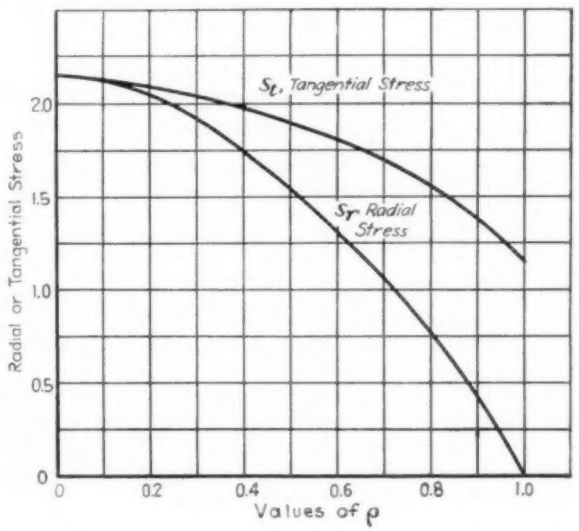

FIG. 8 RADIAL AND TANGENTIAL STRESSES IN A SOLID DISK STRETCHED BEYOND THE YIELD POINT FOR $\beta = 5.5$, $V = 1.5V_0$

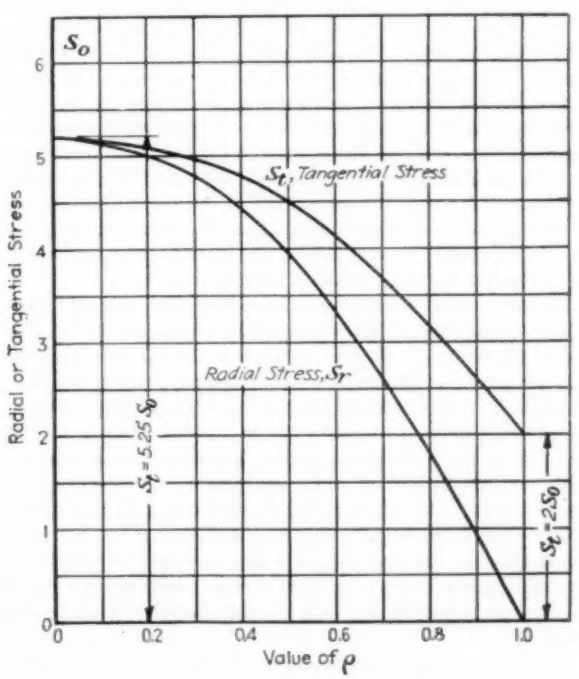

FIG. 10 RADIAL AND TANGENTIAL STRESSES IN A SOLID DISK STRETCHED BEYOND THE YIELD POINT FOR $\beta = 12.5$, $V = 2.24\ V_0$

of least squares, for by trial with several values of β one finds easily the approximate values required.

The results of two calculations for a solid disk are as follows: The value of β when the first yield occurs is

$$\beta = \frac{8}{3 + \nu} = 2.43$$

as was shown above. The circumferential speed V is then

$$V = \sqrt{2.43}\frac{gS_0}{\lambda}$$

If we call this value of $V = V_0$, then for a disk stretched on its circumference permanently by 2 per cent in a tangential direction,

$$\beta = 5.5 \qquad V = 1.5V_0$$

and for a disk stretched by 10 per cent on its circumference,

$$\beta = 12.5, \qquad V = 2.24\,V_0$$

For these two cases the corresponding distribution of the radial and tangential stresses are shown in Figs. 8 and 10. Figs. 7 and 9 show the two curves for the function k, which curves should coincide, if the assumed form for the stress distribution were exact.

As one can see, for example, from Fig. 8, the tangential stress on the circumference is 1.2 times the yield stress S_0 and at the middle point of the disk both the radial and tangential stresses are 2.15 times the yield stress S_0.

The authors wish to express their great thanks to S. M. Kintner, Manager of the Research Department of the Westinghouse Electric & Manufacturing Co., and to Mr. J. M. Lessells, in charge of the Mechanics Section, for the opportunity given them to work out these cases of plastic flow.

Discussion

S. Timoshenko.[15] It is now a general practice to run high-speed rotors, after assembly, at overspeed so as to produce a certain plastic flow at the inner bore of the rotor. In this manner not only will the yield point of the material at the bore be raised, but also certain residual stresses will be created, so that when these are combined with the stresses due to inertia forces, a more favorable stress distribution in the rotor will be obtained. There is no doubt that an analytical solution which establishes the relation between the magnitude of the speed and the radius of the region where plastic flow of metal takes place will be of practical interest in establishing the most favorable conditions for the overspeed trials of these large rotors.

The paper is of interest also from the more general point of view of stress analysis when a structure is partially under condition of plastic flow. Such conditions are not rare and sometimes they are produced at service speed, principally due to stress concentration. Till now there has not been a complete solution of the question, at what condition the flow of metal begins, although the authors speak of "exact theory" when comparing the theory based on consideration of strain energy with the usual maximum shear theory. The writer would like to suggest further development of the work in an experimental direction for clearing up this question. There is no doubt that such a work will be very beneficial, and will help very much toward establishing a rational basis for determining working stresses for each kind of stress condition.

As another desired development of the theory presented by the authors, the writer suggests looking into the stress analysis of long rotors where the problem can be considered as a two-dimensional one. There is no doubt that the overspeed treatment is more important in the case of long rotors than in the case of rotating disks.

[15] Professor of Engineering Mechanics, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

M. Stone.[16] In various engineering applications stresses exceed the yield point, but work is done under these conditions, because of the extreme localization of the effects. Such conditions usually occur where "stress concentrations" are present as in bolt threads, tension members with holes, dovetails, and even in some shrink fits. The case that the authors have treated has always been one where it was doubtful to judge the seriousness of the non-uniform stress distribution. Elastic considerations could never go far enough. Certain results that the authors have arrived at should be emphasized.

1 Only a 17 per cent increase in speed after the yield point is exceeded at the center will place the whole disk above the yield-point stress.

2 A disk with a hole, although resulting in a maximum elastic stress twice that of a solid disk, will hardly precipitate general failure any quicker than a solid disk.

The methods of analysis of the authors using a two-line stress-strain curve, considering the failure of material under three-dimensional stress, assuming plastic changes to be isometric in volume, etc., are all critical ones and are pertinent in making this very complex problem capable of analysis and generalization.

G. B. Karelitz.[17] The material given in the paper is very important, the stresses in large rotors being fairly high at present. It would be of interest to continue the analysis for cases where the radial stress at the rim is not zero, as is assumed in the paper. It is true that in a rotating disk the radial stress is zero at the outer rim; when, however, a turbine rotor with blades or a turbo-field with coils or poles is considered, the rim stresses are appreciable. It would be well worth while for the authors to amplify their paper covering this boundary condition, which is frequent in practice.

A. L. Kimball.[18] An interesting thing which appears in this paper is that only one of two component stresses produces yielding, the tangential stress. The yield is in all cases in the tangential direction, while the radial stress remains purely elastic. This shows quite clearly that the yielding actually must have been a sort of shearing displacement. Failures in ductile material take place through a shearing. The shearing planes are often irregular, but nevertheless they account satisfactorily for the yielding.

Alphonse A. Adler.[19] The problem of stress distribution in a rotating rim having teeth is not simple. Machine designers who made similar assumptions in the design of gear teeth[20] showed that by making models of gear teeth of transparent materials and studying stress distribution by means of Nicol prisms and polarized light, the usual assumptions were open to objections.

In looking over the literature one notes such phrases as apparent stresses, true-apparent stresses, etc. Each time it was thought that a more exact theory resulted. The paper speaks of the maximum-shear theory and also of a more exact theory. What is this exact theory?

The Society published the Shafting Committee's report. The writer served with Professor Beyer on that committee. A careful examination was made of the work of A. J. Becker, which

[20] Heymans and Kimball (*Mech. Eng.*, Mar., 1924, p. 129).

s referred to in this paper. Becker discarded the maximum-shear theory after making a large number of tests on shafting. This was believed to be an error, since conclusions drawn from torsion tests on solid bars are apt to be misleading. The committee took for its reason the fact that the less stressed inner layers of the bar assist the more highly stressed outer layers with the result that the shearing resistance is augmented.

Professor Beyer plotted several reported results of torsion tests on tubes. These, under twist, are likely to have a more uniform shear-stress distribution particularly when the wall thickness is small. It appeared, from the curve so obtained, that as the wall thickness of the tube became vanishingly small, the ratio of shear to tensile strength at elastic failure approached 0.5 as a limit. Becker's tests on solid bars showed this ratio to be more nearly 0.6, a value believed too high.

The writer's personal opinion is that shear failure is the only type of failure which really exists. Such notions as tensile and compressive strength are, at best, convenient through inaccurate concepts.

J. M. Lessells.[21] The writer would like to ask Professor Donnell if this theory has been worked out for a material which has no definite yield point. Suppose, for example, an alloy steel were used in the heat-treated condition where the yield point might not be so well defined. Would the same conditions apply?

With regard to Mr. Adler's remarks, it should be borne in mind that the maximum-shear theory is only applied to ductile materials. When dealing with a material like cast iron, having tensile characteristics entirely different from compression, some other theory must be applied. On these grounds the Mohr theory, as developed in Germany, which may be called a special case of the maximum-shear theory, is better. A more exact theory has since been discussed by B. P. Haigh. One cannot talk about any theory as being strictly exact. The remarks of Professor Boyd are interesting, but if the writer's understanding is correct, the maximum-energy theory is midway between the maximum-shear theory and the maximum-strain theory.

Authors' Closure

The use of the word "exact," to describe one of the theories as to the conditions under which yielding takes place, is undoubtedly open to criticism. This theory has the most evidence in its favor at the present time (of which Becker's work is only a part) but it is perhaps premature to speak of it so confidently. A great number of tests under combined stresses with thin tubes, which have been made by W. Lode and others during the last years, seem to indicate clearly that the ratio of the maximal shearing stress under pure shear to the yield stress under pure tension is for ductile materials not 0.5, as after the theory of maximum shear, but about equal to 0.56. As Dr. Timoshenko points out, this is an excellent field for experimental investigation at the present time.

It can hardly be questioned that materials can fail due to overcoming their cohesive forces, that is, due to a pure tensile failure and that brittle materials, and even ductile materials under certain conditions, do fail in this way. If the three principal stresses are equal and all three are tensile stresses, there is no shear. Hence, in this case failure cannot be attributed to shear. Therefore Mr. Adler's remark that shear failure is the only type of failure cannot be maintained. But plastic deformation, yielding, is undoubtedly a purely shearing phenomenon, as both theories used in the paper assume. The difference between them is merely as to whether shearing depends only on the maximum shearing stress or is influenced to some extent by the shearing stresses in other directions.

The same method of analysis could be used to extend the theory to include cases where the radial stress at the rim is not zero. The only difference would come at the start of the analysis in eliminating the integration constants from Equations [7] and [8] by use of the boundary conditions of the elastic region. Extension of the theory to the case of long rotors is more difficult, but is an attractive field for investigation.

Stresses in Heavy Closely Coiled Helical Springs

By A. M. WAHL,[1] EAST PITTSBURGH, PA.

In this paper more exact formulas are derived for computing stress in heavy closely coiled helical springs of the type used frequently in railway work. These formulas indicate that the maximum stress in such springs may, in many practical cases, be from 40 to 60 per cent greater than the stress computed by the use of ordinary helical-spring formulas. The new formulas are verified by strain measurements, using special extensometers on semi-coils of actual springs loaded so as to simulate the axial loading of a complete spring, and on complete springs loaded in compression. The work indicates that the frequent failures of this type of spring in service may, at least in part, be due to the existence of higher stresses than has been thought possible on the basis of ordinary spring formulas.

IT IS common knowledge that heavy closely coiled helical springs, especially those having a comparatively large diameter of wire relative to the coil diameter, often fail in service under loads which are well below the safe load determined by the use of ordinary helical-spring formulas. In this paper it will be shown both analytically and experimentally that the true maximum shearing stress in springs of this type may in many practical cases be from 40 per cent to 60 per cent greater than that calculated by these ordinary formulas, the amount of discrepancy depending on the ratio of mean coil diameter to wire diameter. This maximum stress occurs at points on the wire at the extremities of the inside diameter of the coil, that is, at points a' (Fig. 1*a*). On the other hand, at points of the wire at the extremities of the outside diameter of the coil, such as points a, the stress is much smaller and may be only from one-half to one-third that existing along the inside surface of the coil at a'. For example, in the case of the two springs tested the stress on the inside of the coil was found by actual strain measurements to be respectively 2.4 and 2.3 times the stress on the outside. The fact that failure of these springs always starts along the inside of the coil at a' (Fig. 1), that is, at the point of maximum stress, is, therefore, not surprising. Although this fact has often been attributed largely to faulty heat treatment,[2] it is quite possible that the unexpectedly high concentration of stress here occurring may be sufficient to cause failure even though the metal at this point were up to standard.

A photograph showing a typical fracture in service of a heavy helical spring of the type considered in this paper is shown in Fig. 1*c*. It will be noted that failure starts from a fatigue crack which begins along the inside of the coil at a', that is, near the point of maximum stress as mentioned above and progresses at an angle of about 45 deg. to the axis of the wire.

The purposes of this paper are therefore twofold:

1 To derive formulas suitable for the practical determination of maximum stress in heavy closely coiled helical springs. These formulas will take into account both the difference in fiber length along the inside and the outside of the coil and the direct shear due to the external load.

2 To check up these formulas as far as possible by actual strain measurements on practical springs. To this end the paper will be divided into two major parts, i.e.

Part 1 The derivation of more exact formulas for stress in heavy closely coiled helical springs.

Part 2 Experiments and comparison of experimental data with the results obtained by the new formulas.

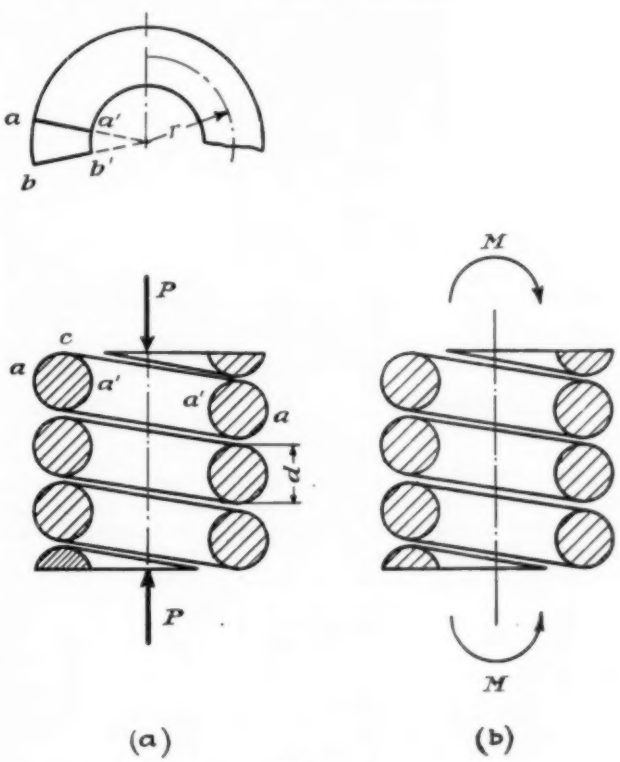

FIG. 1

PART 1 THE DERIVATION OF MORE EXACT FORMULAS FOR STRESS IN HEAVY CLOSELY COILED HELICAL SPRINGS

Consider a heavy closely coiled helical spring of mean coil diameter $2r$ subjected to an axial load P as shown in Fig. 1. The forces acting on any element $aa'\ b'b$ cut out by two neighboring radial planes may be resolved into a twisting moment Pr acting in a radial plane and a direct shearing force P acting in the direction of the axis of the spring.

The twisting moment Pr will cause rotation of the two sections aa' and bb' with respect to each other through a small angle which we will call $d\alpha$. But since the length of the fiber $a'b'$ is much less than the length of the fiber ab it is clear that the shearing strain and hence the shearing stress for any given relative angular rotation of the two cross-sections will be much greater in $a'b'$ than in ab. The stress at a' is further increased by the direct

[1] Research Laboratory, Westinghouse Elec. & Mfg. Co.

[2] The need for an investigation of the kind described in this paper was noted in a paper by G. M. Eaton, of the Molybdenum Co. of America, "Design from a Heat Treating Standpoint," Trans. A.S.S.T., Nov., 1927.

Contributed by the Research Special Committee on Mechanical Springs and presented at the Annual Meeting, New York, N. Y., December 3 to 7, 1928, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

shearing stress due to the axial load P. This stress corresponds to the shearing stress at the neutral axis of a cantilever beam of circular cross-section loaded with a load P.

The shear stress distribution, due to the twisting moment Pr, along a transverse diameter of the wire is somewhat as shown by the shaded area of Fig. 3, the stress at a' being much greater than that at a. To this stress at a' must be added the direct shear stress due to the external load P.

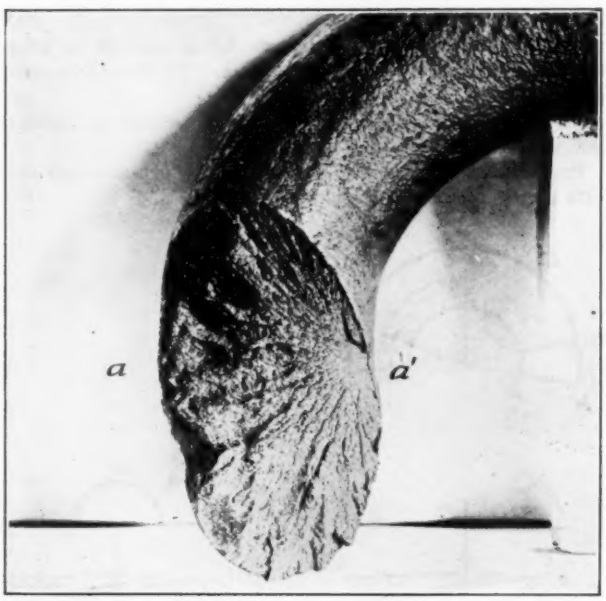

FIG. 1c

MORE EXACT HELICAL-SPRING FORMULAS

In line with the above considerations, a more exact formula for determining the maximum shearing stress at a' for the case of a helical spring axially loaded (Fig. 1) was derived. (See Appendix.) This formula is

$$S = \frac{16\,Pr}{\pi d^3}\left(\frac{4c-1}{4c-4} + \frac{0.615}{c}\right) \quad \ldots\ldots\ldots\ldots [1]$$

In this formula:

P = axial load on spring
d = diameter of wire
r = mean radius of coil
S = maximum shear stress, lb. per sq. in.
c = ratio $\frac{2r}{d} = \frac{\text{mean coil diameter}}{\text{wire diameter}}$

Evidently we have here simply the ordinary formula for stress in helical springs $16Pr/\pi d^3$ multiplied by a certain factor k which depends on the ratio c of mean coil diameter to wire diameter. The formula thus is

$$S = \frac{16Pr}{\pi d^3}\,k \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

where

$$k = \frac{4c-1}{4c-4} + \frac{0.615}{c}$$

We call k the stress multiplication factor.

In Table 1 are given numerical values of k for various integral values of the ratio c computed from this formula.

TABLE 1

c = mean coil diameter ÷ wire diameter	3	4	5	6	8	10
k = stress multiplication factor	1.580	1.404	1.310	1.252	1.184	1.145

Using the data of Table 1 the curve of Fig. 2 was plotted to simplify the practical application of Equation [2].

In order to apply this formula to any practical case of a helical spring loaded axially it is only necessary to compute the stress using the ordinary helical-spring formula and multiply the resulting value of stress by the stress multiplication factor k obtained from the curve of Fig. 2.

A formula for computing the stress on the outside of the coil, i.e., at a, Fig. 1, was also derived (see Appendix). This formula is

$$S' = \frac{16\,Pr}{\pi d^3}\left(\frac{4c+1}{4c+4} - \frac{0.615}{c}\right) \quad \ldots\ldots\ldots\ldots [3]$$

In case a pure bending moment M acts on the spring as shown in Fig. 1*b*, the formula for computing the maximum shearing stress is (from Equation [11] of the Appendix)

$$S = \frac{16\,M}{\pi d^3}\left(\frac{4c-1}{4c-4}\right) \quad \ldots\ldots\ldots\ldots\ldots [3a]$$

This is likewise the ordinary formula for shearing stress in a rod of circular cross-section subjected to a twisting moment M multiplied by a factor $\frac{4c-1}{4c-4}$ which depends only on the value of the ratio of mean coil diameter to wire diameter.

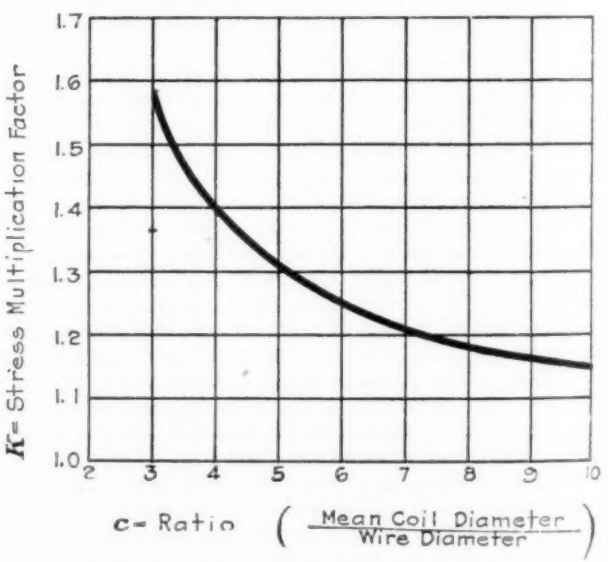

FIG. 2 CURVE FOR DETERMINING THE STRESS MULTIPLICATION FACTOR K

PROCEDURE IN DESIGN

In the practical design of heavy closely coiled helical springs, Equation [2] may be applied for the determination of stress due to axial loads. When, in addition to these axial loads, bending moments such as shown in Fig. 1*b* are acting on the spring, the stresses due to these must be superimposed on those due to the axial load. These stresses may be determined by applying Equation [3*a*]. When the load is not axially applied, as is the case in Fig. 4*a*, the spring may be considered subjected to a direct axial load P and a bending moment Pe where e is the eccentricity of the load. As mentioned above the stresses due

to this bending moment Pe should be superimposed on those due to the axial load P.

PART 2 EXPERIMENTS AND COMPARISON OF EXPERIMENTAL DATA WITH THE RESULTS OBTAINED BY THE NEW FORMULAS

In order to check the correctness of the new helical-spring formulas given in Part 1, strain measurements were made on heavy helical springs of the type used frequently in railway work. The springs tested had a ratio of mean coil diameter

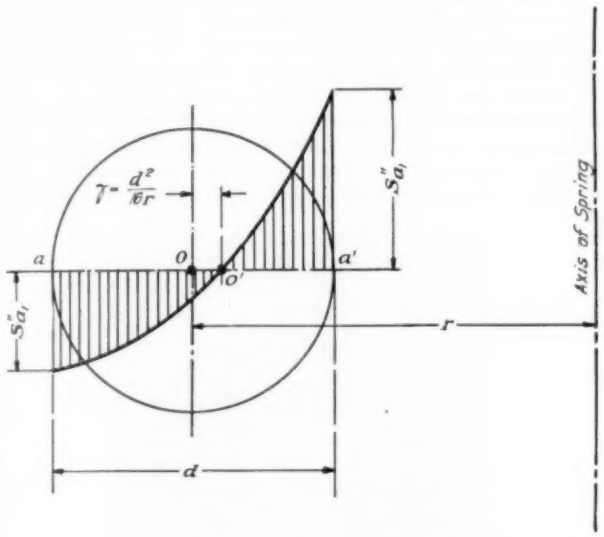

Fig. 3 Stress Distribution Along a Transverse Diameter a-a' Assuming Rotation About the Point O'

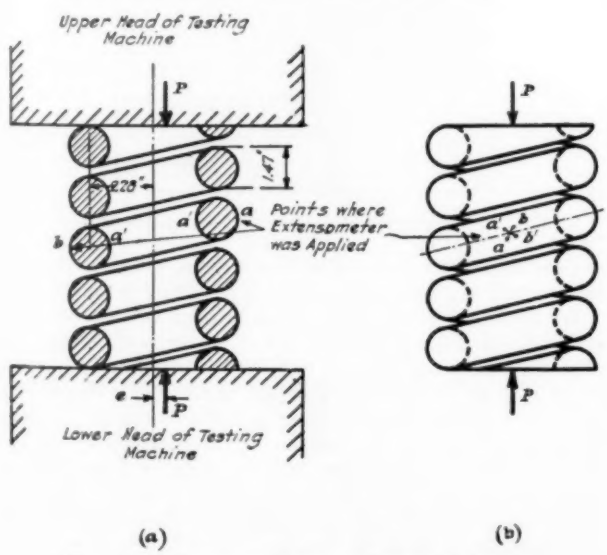

Fig. 4 Compression Test of Complete Spring

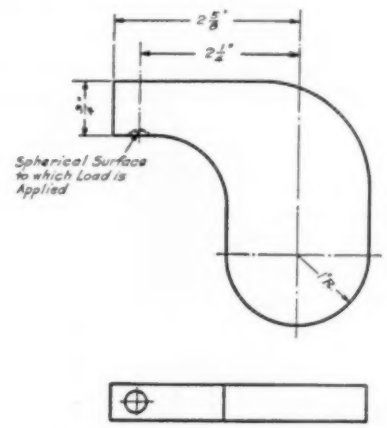
to wire diameter of approximately 3, that is, $c = 2r/d = 3$. While this ratio is somewhat lower than that existing in the great bulk of springs used, nevertheless there exist certain applications where springs of these dimensions are used. By testing a spring having a small value of the ratio c, the validity of the new formulas may be more conclusively shown, since it is in such cases that the stress determined by these formulas (which are derived by approximate methods) will deviate a maximum from the true value. Hence, if the new formulas are found approximately correct for $c = 3$ we may assume that they will also be practically correct for larger values of c, since



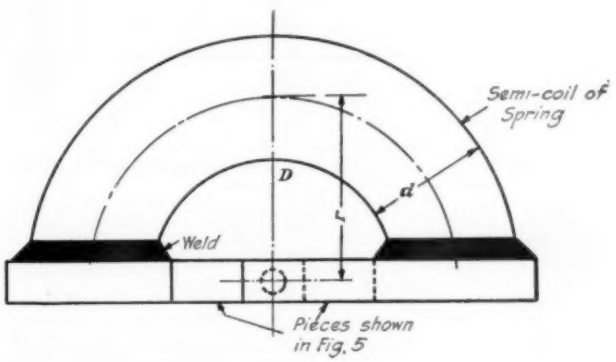


Fig. 5 Steel Arm for Welding to Semi-Coil of Spring

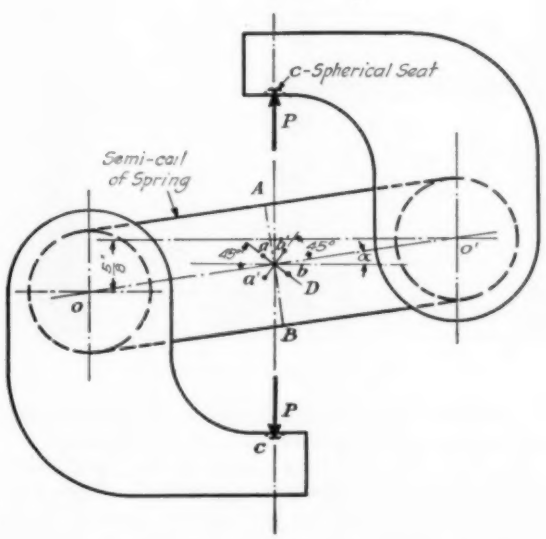

Fig. 6 Semi-Coil Spring Test Arrangement

as c becomes larger the new formulas more nearly approximate the ordinary helical-spring formulas and the assumptions on which they are based are more nearly exact.

The tests comprised strain measurements on semi-coils of

actual springs as well as strain measurements on full or complete springs. All springs tested had approximately $1^1/_2$-in. diameter wire and had a mean coil diameter of about $4^1/_2$ in.

Tests on Semi-Coils of Actual Springs

Since the dimensions of the springs tested were such that it was impossible to apply an extensometer on the inside surface of a complete spring, that is, at points a' (Fig. 1*a*), semi-coils were

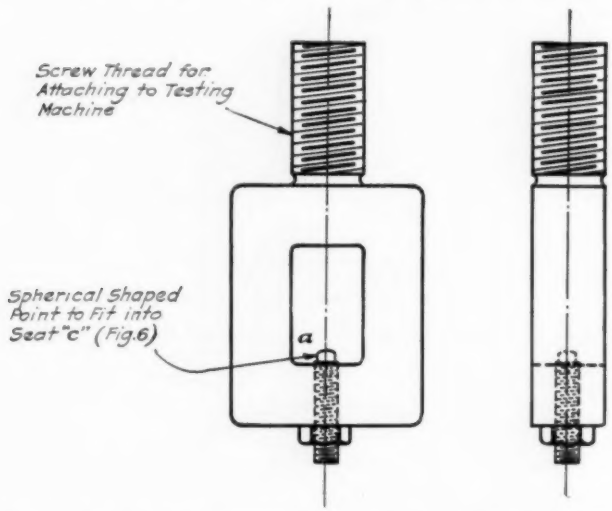

Fig. 7 Eyebolt for Applying Load to Semi-Coil of Spring

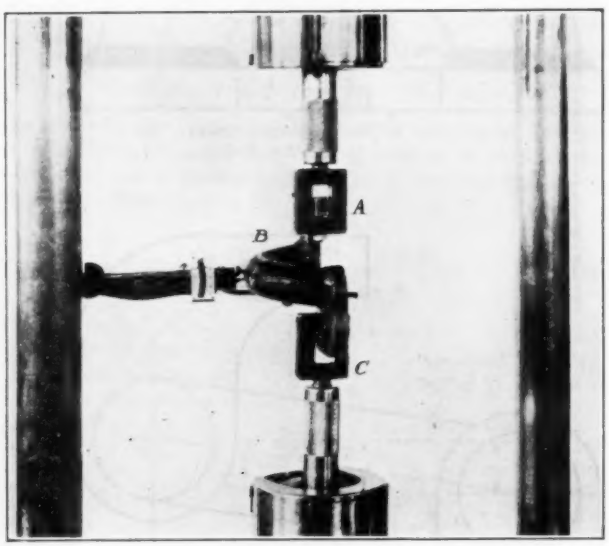

Fig. 8 Semi-Coil Test Arrangement

cut from actual springs and loaded in such a way as to simulate the actual loading of a helical spring under an axial load.

For this purpose two steel arms having the shape and dimensions shown in Fig. 5 were welded to each end of a semi-coil cut from an actual spring to form the arrangement shown in Fig. 6. The load P was applied to this arrangement through the intermediary of two eyebolts (Fig. 7) which are attached to the two heads of a testing machine. The screws a having spherical points fit into the spherical seats c (Fig. 6). In this manner two equal and opposite loads P are applied axially, as in the actual spring, while at the same time there is space for applying special extensometers along the inside surface of the coil at position D, Fig. 6. This could not have been done if a complete spring were used. The helix angle of the semi-coil was made so as to correspond approximately with the helix angle of the actual spring when loaded.

A photograph showing the test arrangement in an Amsler testing machine is shown on Fig. 8. Here the eyebolts A correspond to Fig. 7 while the semi-coil B corresponds to Fig. 6. In this case the extensometer is in position for measuring the stress on the outside of the coil, corresponding to points a (Fig. 1*a*). Fig. 9 shows the extensometer in position for measuring the stress on the inside of the coil corresponding to points a' (Fig. 1*a*) while Fig. 10 shows the position of the extensometer for measuring the stress corresponding to point c (Fig. 1*a*).

In all cases the gage length of the extensometer was 1 cm. The points were applied first at a and b, and then at a' and b', (Fig. 6) so that the strains at an angle of 45 deg. to the axis of the wire and to the line OO' were measured. Because there is a slight slope to the wire, there acts over the cross-section AB not only a twisting moment $M = Pr \cos \alpha$ where α is the helix

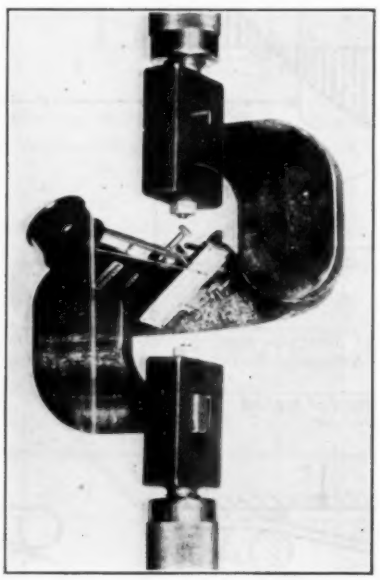

Fig. 9 Test With Extensometer on Inside of Coil

angle of the coil and a shearing force $P \cos \alpha$, but also a bending moment $M' = Pr \sin \alpha$ which acts in the plane of the coil.

We consider first the effect of the twisting moment $M = Pr \cos \alpha$ and the shearing force $P \cos \alpha$ acting across the section AB (Fig. 6). This moment and force will produce in an element at D a condition of practically pure shear. This means that we have a tensile stress S, equal in value to the shear stress, acting at 45 deg. to the direction of the shear stress, that is, in the direction of the fiber $a'b'$. Likewise for pure shear an equal compressive stress S acts along the fiber ab. The unit elongation along $a'b'$ will be[3] (from the ordinary formula for two-dimensional stress conditions):

$$e = \frac{S}{E} + \frac{1}{m}\frac{S}{E} = \left(1 + \frac{1}{m}\right)\frac{S}{E} \quad \ldots\ldots\ldots\ldots [4]$$

In this E is the modulus of elasticity and $1/m$ = Poisson's ratio for the material. Moreover, for this case (pure shear) the unit compression along ab is of the same value as the extension along $a'b'$ and is likewise given by Equation [4].

[3] See "Applied Elasticity," Timoshenko and Lessells, p. 12, regarding this formula.

On the strains produced by the twisting moment $Pr \cos \alpha$ and the shearing force $P \cos \alpha$ we now superimpose those produced by the bending moment $M = Pr \sin \alpha$ acting in the plane of the coil. This bending moment produces a relatively slight but definite elongation of both the fibers ab and $a'b'$ and of equal amounts. When these elongations are superimposed on the pure shearing strains discussed above the result is that the total elongation of the fiber $a'b'$ is slightly increased while the total compression of the fiber ab is slightly reduced by an equal amount. This was actually found to be the case in the springs tested although the difference between the measured elongation and the measured compression was never greater than about 10 per cent. In order to get the strains due only to the twisting moment $Pr \cos \alpha$ and the shearing force $P \cos \alpha$ we must, therefore, take the average between the absolute value of the compressive strain along ab and that of the tensile strain along $a'b'$. For practical purposes this is the strain due to a twisting moment Pr and an axial force P since $\cos \alpha$ for closely coiled springs has a value very nearly unity. This value of strain is then used in Equation [4] to determine the shearing stress.

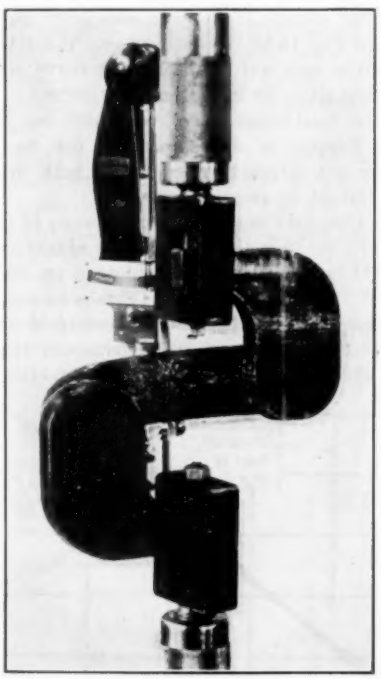

FIG. 10 TEST WITH EXTENSOMETER AT MEAN POSITION

Two semi-coils were made and tested in the following manner. Load was applied to the semi-coils in the testing machine (Fig. 8) up to a maximum of 3000 lb., readings of the extensometer being taken at 500 lb. increments. This load produced a maximum shearing stress in the coil of about 18,000 lb. per sq. in. It was not thought advisable to go to higher loads because of the possible failure of the welded joint and because an excessive pressure might be produced on the point a of the eyebolt (Fig. 7) which had a diameter of only $^{5}/_{16}$ in.

The unit compressive strain along ab (Fig. 6) and the unit tensile strain along $a'b'$ were thus determined by means of the extensometer for each 500-lb. increment of load. In line with the considerations mentioned above, the average value of the compressive strain and the tensile strain was taken as a basis for determining the value of shearing stress at each load. Values of $E = 29 \times 10^6$ lb. per sq. in. and $1/m = 0.3$ were used. The load-stress curves thus obtained for the inside and for the outside of the coil, corresponding to points a' and a (Fig. 1) respectively, are shown in full lines in Figs. 11 and 12, Fig. 11 representing semi-coil 1 and Fig. 12 semi-coil 2.

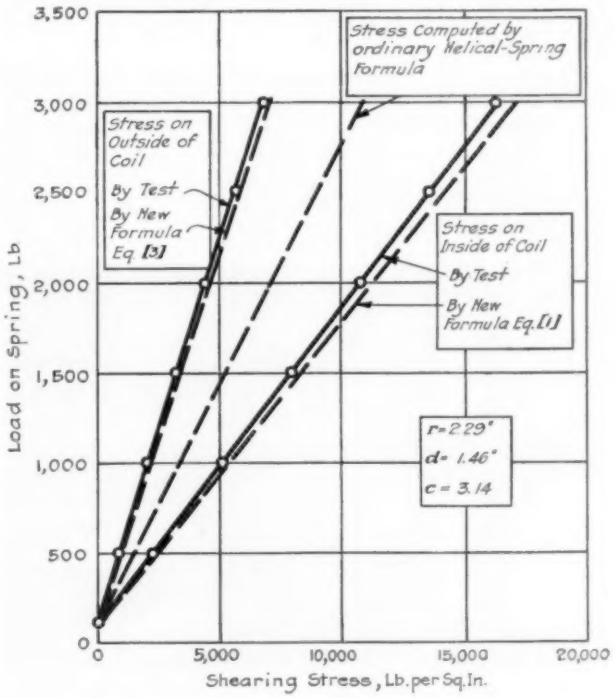

FIG. 11 LOAD-STRESS CURVES FOR SEMI-COIL 1

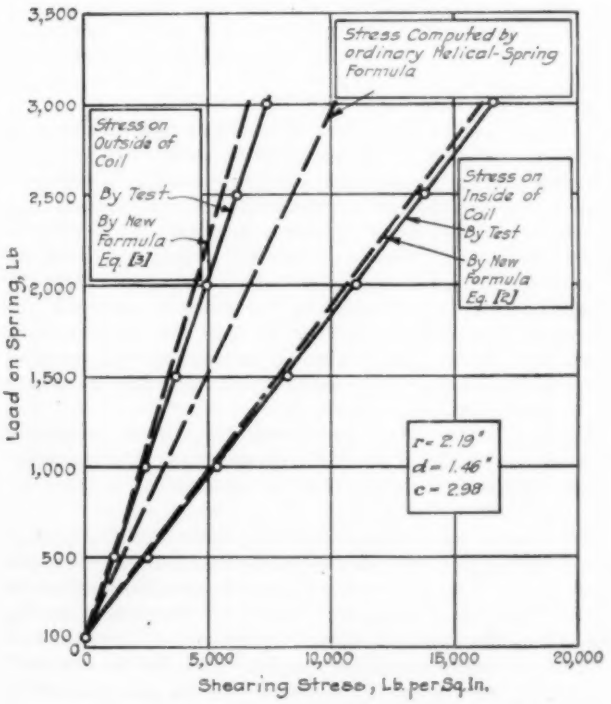

FIG. 12 LOAD-STRESS CURVES FOR SEMI-COIL 2

For comparison with the test load-stress curves, the theoretical load-stress curves computed for the inside of the coil by Equation [2] and for the outside by Equation [3] are shown

by dotted lines. It will be noted that these curves agree within a few per cent with those obtained experimentally. On the other hand, the load-stress curve computed by means of the ordinary helical-spring formula, which curve is also shown dotted, gives approximately a mean value of stress existing between inside and outside of the coil but differs widely from the true value of stress at these points.

For comparison, load-stress curves were taken also with the extensometer in the position of Fig. 10 corresponding to the measurement of stress at point c (Fig. 1). It was found that the stress at this position had approximately a mean value between that on the inside and that on the outside of the coil, and corresponded quite closely with that calculated by the use of the ordinary helical-spring formula.

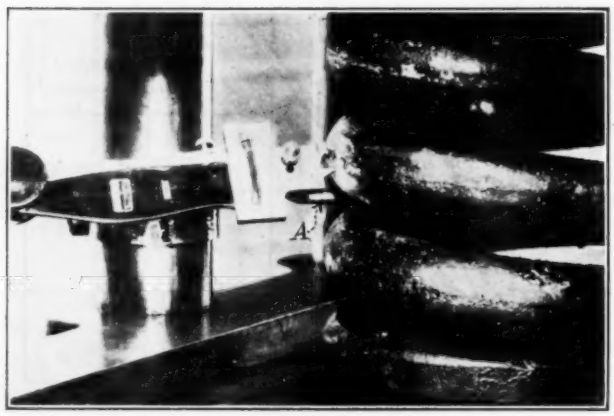

FIG. 13

These tests thus indicate that the true maximum stress in helical springs of this type axially loaded may be determined with sufficient accuracy for practical purposes by Equation [2].

TESTS ON COMPLETE SPRINGS

In order to show that the above-described tests on semi-coils were representative of tests on complete springs axially loaded, a complete spring was tested in compression as shown schematically in Fig. 4*a*. As before extensometers having a 1-cm. gage length were applied at the outside of the coils so as to measure strains at 45 deg. to the axis of the wire, the points of the extensometer having positions represented by the points ab and $a'b'$ (Fig. 4*b*). A photograph showing the spring in position in the testing machine is shown in Fig. 13. Here the clamp A which holds the extensometer in place is shown projecting between the coils of the spring and serves to hold the points firmly against the surface of the coil.

Readings of the extensometer were taken at increments of 1000 lb. up to 10,000 lb. load, corresponding to a maximum shearing stress of about 60,000 lb. per sq. in. on the inside of the coil and 25,000 lb. per sq. in. on the outside.

It was found, as in the case of the semi-coils tested, that because of the helix angle of the coil the tensile strain between the points at a and at b (Fig. 4*b*) was slightly greater than the compressive strain between the points at a' and at b'. To get the shearing stress from the measured strains between a and b and between a' and b' we proceed exactly as was done above for the semi-coils by taking the average of the values of both the compressive strain between a' and b' and the tensile strain between a and b and using this value in Equation [4] with a modulus $E = 29 \times 10^6$ lb. per sq. in. and Poisson's ratio $1/m = 0.3$.

The load-stress curves thus obtained at points a and b (Fig. 4*a*) (which were on opposite sides of the spring) are shown in Fig. 14, the stress at b being slightly larger than that at a. The load-stress curve, computed by Equation [3] for stress on the outside of the coil in a spring loaded axially and using the dimensions given in Fig. 4*a* is shown by the dotted line.

The reason the stress at b is slightly greater than that at a may be explained by the fact that it is almost impossible to load a helical spring exactly centrally because a slight amount of play in the guides of the testing machine and because of irregularities in the flattened ends of the spring. Hence the resultant load P on the spring is not axial but is displaced a slight amount ϵ from the axis as shown in Fig. 4*a*. This loading condition is equivalent to an axial force P and a bending moment $M = P\epsilon$. The axial load P will produce shearing stresses at a and b which may be computed by Equation [3]. In addition, the bending moment $P\epsilon$ will produce a slight stress which may be determined from Equation [3*a*]. This stress will increase the stress at b by a small amount and decrease that at a by an equal amount. To get the value of shear stress due only to the axial load P, we must therefore take the mean value of shear stress at a and b. This was done for each load and the resulting load-stress curve is given on Fig. 15. For comparison the load-stress curve for stress on the outside of the coil, computed using Equation [3], is shown on Fig. 15 by the dotted line. It will be noted that this curve agrees very well with the test curve, and indicates that the formula given by Equation [3] is correct. As a matter of interest the load-stress curve computed by the ordinary helical-spring formula is also shown. It can be clearly seen that while the new formula agrees closely with the test curve, the ordinary formula is greatly in error.

Another fact brought out by an examination of the test load stress curve of Fig. 15 is that it coincides almost exactly up to a load of 3000 lb. with the curve obtained on semi-coil 1 for the outside of the coil (Fig. 11). (This semi-coil had nearly the same values of r and d as did the complete spring.) The coincidence of these curves shows conclusively that the test-arrangement shown in Fig. 8 simulates the condition of a helical

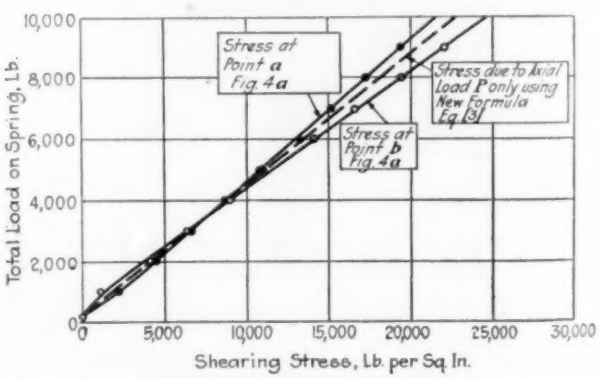

FIG. 14 LOAD-STRESS CURVES ON COMPLETE SPRING LOADED AS IN FIG. 4*a*

spring axially loaded. The important point to note is that had it been possible to take strain measurements along the inside of the complete spring at points a' (Fig. 4*a*), there is every reason to believe that at a given load we would have found the same stress as obtained on the inside of semi-coil 1, that is, a stress from 50 to 60 per cent greater than that computed by the ordinary helical-spring formulas, but in good agreement with the stress computed by Equation [2].

THE PRACTICAL SIGNIFICANCE OF THE NEW FORMULAS

Let us consider what the new formulas given in this paper mean in the practical design of springs. Take, for example,

the case of railway passenger-car springs. These are often designed so that the shearing stress at their working load computed by ordinary helical-spring formula is about 65,000 lb. per sq. in. Applying the more exact formulas given in this paper (see Equation [2]) to the case of these springs which commonly have a ratio of mean coil diameter to wire diameter of 4, we find that the actual shearing stress is 90,000 lb. per sq. in. at the working load. On this stress at the working load may be superimposed a vibratory stress due to a vibrating load which may possibly at times, as when passing over track irregularities, be sufficient to compress the spring nearly solid. These springs are often designed for a shearing stress when compressed solid of 110,000 lb. per sq. in. computed by ordinary formulas, or 155,000 lb. per sq. in. computed by the more exact formulas (Equation [2]). This does not mean that this stress may actually exist in these springs when they are compressed solid, since some yielding of the material at the point of maximum stress may take place and when the load is removed residual stresses of opposite sign will be induced. However, these residual stresses will be such that the range of stress between no load and solid load is approximately 155,000 lb. per sq. in., even if the maximum is not. Since even good spring steel does not have an endurance limit[4] greater than about 60,000 lb. per sq. in. in torsion or a total range of 120,000 lb. per sq. in. it seems not surprising to the writer that these springs so frequently fail in service.

Furthermore, the coil diameter of helical springs is often reduced with the idea of decreasing the stress. The formulas brought out in this paper show that there is a limit to the gain which may be possible by this procedure. For example take the case of a spring where the ratio c of mean coil diameter to wire diameter is 4. By decreasing the coil diameter so that $c = 3$,

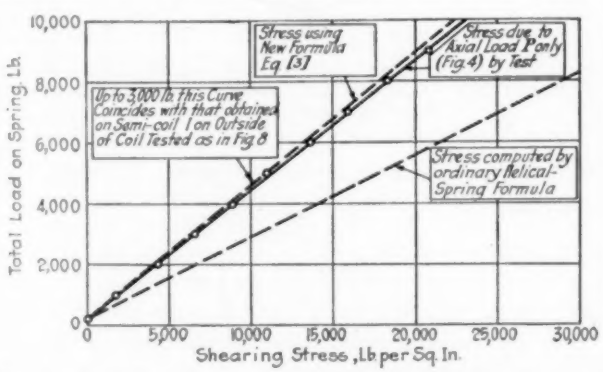

FIG. 15 LOAD-STRESS CURVES FOR COMPLETE SPRING LOADED AS IN FIG. 4*b*

the twisting moment Pr is reduced about 25 per cent but at the same time the stress multiplication factor k is increased about 15 per cent. Consequently the net reduction in stress is not 25 per cent as would be expected using ordinary spring formulas, but considerably less. At the same time, reducing the diameter has the serious disadvantage of greatly reducing the flexibility of the spring, the flexibility being proportional to the cube of the coil diameter.

SUMMARY AND CONCLUSIONS

In this paper it has been shown that the true shearing stress in heavy closely coiled helical springs axially loaded may in many practical cases be from 40 to 60 per cent greater than that calculated by ordinary helical-spring formulas. Certain more exact formulas have been derived for facilitating the practical calculation of maximum shearing stress in springs of this type. These new formulas have been checked by means of strain measurements on semi-coils of actual springs and on full springs loaded in compression.

It should be noted that the new formula herein given applies not only to the calculation of heavy springs having a small ratio c of mean coil diameter to wire diameter, but also to light springs where the value of c is large. In any case the new formula applies with greater accuracy than the ordinary helical-spring formula; however, where the ratio of diameters c is greater than 6, the ordinary formula is accurate within 25 per cent as may be seen by reference to the curve of Fig. 2.

Since these new formulas have been thus shown to be correct, it is the writer's opinion that they should be applied in the practical design of helical springs of this type. It is also the writer's belief that the frequent failures of heavy helical springs may at least in part be explained by the existence of much greater stresses than thought possible, on the basis of ordinary spring theory.

The writer desires to thank Drs. Timoshenko and Nadai and other Westinghouse engineers for the suggestions made.

Appendix

DERIVATION OF FORMULAS FOR STRESS IN A HEAVY CLOSELY COILED HELICAL SPRING

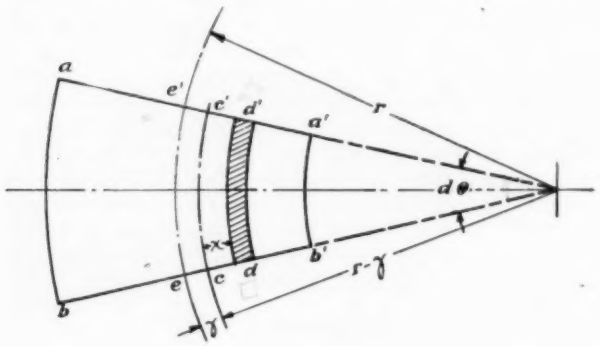
This derivation[5] is based on several assumptions which are not rigidly correct, but which, it is believed, will give results accurate enough for practical purposes.

In the first place, since the springs with which we are dealing are closely coiled, it will be sufficiently accurate to assume that the helix angle of the spring is zero. Furthermore it may be shown that a change in slope from zero to 10 deg. does not change the resulting maximum shear stress more than a few per cent.

Consider an element of an axially loaded helical spring (Fig. 16). This element is formed by two neighboring cross-sections aa' and bb' and having a mean radius of curvature r.

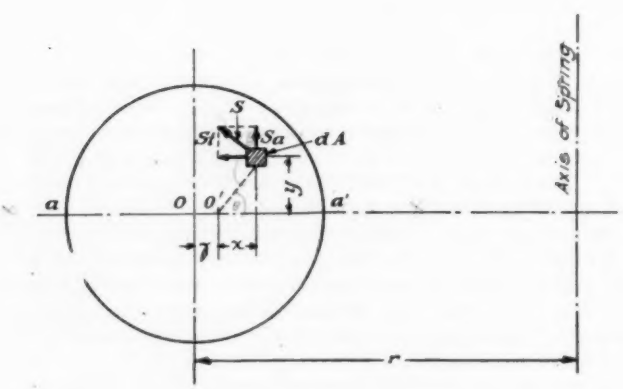
In a closely coiled helical spring axially loaded, we may resolve the forces acting on this element into a twisting moment $M = Pr$ acting in a radial plane and a direct axial shearing force P. We will consider first the stresses set up by this twisting moment, and on these will later superimpose the stresses due to the direct shear load P.

Under the action of this twisting moment M the two cross-sections aa' and bb' (Fig. 16) rotate with respect to each other, through a small angle $d\alpha$. Since the length of the fiber ab is much greater than the length of the fiber $a'b'$, the shearing deformation per unit length of the fiber $a'b'$ will be greater than that existing in the fiber ab. Hence the stress in the fiber ab will be less than that in the fiber $a'b'$.



We now consider the shear stresses S acting over the cross section to be divided into two components, one, which we denote by S_a, in a direction parallel to the axis of the spring and the other, which we denote by S_t, in a direction perpendicular to the axis of the spring (Fig. 16*b*).

If we assume that the two neighboring cross-sections aa' and bb' rotate relative to each other and about an axis ee' perpendicular to their surfaces and passing through their centers O,



[4] See "The Fatigue of Metals," by H. J. Gough, p. 169, and University of Illinois Bulletin No. 142, Engineering Experiment Station, by H. F. Moore and T. M. Jasper, p. 49, for data on endurance limits in torsion for high-carbon and nickel-chromium steels which are commonly used for springs.

[5] The approximate solution of this problem here given differs in several particulars from an approximate derivation given by A. Röver, "Beanspruchung Zylindrische Schraubenfederr mit Kreisquerschnitt," Zeitschrift des Vereines deutscher Ingenieur, 1913, p. 1907. The final result is also different but agrees within 0.7 per cent with the results of a more exact but very complicated solution worked out by Röver for the particular case of a spring where the ratio c of mean coil diameter to wire diameter was 4.

the distribution of the axial components of stress S_t over the cross-section will be somewhat as shown by the shaded area of Fig. 17. It is clear that since we are considering only the effects of a twisting moment M this stress distribution would be impossible, since the area to the right of O is greater than that to the left of O and hence a resultant external force is produced. However, if we assume that rotation occurs about some point O' (Fig. 3) displaced toward the axis of the spring, instead of about point O, we obtain a stress distribution which consists of a pure couple only and which may be in statical equilibrium under the action of the moment M. From considerations of

(a)

(b)

FIG. 16

symmetry the transverse stress components S_t will be in statical equilibrium when rotation occurs about any point on the axis xx. We now determine the point O' as follows.

Under the assumption of rotation about O' the stress S acting on any element dA (Fig. 16*b*) having the coordinates x and y may easily be found. When the sections aa' and bb' have rotated through an angle $d\alpha$ with respect to each other, the relative movement of the ends of the filament dd' corresponding to the element dA will be $d\alpha\sqrt{x^2+y^2}$ and since the length of the filament is $(r-\gamma-x)d\theta$, the shearing stress S acting on this element will be:

$$S = \frac{Gd\alpha\sqrt{x^2+y^2}}{(r-\gamma-x)d\theta} \quad \ldots\ldots [5]$$

The axial components Sa of the stress S will be (Fig. 16*b*), using Equation [5]

$$S_a = S\frac{x}{\sqrt{x^2+y^2}} = \frac{xGd\alpha}{(r-\gamma-x)d\theta} \quad \ldots\ldots [6]$$

Since y does not appear in this equation the values of S_a depend only on the value of x and are independent of the value of y. This equation is identical with the equation of stress distribution in a curved bar[6] and the distribution of the components S_a is hyperbolic. We may, therefore, apply curved-bar theory to this problem. The distance γ must be determined as in curved-bar theory so that the integral of $S_a dA$ taken over the cross-section is zero. For γ we use the known approximation:[7]

$$\gamma = \frac{d^2}{16r}\left(\frac{1}{1+\frac{d^2}{16r^2}}\right) \approx \frac{d^2}{16r} \quad \ldots\ldots [7]$$

We neglect $\frac{d^2}{16r^2}$ since $\frac{d}{2r}$ is seldom greater than $\frac{1}{3}$ in practical

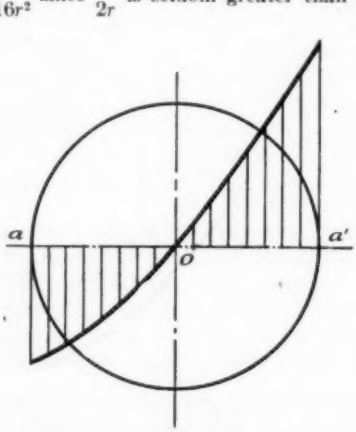


FIG. 17 SHEARING-STRESS DISTRIBUTION ALONG A TRANSVERSE DIAMETER a-a' ASSUMING ROTATION ABOUT THE CENTER POINT O OF THE CROSS-SECTION

cases; hence, $\frac{d^2}{16r^2}$ is small compared to unity. Putting [7] in [6] we get:

$$S_a = \frac{xGd\alpha}{\left(r-\frac{d^2}{16r}-x\right)d\theta} \quad \ldots\ldots [8]$$

From the ordinary formula for angle of twist of circular sections, the value of $d\alpha$ is:

$$d\alpha = \frac{32Mrd\theta}{G\pi d^4} \quad \ldots\ldots [9]$$

Putting this in [8] we get:

$$S_a = \frac{32xMr}{\pi d^4\left(r-\frac{d^2}{16r}-x\right)} \quad \ldots\ldots [10]$$

It is clear that the maximum value of S_a will occur when $x = \frac{d}{2}-\frac{d^2}{16r}$ that is, at point a' Fig. 16.

Putting this value in [10] and also putting $c = 2r/d$ we get:

$$S'_{a1} = \frac{16M}{\pi d^3}\left(\frac{4c-1}{4c-4}\right) \quad \ldots\ldots [11]$$

[6] See for example "Applied Elasticity," Timoshenko and Leasells, p. 217.

[7] *Loc. cit.*, Equation [216], p. 224.

Likewise the stress at point a (Fig. 16) will be (putting $x = -\frac{d}{2} - \frac{d^2}{16r}$ in [10] and taking $c = \frac{2r}{d}$)

$$S'_{a2} = \frac{16M}{\pi d^3}\left(\frac{4c+1}{4c+4}\right) \quad [12]$$

We here take the absolute value of S'_{a2}, in other words, we drop the negative sign, which signifies merely that the direction of the stress S'_{a2} is opposite to that of S'_{a1}.

These are the shearing stresses which would be produced by a pure bending moment M acting on the spring as in Fig. 1*b*.

In the case of an axial load P acting on the spring we may, as mentioned above, replace the external forces acting over the cross-section of Fig. 3 by a twisting moment $M = Pr$ and a direct shear force P. The stress, due to the moment M, may be found by substituting $M = Pr$ in Equations [11] and [12]. We then obtain:

$$S''_{a1} = \frac{16\,Pr}{\pi d^3}\left(\frac{4c-1}{4c-4}\right) \quad [13]$$

$$S''_{a2} = \frac{16\,Pr}{\pi d^3}\left(\frac{4c+1}{4c+4}\right) \quad [14]$$

S''_{a1} and S''_{a2} are thus the shear stresses at points a' and a (Fig. 3), respectively, due only to the twisting moment. On these we must superimpose the shearing stress at a and a' due to the axial shear load P (Fig. 3). For this purpose we may use the value given by the theory of elasticity of shearing stress at the outer edges of the neutral surface of cantilever having a circular cross-section of diameter d and loaded with a load P. This exact value is[8] $\frac{1.23\,P}{\pi d^2/4}$. In this connection we note that this shear stress acts in the same direction as the stress S''_{a1} but in an opposite direction to the stress S''_{a2}. We therefore add and subtract this value to Equations [13] and [14] respectively, to obtain the true resultant values of stress at a' and a. The maximum stress at a' then becomes:

$$S_{a1} = \frac{16\,Pr}{\pi d^3}\left(\frac{4c-1}{4c-4} + \frac{0.615}{c}\right) \quad [15]$$

while the stress at a is:

$$S_{a2} = \frac{16\,Pr}{\pi d^3}\left(\frac{4c+1}{4c+4} - \frac{0.615}{c}\right) \quad [16]$$

Discussion

R. Eksergian.[9] The author is to be congratulated on a very interesting analysis and carefully conducted experimental verification of the nature of stress concentration in helical springs.

From an examination of the upper diagram of Fig. 1, we might anticipate with a relative rotation of sections $a - a'$ and $b - b'$, that a necessarily greater shear must take place along the inner edge, and this condition will increase with a smaller radius of helix and larger wire diameter. The condition would suggest the analogy to the bending action of a curved bar and corresponding stress concentration at the inner edge.

The ingenious feature of the analysis is Equation [6] and the recognition that this equation is identical in form to the equation for the tensile stress in a curved beam. The location of the offset center of rotation corresponding to the neutral axis of a curved beam follows in a way analogous to the curved-beam theory, because, since we have pure torsion, the small vertical shear being superimposed later, the summation of the vertical components of the shear is nil. That is,

$$\int S_a dA = \frac{Gd\alpha}{d\theta}\int \frac{x}{r'-x}\,dA = 0$$

where $r' = r - \gamma$ = the radius to the neutral axis.

It is interesting to compare the similarity of the equations for bending of a curved beam and for torsion of a curved wire. In both cases we assume plane sections to remain plane after bending and torsion, respectively. If $\Delta d\phi$ is the change in angle for a slice of a beam subtending an angle $d\phi$, x is the distance from the neutral axis, and r' its radius from the initial center of curvature, then for a curved beam we have:

$$\int p dA = \frac{E\,\Delta d\phi}{d\phi}\int \frac{x dA}{r'-x} = 0 \quad [17]$$

$$\int py dA = \frac{E\,\Delta d\phi}{d\phi}\int \frac{x^2 dA}{r'-x} = M_b \quad [18]$$

From [17] we may obtain r' or r, which substituted in [18] permits us to solve for $E\frac{\Delta d\phi}{d\phi}$, and thus we may determine the stress, since

$$p = E\frac{\Delta d\phi}{d\phi}\frac{x}{r'-x}$$

For the torsion of a curved wire, we have approximately:

$$S = \frac{Gd\alpha}{d\theta}\frac{\sqrt{x^2+y^2}}{r'-x}$$

with radial and tangential components

$$S_r = -\frac{Gd\alpha}{d\theta}\frac{y}{r'-x}$$

and

$$S_t = S_a\frac{Gd\alpha}{d\theta}\frac{x}{r'-x}$$

The corresponding equations are:

$$\int S_t dA = \frac{Gd\alpha}{d\theta}\int \frac{x}{r'-x}\,dA = 0 \quad [17a]$$

$$\int (S_t x + S_r y)\,dA = \frac{Gd\alpha}{d\theta}\int\left(\frac{x^2}{r'-x} + \frac{y^2}{r'-x}\right)dA = M_t \quad [18a]$$

Substituting r' from [17*a*] in [18*a*], we obtain $\frac{Gd\alpha}{d\theta}$ and thence the corresponding torsional shear.

The location of the neutral axis follows from the solution of the integral

$$\int \frac{x}{r'-x}\,dA = 0$$

so that we may use the solutions already worked up for the ordinary curved-beam theory.

Comparing Equation [18*a*] with Equation [18], we note an additional term in the integral, so that the evaluation of $\frac{Gd\alpha}{d\theta}$

[8] This value may be derived using the formulas given by Love, "The Mathematical Theory of Elasticity," chapter XV.

[9] Engineer, Baldwin Locomotive Works, Philadelphia, Pa. Mem. A.S.M.E.

for torsion is more complicated than the evaluation of $\frac{E\,\Delta d\phi}{d\phi}$ for bending.

A considerable simplification has been made by the author in Equation [9] by assuming the angle of twist of adjacent sections to be approximately the same as if the neutral axis were at the center. This assumption is apparently justified by the close experimental verification.

Thus, to recapitulate, the two simplifying assumptions the author has made which differ from a more rigid analysis are (1) plane sections remain plane in torsion and (2) the effect of the small shift of neutral center from geometric center of wire for ordinary proportions of springs permits the assumption of calculating the angle of torsion from the simple torsion formula for round wires.

In considering the experimental phase of this work the problem resolves itself to measure the diagonal tensile and compressive stresses (which are numerically equal to the shear stresses) for a differential cube at the inner and outer portions of the

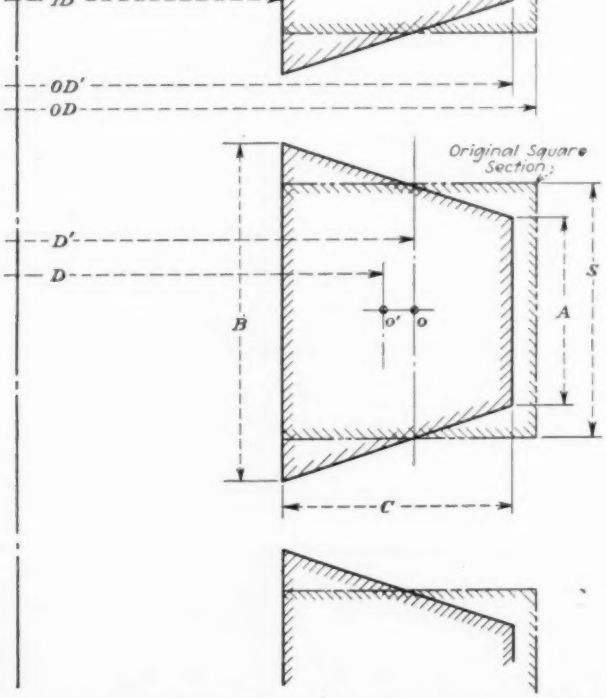

FIG. 18 DEFORMATION IN HELICAL SPRING MADE OF SQUARE WIRE

wire of the helix. Obviously, the choice of a small gage length is desirable, since with increasing gage lengths serious errors due to curvature and variation of stress would vitiate the results. On the other hand, the smallest satisfactory measurement experienced by the writer of a mechanical strain gage appears around 0.00005 in. With a 2-in. gage length, the stress can be measured to 750 lb. per sq. in., with a 1-in. gage length to 1500 lb. per sq. in., and with a half-inch gage length to 3000 lb. per sq. in. Of course, by interpolations and repeated workings, a closer accuracy could undoubtedly be obtained. The selection of an inch gage length would seem to the writer to place a limitation of 1000 lb. per sq. in. minimum error for the gage readings. With workings at 18,000 lb. per sq. in., this introduces an error of approximately 5 per cent, due to the instrument readings.

Another factor is the proper value of Poisson's ratio. In comparing the ratios of inner and outer stresses, this factor would not be so important.

The simplest procedure of increasing the accuracy of the experimental work is to operate with much larger stresses. This incidentally would be a very good test for a welded joint for the extension arms.

On the whole, this paper is a very creditable piece of work. The paper moreover represents a procedure that should be very much encouraged and that is a sufficient approximation in an analysis combined with experimental verification, and finally the boiling down of the work to suitable design formulas.

The formulas and tables suggested should be incorporated in the A.S.M.E. Spring Code, since the results appear sufficiently accurate for the proportions used in ordinary spring proportions.

T. C. RATHBONE.[10] The author's analysis of maximum stresses in helical springs and his substantiation of theory by actual experiment leave no other alternative than to accept the fact that the usual spring formulas are inadequate. His correction to be applied to the usual formulas is so simple and direct that it may well be adopted in future handbooks and textbooks.

It would be interesting to learn how this correction applies to such springs of square section. When closely coiled springs are made of square wire, a considerable deformation occurs, the section becoming trapezoidal, as shown in Fig. 18. The inner side is widened while the outer side is shortened. As the maximum stress occurs on the inside of the coil, the widening from deformation may, partially at least, prevent the unequal stress distribution as shown for round wire in Fig. 3, and thus lessen the correction to be applied.

M. STONE.[11] The question of the action of a closely coiled spring has always been the subject of analyses and researches concerning deflection characteristics, elastic characteristics, stress distributions, failures under various types of loading, and similar problems. Nevertheless, the action of this important mechanical element is not completely known. Such considerations have included variation of pitch angle, ratio of wire diameter to coil diameter, ratio of height of coil to coil diameter, lateral stability, type of wire section, and allied considerations.

The author's thesis is one that has been attracting the attention of engineers and designers of heavy coil springs for locomotive suspension, shock absorbers, and the like for some few years. The recognition of a hyperbolic distribution of shear stress in coil springs was first made by A. Röver,[12] although some consideration of stress distribution in closely coiled springs was made earlier by Siebeck, also in Germany, Röver worked out an approximate analysis of the problem, and justified his assumptions by giving a rigorous solution from the mathematical theory of elasticity. His work must be considered for its full worth, and particularly must he be credited with the recognition of the problem, which is in the nature of a major advance in thinking on the subject.

Mr. Wahl's experimental verification of the existence and quantitative measurements of the Röver distribution of shear stress is a valuable extension of the subject. Such work brings the more theoretical consideration out of the realm of hypothesis into the field of reality, and forces it to the attention of designing

engineers. The tests are ingeniously devised, the use of the Heaggenberger extensometers demonstrating the value of such instruments.

A more practical and perhaps a more important test of the existence of high stress concentrations on the inside of the coil springs would be to subject such springs to fatigue loading, placing the spring in a Haigh fatigue machine, or some more suitably designed apparatus. Any high stress always shows up in a fatigue test; at the same time, the test would give some definite information on how highly we may stress the springs. It must be recognized that a knowledge of the stress distribution and that of failure are ideas not always simply connected. Complexity is introduced in *this* problem immediately when it is seen that although the high shear-stress values are on planes perpendicular to the axis of the wire, the spring failure that Mr. Wahl shows in Fig. 1c occurs on a plane 45 deg. to the axis. There are many other similar instances.

In the appendix, Mr. Wahl has derived an expression for the stress at the inner and outer fiber. His approximate method differs somewhat from that given by Röver, but the results are close. In any approximate method, it is always a question of what are the conservative assumptions. In the author's transition from Equation [8] to [10] he uses Equation [9] which is derived for straight bars under twist. To maintain consistency, the similar expression derived from consideration of the curved bar should be used. This becomes, when we realize that the stresses integrated over the cross-section around the center of twist must balance the external moment,

$$M = \int\int S\sqrt{x^2 + y^2}\,dx\,dy$$

$$= \frac{Gd\alpha}{d\theta}\int_{-\frac{d}{2}-\gamma}^{\frac{d}{2}-\gamma}\int_{-\sqrt{\frac{d^2}{4}-(\gamma+x)^2}}^{+\sqrt{\frac{d^2}{4}-(\gamma+x)^2}} \frac{x^2+y^2}{r-\gamma-x}\,dx\,dy$$

The integration of this will give an expression similar to that of [9] but which may depart by more than 5 per cent for certain values of c.

Although all derivations have been carried through with the pitch angle assumed to be zero, any departure from this will increase the magnitude of the stresses. For a ratio of $\frac{d}{2r} = \frac{1}{3}$, the pitch of the helix can be no less than $\tan^{-1} 0.17 = 10$ deg., and in Röver's original work, this corresponds to an increase in stress of about 10 per cent. It is significant to note, however, that the stress never exceeds more than 25 per cent, even for what we ordinarily call "open coil springs."

Joseph K. Wood.[13] This paper is one of the most valuable contributions made in recent years to the mechanical-spring art. In this instance, the testing specialist has been called in and he has successfully diagnosed what might be called the spring-index ill of the art. The situation regarding the spring index (ratio of mean coil diameter to bar diameter) previous to the presentation of Mr. Wahl's paper, was as follows:

a It was known for many years that springs with low indexes were stressed considerably beyond the calculated values due to such causes as the relative increase in vertical shear. For example, it has been known that vertical shear in a helical spring having an index of 3 is equal to 16 per cent of the regular torsional shear, while in a spring having an index of 8 the vertical shear is equal to only 6 per cent of the torsional shear. This increase in stress, however, was insufficient to account for breakages obtained in service, and consequently it has been considered good practice to avoid indexes in design less than 5, and preferably 7. In cases where low indexes have been unavoidable, due to space and other limitations, the best practice has been to use low stresses as calculated by the usual formula, but never as high as 65,000 lb.

b The complete solution of the "index" problem has been delayed for two reasons, namely, the limited use of the advanced theory of elasticity in this country, and to the lack of adequate testing equipment for the confirmation of the theory. It might be opportune at this point, to suggest the adoption of a regular course on the advanced theory of elasticity by the various technical universities throughout the country. Regarding the theoretical solution of the "index" problem, A. Röver in 1913 accomplished this important task by a slightly different and somewhat more direct method than that described in Wahl's paper. Röver obtained practically the same curve illustrated in Fig. 2 of Wahl's paper, which gives the relation between the index c and the stress multiplication factor k.

It took a period of 15 years since the publication of Röver's results, to produce a testing genius like Wahl to prove the truth of Röver's theoretically deduced curve, by the proper set-up of equipment. The results of this research are particularly gratifying to the writer because they represent a response to an appeal made by him in his paper "A Code of Design for Mechanical Springs" several years ago, to the effect that the constants in the present spring formulas be more accurately determined. To quote from this paper, "the entire question of whether the constants in the present spring formulas are sufficiently accurate in all cases, is in need of considerable research."

Wahl's derivation of the new formulas, differing in certain respects from Röver's, gives an expression for k dissimilar in the arrangement of the terms, but with both yielding practically the same calculated results.

The discovery which led to the solution of the "index" problem, and which is the basic assumption in the derivation of the new formula, was that for a given angle of twist the fiber on the extreme inner side of the coil is very much shorter than the fiber on the extreme outer side of the coil, which gives rise to differences of appreciable magnitude in the unit deformations for those fibers. Röver deserves full credit for this discovery and for the resulting formula. It required experimental confirmation of Röver's work, however, to provide that confidence which industry requires for the practical application of new formulas. Wahl without question has provided the required experimental proof of Röver's results. In attempting to improve upon Röver's derivation of a formula, Wahl resorts to the indirect use of the flexural curved-beam formula to overcome certain mathematical difficulties. From a mathematical point of view this is perfectly proper, but in the average case, something is likely to be lost in the process from the physical point of view. For example, it is conceivable that the flexural curved beam could be in error, so far as physical concepts are concerned. Apparently Wahl's difficulty was encountered when he attempted to obtain an expression for the amount of offset of the neutral axis from the geometrical axis of the wire. Röver ignored this offset, and consequently was in error, but only to a relatively small extent since Wahl obtains practically the same result as he does. Wahl differs with Röver in the evaluation of pure vertical shear, the former using 1.23 of the vertical load. The writer does not agree with Röver on this point and until Love's value of 1.23 is confirmed by experiment, fails to see why this value should be used in preference to unity.

Since neither Röver nor Wahl have provided the deflection formula on the basis of the former's discovery, the writer will

[13] Consulting Engineer, New York, N. Y. Assoc-Mem. A.S.M.E. Chairman, A.S.M.E. Special Research Committee on Mechanical Springs.

endeavor to make this derivation. Before making this derivation, however, a simplified derivation of the stress formula will be given somewhat along the lines first laid down by Röver.

According to old and well-established principles we have by definition:

$$G = \frac{\text{stress}}{\text{strain}} = \frac{S}{\epsilon}$$

or

$$S = \epsilon G \quad \ldots\ldots [19]$$

Referring to Fig. 19

$$\epsilon = \frac{\delta\alpha d}{2}\frac{1}{\delta z_0} = \frac{d}{2}\frac{\delta\alpha}{\delta z_0} \quad \ldots\ldots [20]$$

Now for small strip δz_0,

$$S_{s0} = \frac{d}{2}\frac{\delta\alpha}{\delta z_0} G = \frac{d}{2}\frac{Pr}{J}$$

whence

$$G = \frac{\delta z_0}{\delta\alpha}\frac{Pr}{J} \quad \ldots\ldots [21]$$

Also for small strip δz (neglecting pure vertical shear)

$$S_s = \frac{d}{2}\frac{\delta\alpha}{\delta z} G \quad \ldots\ldots [22]$$

Now simply impose upon Formula [22] the new condition $\delta_s = \delta z_0 \frac{r-x}{r}$ obtained geometrically from Fig. 19

$$S_s = \frac{d}{2}\frac{\delta\alpha}{\delta z_0}\frac{r}{r-x} G \quad \ldots\ldots [23]$$

and substituting G from [21] we get

$$S_s = \frac{d}{2}\frac{\delta\alpha}{\delta z_0}\frac{r}{r-x}\frac{\delta z_0}{\delta\alpha}\frac{Pr}{J} = \frac{d}{2}\frac{r}{r-x}\frac{Pr}{J} \quad \ldots\ldots [24]$$

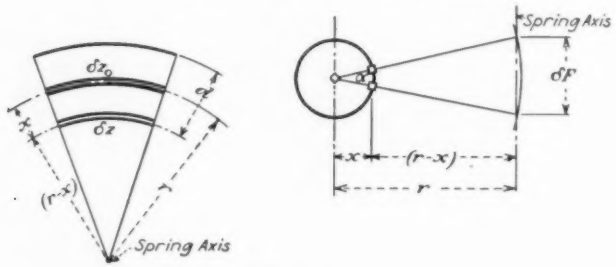

FIG. 19

Now to obtain maximum stress at z the direct vertical shear must be added to [24]

$$S_s = \frac{d}{2}\frac{r}{r-x}\frac{Pr}{J} + \frac{4P}{\pi d^2} \quad \ldots\ldots [25]$$

Reducing and substituting the value of $J = \frac{\pi d^4}{32}$ and $x = \frac{d}{2}$ (approximate) we get

$$S_{s(\max.)} = \frac{16\,Pr}{\pi d^3}\left(\frac{c}{c-1} + \frac{1}{2c}\right) \quad \ldots\ldots [26]$$

in which

$$c = \frac{2r}{d}.$$

According to this derivation, the calculated value of $k = \left(\frac{c}{c-1} + \frac{1}{2c}\right)$ is practically equal to Röver's or Wahl's value of k, the slight difference in each case being due to the value of the vertical shear loads used.

Derivation of Deflection Formula

By definition

$$G = \frac{\text{stress}}{\text{strain}} = \frac{S}{\epsilon}$$

Considering strip δz where stress is maximum we have

$$\epsilon_s = \frac{d}{2}\frac{\delta\alpha}{\delta z} \text{ (approximately)} \quad \ldots\ldots [27]$$

and since

$$\delta z = \delta z_0 \frac{r-x}{r}$$

$$\epsilon z = \frac{d}{2}\frac{\delta\alpha}{\delta z_0}\frac{r}{r-x} \quad \ldots\ldots [28]$$

Substituting $\delta\alpha = \frac{\delta F}{r}$ and $\frac{\delta F}{\delta z_0} = \frac{F}{l}$, we get

$$\epsilon z = \frac{d}{2}\frac{F}{rl}\frac{r}{r-x} \quad \ldots\ldots [29]$$

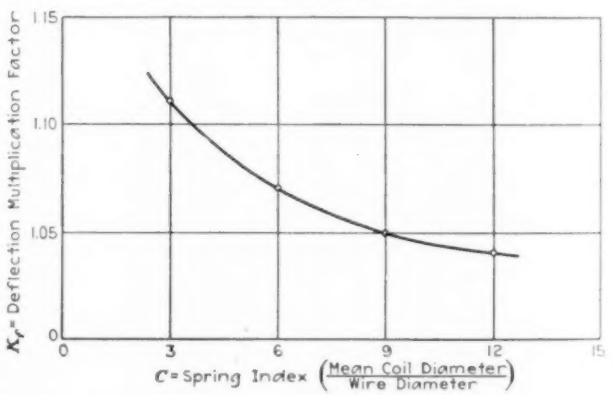

FIG. 20 CURVE FOR DETERMINING THE DEFLECTION MULTIPLICATION FACTOR K_f

Now,

$$S_s = \frac{d}{2}\frac{r}{r-x}\frac{Pr}{J} + \frac{4P}{\pi d^2} \text{ (approximately)} \quad \ldots\ldots [30]$$

therefore,

$$G = \frac{S_s}{\epsilon_s} = \left(\frac{d}{2}\frac{r}{r-x}\frac{Pr}{J} + \frac{4P}{\pi d^2}\right) \times \left(\frac{2}{d}\frac{rl}{F} \times \frac{r-x}{r}\right)$$

$$= \frac{Pr^2 l}{FJ} + \frac{8Prl}{\pi F d^3} \times \frac{r-x}{r} \quad \ldots\ldots [31]$$

Substituting $J = \frac{\pi d^4}{32}$ in [31] we get,

$$G = \frac{32Pr^2 l}{\pi F d^4} + \frac{8Prl}{\pi F d^3} \times \frac{r-x}{r} \quad \ldots\ldots [32]$$

or deflection

$$F = \frac{32Pr^2 l}{\pi G d^4}\left(1 + \frac{d}{4r} \times \frac{r-x}{r}\right) \quad \ldots\ldots [33]$$

Letting $x = \frac{d}{2}$ (approximate) and $\frac{2r}{d} = c$ we get

$$F = \frac{32Pr^2l}{\pi Gd^4}\left(\frac{2c^2+c-1}{2c^2}\right) \quad \ldots\ldots\ldots\ldots\ldots [34]$$

Calling $\left(\frac{2c^2+c-1}{2c^2}\right)$ the deflection multiplication factor K_f the curve in Fig. 20 of this discussion has been plotted in much the same manner as was done for the stress multiplication factor k. This correction factor for the deflection formula gives slightly larger deflections than those calculated by the old formula, a result which is somewhat unexpected. The writer hopes that Wahl will give the same attention to the deflection formula as he has to the stress formula by making appropriate tests to prove or disprove the writer's theoretical deductions.

Attention is drawn to Wahl's use of fatigue endurance limit in his discussion of this problem. It is the writer's opinion that the regular torsional endurance limit should not be applied to this problem until further research is made to determine actual endurance limits for the type of stress gradient involved.

W. M. Austin.[14] The writer has made several attempts to solve the helical-spring problem by the general method employed by the author. He has worked with both polar and rectangular coordinates. With rectangular coordinates he found an equation connecting the author's value γ, the radius of the wire, and the mean radius of the coil. This equation represented a very complicated surface. By dividing through by the mean radius he got an equation of two variables, one of which was the radius of wire divided by coil radius and the other was the author's γ divided by the wire radius.

The equation was still so involved that it took several hours to establish, by cut and try methods, one point on the curve. He finally abandoned this method of attack for the more general, but in this case simpler, method outlined in the following.

Let a force W act along the axis of a helical spring whose mean radius is r and wound of wire of radius a. (See Fig. 21.) Let CC be a line perpendicular to the axis of the spring and intersecting the axis of the wire at o. At some point g on CC the stress due to the force W is zero. This point is at o, or nearer the axis of the spring than o, or farther from the axis than o. I have drawn it farther from the axis mainly because that is the way the solution results, that is e is $+$.

The equation to the circle Fig. 21 of radius a referred to point Q as origin, the axis of the spring as the y-axis and line CC as the x-axis, is $(x-r)^2 + y^2 = a^2$

or

$$y = \pm\sqrt{a^2-(x-r)^2}.$$

The moment of inertia about g of the area of a thin section of the wire between two planes intersecting in the axis of the spring, each elementary area being divided by the ratio which its thickness bears to the thinnest part of the section, is

$$MI = (r-a)\int\frac{(x-r-e)^2+y^2}{x}\,dX\,dy \ldots\ldots [35]$$

The limits of y are $+\sqrt{a^2-(x-r)^2}$
and $-\sqrt{a^2-(x-r)^2}$
The limits of x are $r+a$
and $r-a$

$$MI = 2\pi(r-a)\left[\frac{2}{3}r^3 + e^2r + 2er^2 - a^2e - \sqrt{r^2-a^2}\left(\frac{2}{3}r^2 + e^2 + 2er + \frac{1}{3}a^2\right)\right] \ldots\ldots [36]$$

[14] Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

The section modulus is

$$\frac{2\pi(r-a)}{a+e}\left[\frac{2}{3}r^3 + e^2r + 2er^2 - a^2e - \sqrt{r^2-a^2}\left(\frac{2}{3}r^3 + e^2 + 2er + \frac{1}{3}a^2\right)\right] \ldots\ldots [37]$$

If S = the maximum shearing stress, the torsional moment is

$$\frac{2\pi S(r-a)}{a+e}\left[\frac{2}{3}r^3 + e^2r + 2er^2 - a^2e - \sqrt{r^2-a^2}\left(\frac{2}{3}r^2 + e^2 + 2er + \frac{1}{3}a^2\right)\right] = (r+e)W \ldots [38]$$

$$W = \frac{2\pi S(r-a)}{(a+e)(r+e)}\left[\frac{2}{3}r^3 + e^2r + 2er^2 - a^2e - \sqrt{r^2-a^2}\left(\frac{2}{3}r^2 + e^2 + 2er + \frac{1}{3}a^2\right)\right] \ldots\ldots [39]$$

Now let us take the axial component of the stress of expression [35]. We have

$$\frac{S(r-a)}{a+e}\int\frac{(x-r-e)}{x}\,dxdy + W = 0$$

using the same limits as in expression [35] we have

$$\frac{2\pi S(r-a)}{a+e}\left[-\left(r^2+re-\frac{a^2}{2}\right) + (r+e)\sqrt{r^2-a^2} + W = 0\right] \ldots\ldots [40]$$

Substituting for W its value in [39] and dividing the equation by

$$\frac{2\pi S(r-a)}{(a+e)(r+e)}$$

and simplifying we get

$$e = \frac{\frac{2}{3}(r^2-a^2)^{3/2} + a^2r - 2/3\,r^3}{a^2} \ldots\ldots [41]$$

let $e/a = u$ and $a/r = V$ and Equation [41] reduces to

$$u = \frac{2}{3}\left(\frac{1}{v^2}-1\right)^{3/2} + \frac{1}{v} - \frac{2}{3v^3}$$

$$u = \frac{1}{4}v + \frac{1}{24}v^3 + \frac{1}{64}v^5 + \frac{1}{128}v^7 + \ldots\ldots [42]$$

giving to v the values

$$\text{if } v = \frac{1}{2}, \frac{1}{3}, \frac{1}{4}, \frac{1}{5}, \frac{1}{6}, \frac{1}{8}, \text{ and } \frac{1}{10}$$

$u = 0.1308, 0.0849, 0.0632, 0.0504, 0.0418, 0.0313, 0.0257.$

If we divide the second member of Equation [39] by r^2 and multiply it by a^2/v^2 we get

$$W = \frac{2\pi Sa^2(1-v)}{2v^2(1+uv)(1+v)}\left[(1-\sqrt{1-v^2})\left(\frac{2}{3}+u^2v^2+2uv\right) - uv^3 - \frac{1v^2}{3}\sqrt{1-v^2}\right] \ldots\ldots [43]$$

let $d = 2a$

$$W = \frac{\pi d^2S(1-v)}{2v^2(1+uv)(1+v)}\left[(1-\sqrt{1-v^2})\left(\frac{2}{3}+u^2v^2+2uv\right) - uv^3 - \frac{1}{3}V^2\sqrt{1-v^2}\right] \ldots\ldots [44]$$

The expression

$$\frac{\pi(1-v)}{2v^2(1+uv)\,(1+v)}\left[(1-\sqrt{1-v^2})\left(\frac{2}{3}+u^2v^2+2uv\right)-uv^3-\frac{1}{3}\,v^2\,\sqrt{1-v^2}\right]$$

can be reduced to

$$\pi\left[\frac{1}{8}\,v-\frac{1}{4}\,v^2+\frac{59}{192}\,v^3-\frac{35}{96}\,v^4+\frac{115}{256}\,v^5-\frac{205}{384}\,v^6+\frac{4969}{9216}\,v^7-\frac{5036}{9216}\,v^8+\ldots\ldots\right]\ldots[45]$$

by expanding $\sqrt{1-v^2}$, substituting for u its value in [42] and dividing by the denominator.

Tables and curves can be made up for the expression [45] for many values of v. Then all that will be necessary in calculating the safe load on a spring is to get v by dividing the diameter of the wire by the mean diameter ($2r$) of the coil; get the value of [45] from the table or curve, then multiply by the stress desired and by the square of the diameter of the wire.

Very few approximations are made in the derivation of Formula [44]. I have assumed that the length of the various helical elements to be π times the diameter of the particular helix times its number of turns. I have also assumed that a plane section of the wire through the axis of the spring remains a plane when the spring is loaded. This is nearly, but probably not exactly true. I have also not taken into account the complicated nature of torsional shear. It is presumed that experiments can be made on straight bars of spring material to determine the torsional modulus, the proportional limit, the elastic limit, and ultimate strength, and the values thus obtained used without modification in the calculation of the spring.

The writer made an attempt once at a graphical solution of this problem. While he did not get the solution he found an interesting condition governing the stress distribution over the wire section. He found that lines of equal stress were conic sections having the point g of Fig. 21 for a common focus and the axis of the spring for a directrix.

If the inside diameter of the spring is greater than the diameter of the wire, there conics are all ellipses, but if the inside diameter is smaller than the wire diameter there will be one parabola and outside of that hyperbolas with ellipses inside of the parabola.

On account of the consequent shear longitudinally of the wire these lines of equal stress no doubt deviate from the true conic section near the surface and intersect the circumference of the wire radially, or nearly so.

To calculate the deflection of the spring,

$$F=\frac{2S\pi(r-a)\,(r+e)}{G(a+e)}=\text{the deflection per turn}$$

because S/G = strain on inside diameter of spring on unit length, $2\pi(r-a)$ = length per turn and $\frac{r+e}{a+e}$ = the ratio of distance of torsional axis from spring axis divided by distance of torsional axis to the inside of spring. Dividing both numerator and denominator by r we have

$$F=\frac{2\pi S(1-v)\,(1+uv)r}{G(v+uv)x}$$

$$=\frac{2\pi SV(1-V)(1+uV)a}{G(V+uV)V}=\frac{\pi S(1-V)(1+uV)d}{G(1+u)V^2}$$

$$=\frac{\pi S}{G}\left[\frac{1}{v^2}-\frac{1^1/_4}{v}+\frac{9}{16}-\frac{83}{192}\,v+\frac{155}{768}\,v^2-\frac{403}{3072}\,v^3+\frac{3168}{36864}\,v^4-\ldots+\right]\ldots\ldots[46]$$

This solution is presented as an approximation to the true conditions of shear in the spring, not as substitute or criticism of the author's formula. They are both approximations. One may prove to be better in certain situations while in other situations the other may come nearer to the truth.

It is presented as added evidence that the old spring formula is far from accurate and that a more economical and safer design of springs can be had by using one of the improved formulas.

Formulas [44] and [46] should permit accurate calculation of the stress and deflection in springs that have little or no internal stress when free. It is well known to spring makers that they can, by surging a spring several times beyond the elastic limit cause the spring to take up a shorter free length. It is at once noticed in such a spring that the deflection for a given load has increased. The reason for this is that the point g, Fig. 21, is now farther from the axis of the spring.

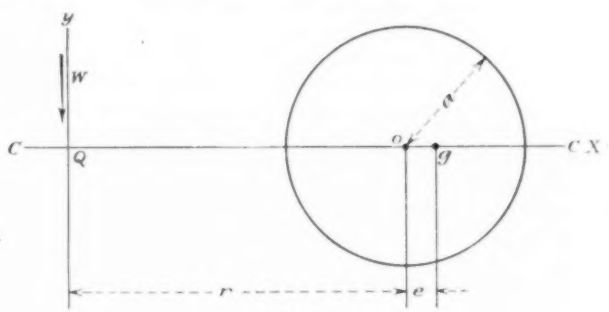

FIG. 21

Several years ago I had 12 springs made by cold-winding $^1/_4$ in. wire with a spring approximately 2 in. in diameter. These springs all had the same diameter but varied progressively in pitch of turn. Two of the springs when surged solid did not take any set. The two longest springs while differing considerably in original height were nearly the same height when surged and offered nearly this same resistance when compressed nearly solid.

Figs. 22 and 23 show the springs before and after surging.

The load sustained by the longest springs was approximately 29 per cent greater than that required to produce set in all of the ten longer springs. The deflection per pound per turn was measurably greater than it was before surging. Only about one-fourth to one-third of this greater deflection could be accounted for by the slightly increased outside diameter after surging.

If as an approximation we assume that Hooke's law holds up to the elastic limit, and that after permanent set takes place the shearing stress in the outer portions of the wire increases much more gradually but does increase as the deflection increases and that then the load is decreased slightly, we shall be able to find a deflection that will accompany a uniform (or nearly uniform) shearing stress in the outer portion of the wire surrounding a stress gradually decreasing to zero at the axis. Starting at the point g, Fig. 21, the point of zero stress moves farther and farther from the axis of the spring as the set goes farther and farther into the wire. It is of course impossible with any spring material to get the set to go clear to the axis; rupture would

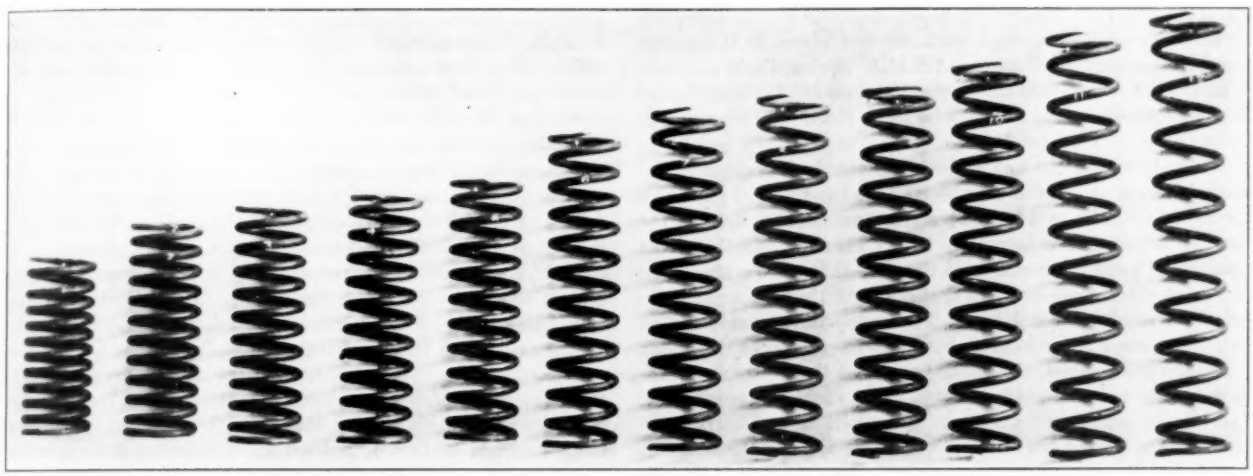

FIG. 22

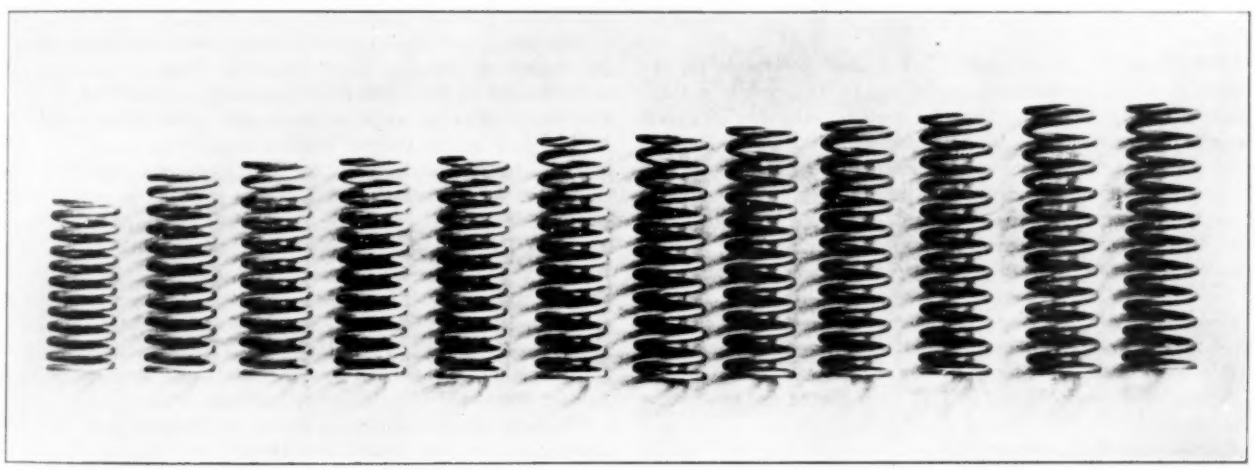

FIG. 23

occur first. However, we can by assuming set clear to the axis find the limit beyond which we cannot go.

For the above conditions we have:

$$W(r+e) = 2S \int\int_{\substack{t=0,\ \theta=0}}^{t=-e\cos\theta+\sqrt{a^2-e^2\sin^2\theta},\ \theta=\pi} t^2 dt d\theta$$

The limit of t is gotten from the polar equation to the circle

$$(t\cos\theta + e)^2 + t\sin^2\theta = a^2$$

from which

$$t = -e\cos\theta + a - \sqrt{a^2 - e^2\sin^2\theta}$$

we use the + sign since t is always positive.

Again, let $\frac{e}{a} = u$; then

$$W = \frac{\pi S a^3}{r+e}\left[\frac{2}{3} + \frac{1}{2}u^2 - \frac{1}{32}u^4 - \frac{1}{384}u^6 \ldots\right] \ldots [47]$$

For the vertical component of this stress we have the relation

$$2S \int\int_{\substack{t=0\ \theta=0}}^{t=-e\cos\theta+\sqrt{a^2-e^2\sin^2\theta},\ \theta=\pi} t\cos\theta\, dt d\theta + W = 0$$

Integrating and substituting for W its value from [47] and letting $\frac{a}{r} = v$ and solving for v we have

$$v = \frac{u - \frac{1}{8}u^3 - \frac{1}{64}u^5 \ldots}{\frac{2}{3} - \frac{1}{2}u^2 + \frac{3}{32}u^4 \ldots} \ldots [48]$$

This equation can be plated alongside the other equation between u and V, for any value of V in a surged spring the value of u will lie somewhere between the two curves near the first curve if only a little surging has been done and near the second if very severe surging has been resorted to.

There is no gain in severely surging a spring that has to operate from zero load to maximum load very often. If the maximum load seldom occurs or if the minimum load is one-half or more of the maximum load, great economy in space and material can be secured. It is almost an axiom that large stresses should not be used in any spring, the failure of which would cause loss of life or injury or damage to property. In these cases liberally designed springs are cheap insurance.

AUTHOR'S CLOSURE

As was suggested in the discussions by Messrs. Eksergian

and Rathbone, it appears desirable that one of the improved formulas for helical springs, such as that given in the paper, should be incorporated in the A.S.M.E. Spring Code and also in future handbooks and textbooks. It does not matter whether Röver's formula or the author's be used, since both give practically the same final results.

The only reason the author included the derivation of a new formula in the paper was that he believes the physical reasoning involved in its derivation was clearer than that involved in the derivation of Röver's formula. Röver assumes, in effect, that rotation of adjacent sections of the wire takes place about the center of these sections. He realized that this assumption involved a resultant axial force; consequently he *assumed* that *half* the vertical shear load was used up in producing this force.

On the other hand, the author assumed that rotation of adjacent sections took place about a point displaced toward the axis of the spring, producing a hyperbolic stress distribution similar to a curved bar in bending. This type of stress distribution would be produced by a pure torque moment. On this the shearing stress due to the vertical shear load was superimposed. This gave a simple solution and one which agreed within 0.7 per cent with Rover's exact solution for a spring with an index $c = 4$.

Mr. Wood, in his discussion, has derived a formula for the stress in which he assumes, as did Röver, that rotation takes place about the center of the wire section. On this he superimposes the *total* stress due to the vertical shear load. He thus neglects the fact that some of the vertical shear load is used up in producing a stress distribution compatible with the assumption of rotation about the center of the wire. His solution is still, however, another approximation, which differs from Röver's exact solution by about 3 per cent for a spring with an index $c = 4$. This compares with 0.7 per cent difference for the author's or about 1 per cent for Röver's approximate solutions. It should be noted, however, that even 3 per cent is a comparatively small amount, especially when applied to spring design.

The author used the value 1.23 as a factor for evaluating the stress due to the vertical shear load since this value and its method of derivation are generally accepted by authorities on the theory of elasticity.

The author did not pay much attention to the question of the exactness of the deflection formula ordinarily used for computing helical springs since it was his opinion that the difference between the ordinary deflection formula and a more exact one was quite small. Mr. Wood's derivation of a new deflection formula, in the author's opinion, gives an approximate formula which will give results probably nearer the truth than will the commonly used deflection formula. However, it should be noted that the difference in the results calculated by Mr. Wood's deflection formula and those computed by the ordinary deflection formula will not be greater than 11 per cent for nearly all springs used in practice which have indices greater than 3. This difference of 11 per cent could possibly be nullified by variations in spring-coil diameter and wire diameter of only slightly more than $1^1/_2$ per cent. At present, tests are in progress by the author to determine the correctness of Mr. Wood's formula, and if this is shown to be correct, he believes it should also be incorporated into future spring tables.

Regarding Mr. Stone's discussion, the author agrees that to maintain consistency the stresses should be integrated over the cross-section, as Mr. Stone suggests. The author attempted to do so when he first considered the problem, but on account of the mathematical difficulty involved he made the assumption mentioned by Mr. Stone, relative to the angular twist of adjacent sections. He believes this assumption gives sufficiently accurate results for practical work.

The author believes actual fatigue tests of springs should be carried out, as Mr. Stone suggests. Work of this kind is now planned by the Research Department of the Westinghouse Company. Further spring tables should, in the author's opinion, be based on actual fatigue tests such as these.

The question brought up by Mr. Rathbone regarding the correction factor for springs of square wire is one which is at present being investigated by the author at the Westinghouse Research Laboratory. Preliminary results indicate that the correction factor for square wire is approximately the same as that for round wire. As in the case of the round wire, the stress on the inside of the coil was found to be approximately 2.5 times that on the outside, even though the section was somewhat trapezoidal, as pointed out by Mr. Rathbone. A paper on this subject is planned when the work is completed.

The approximate solution to the spring problem given by Mr. Austin is based on somewhat different assumptions than those made by the author. However, Mr. Austin's solution gives results not greatly different from those obtained using Röver's or the author's formula, and, as Mr. Austin points out, furnishes added evidence that the ordinary spring formulas are inadequate.

APM-51-18

Graphical Methods for Least-Square Problems

By EVERETT O. WATERS,[1] NEW HAVEN, CONN.

IT IS a well-known fact that engineering test data are commonly presented in the form of curves. Simultaneous observations are made of two varying quantities, such as temperature and time, speed and horsepower, or payroll and production; these observations are plotted as points on a plane chart which affords an x-value and a y-value for each point; and a curve is then drawn through or near the points with the tacit assumption that there is some sort of relation between these x- and y-values. If the points are exactly traversed by the curve, this relation is evidently a simple mathematical equation in x and y. If, as is much more often the case, the curve is merely adjacent to the points, it is still assumed that the mathematical relation exists, but that the discrepancy is due to unavoidable errors of observation or to unexplained factors which the chart is supposed to suppress rather than emphasize.

Naturally, therefore, the curve should be drawn so as to reduce these errors to a minimum. It may be located by placing a transparent straight edge or curved rule on the plot and moving it about until the errors *appear* to be as small as possible, the eye of the draftsman being the sole guide to the fit of the curve, or the points may be separated into groups, the mean of each group located, and a line drawn through these mean points. In this case an exact calculation has been substituted for visual guesswork. But the question may fairly be asked: Is this line the "best" one that can be drawn? Obviously, the answer is ambiguous, since different groupings give different averages and the resulting curves would be far from identical.

In any case the best curve will be that one which reduces the standard error to a minimum, the standard error being defined as the root-mean-square of the errors of all the plotted points.[2] If the x-observations are perfect and the y-observations are inexact, these errors will be the differences between the y-values of the plotted points and the y-values of the curve for corresponding x-values. If both x- and y-observations are inexact and to an equal degree, the errors are the distances from the plotted points to the curve. No proof of these statements is given here, as ample substantiation may be found in most treatises on statistics or the theory of probability. An obvious corollary is this: by making the number of coefficients in the equation relating x and y equal to the number of plotted points, the standard error may be reduced to zero. But the snakelike curve resulting would defeat its own purpose by obscuring the relationship that the chart is intended to prove. Generally speaking, the nearer the plotted curve approaches a straight line—i.e., the flatter it is—the more suitable is the diagram for giving a mental picture of the results. Very often a straight line is the most satisfactory one that can be drawn.

Unfortunately, the least-square method has, in the minds of most engineers, one great drawback: the involved computations required. The slide rule cannot be used efficiently, because of the mixture of multiplication and addition; furthermore, it is not accurate enough, because the solution of the normal equations usually brings in small differences of large products, and the observational errors of the slide rule may easily overshadow those of the original data. A simple and accurate device for applying the least-square method without calculation should therefore meet with ready acceptance. Such a method will be outlined in the following paragraphs. The process is essentially a graphical one, using the planimeter to perform additions and multiplications simultaneously. A polar planimeter with adjustable arm, such as is used for averaging indicator cards, is most convenient, but a plain planimeter will do about as well.

The following type cases will be discussed, as being those most frequently encountered in engineering practice. However, they are merely representative, and many others could be added before the list would be complete.

- Case 1. Straight line, x-observations perfect, y-observations subject to error
- Case 2. Straight line, x- and y-observations subject to error
- Case 3. Conditioned hyperbola
- Case 4. Parabolic curve, symmetrical about y-axis or origin, exponent has any value
- Case 5. Exponential or logarithmic curve
- Case 6. General parabolic curve
- Case 7. Sine-cosine curve.

Case 1

The construction consists essentially of three steps, which are fundamental not only to this case but to all the others except Case 7. For this reason they are enunciated at the start, and their importance cannot be overemphasized. They are:

1 Transfer of the x- and y-axes to an origin located at the average of the x- and y-values of the plotted points.

2 Summation of x'^2 and $x'y'$ with the planimeter, x' and y' being the coordinates of the plotted points, referred to the new axes.

3 Drawing of the empirical line through the new origin and the point whose coordinates are $\Sigma x'^2$ and $\Sigma x'y'$.

The detailed process of locating the new origin is best performed with the adjustable-arm planimeter, unless there are only a few points, in which case the draftsman may prefer to do his averaging by arithmetic. Mark off equal spaces—inches, half-inches, or some other convenient unit—on the x-axis of the chart, equal in number to the plotted points. In Fig. 1, a, b, c, to h are the plotted points, and j, k, l, to r mark the equal spaces. Set the adjustable points of the planimeter to the total distance jr; start the planimeter at j, go straight up to the abscissa of a, across one space, up to the abscissa of b, across one space, up (or down) to the abscissa of the next plotted point, and so on until the tracing point is directly above r. Then trace down to r and across to j. The reading of the planimeter will now be the average height of the figure traced, which obviously coincides with the average of the observed y-values. The average of the x-values may be measured in the same way, using the y-axis as a base line.

If an averaging planimeter is not available, one of the fixed-arm type may be used. It is a well-known proposition in the theory of this instrument that the area traced equals the length of the tracing arm multiplied by the true rolling distance of the drum.

Hence, if a figure is planimetered whose length equals the arm length times one-tenth the circumference of the contact flange of the drum,[3] the reading of the drum will coincide with the

[1] Associate-Professor of Mechanical Engineering, Yale University. Assoc-Mem. A.S.M.E.

[2] "Statistical Methods," by F. C. Mills, p. 368.

Contribution by the Applied Mechanics Division and presented at the Annual Meeting, New York, December 3 to 7, 1928, of The American Society of Mechanical Engineers.

[3] Assuming that the customary graduation is engraved on the drum: ten major divisions, each of which registers 1 sq. in.

average height of the figure. Accordingly, if a fixed-arm instrument is to be used, the distance jr (Fig. 1) should be made equal to $\pi cda/10$, where c = a simple constant like 5 or 10, d = diameter in inches of contact flange of drum, and a = arm length in inches from pivot to tracing point. This distance, which is a constant for any planimeter, can then be subdivided into the requisite number of equal parts and the averaging process performed exactly as described in the preceding paragraph, except that the planimeter reading must be divided by c.

The point determined by these two averages is O, Fig. 1.

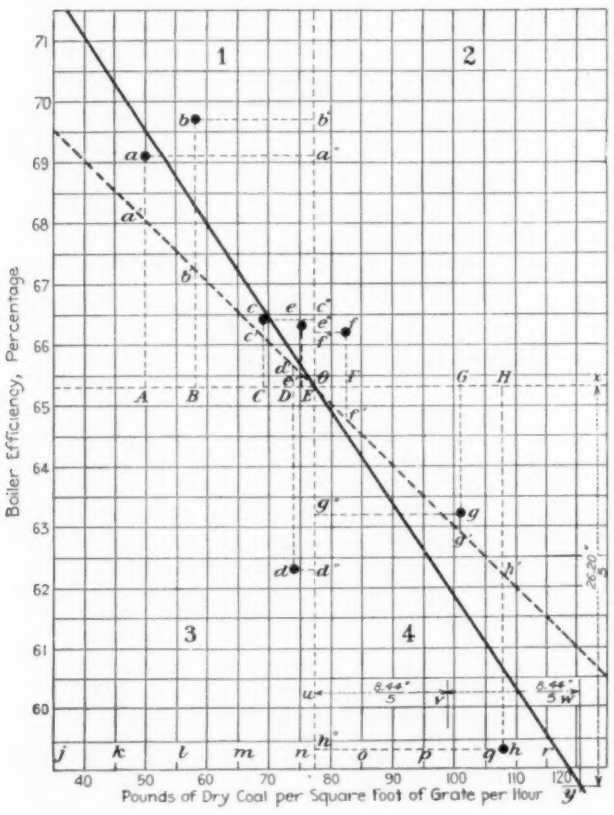

FIG. 1

Next, the planimeter is again brought into play, and the total area of the 45-deg. triangles OAa', OBb', OCc', etc. is obtained in the usual manner. It is not necessary to note down the area of each individual triangle or to pay any attention to the scale of the diagram; simply start at O and trace the lines OA, Aa', $a'O$; OB, Bb', $b'O$; etc. in turn, remembering always to go around in a clockwise direction, until all the triangles have been accounted for. The final result is then read off the dial or drum of the planimeter, and a numerically equal distance is laid off *twice* to the right (or left) of the vertical line through O. In Fig. 1, for instance, the triangles added up to 8.44 sq. in. on the author's original layout; so $\frac{8.44}{5}$ in. were laid off from u to v and again from v to w. Here, again, it should be explained that the particular scale that is used makes no difference, but for the sake of accuracy it is well to make it as large as possible, and the nearer w is to the edge of the chart, the better will be the final result. In this manner the x'^2-summation is obtained.

The $x'y'$-summation is very similar, the only difference being that instead of taking the areas of a number of triangles the rectangles $OAaa''$, $OBbb''$, $OCcc''$, etc. are measured and the total area obtained. In the original of Fig. 1 this was 26.20 sq. in.; accordingly, 26.20 units of the same size as in the preceding paragraph (fifth-inches) were laid off downward from a random point x on the horizontal through O, giving point y at the intersection with the previously drawn line through w. A straight line through y and O is, then, the "best" straight line that can be drawn to indicate the relation between boiler efficiency and rate of firing, for the particular set of tests recorded.

It will be noticed that the horizontal and vertical lines that were drawn through the central point O divide the diagram into four sections or quadrants that may be numbered 1, 2, 3, 4, as indicated. In this example, all the points a, b, c, etc., lie in the diagonally opposite quadrants 1 and 4, with the exception of d and f, which are in quadrants 3 and 2. The rectangles which these two points locate should therefore be traced *counterclockwise* by the planimeter, in distinction from the clockwise direction used for the points in the quadrants which contain the 45-deg. line. In all cases the triangles are traced in a clockwise direction.

The equation for the empirical line is $Y = aX + b$, where a is the ratio of $x'y'$ to x'^2, as found by the planimeter, and b is the intercept of the line on the original y axis.

CASE 2

If the x- and y-observations are both in error, a good approximate rule to follow is this: Draw an empirical line, by the

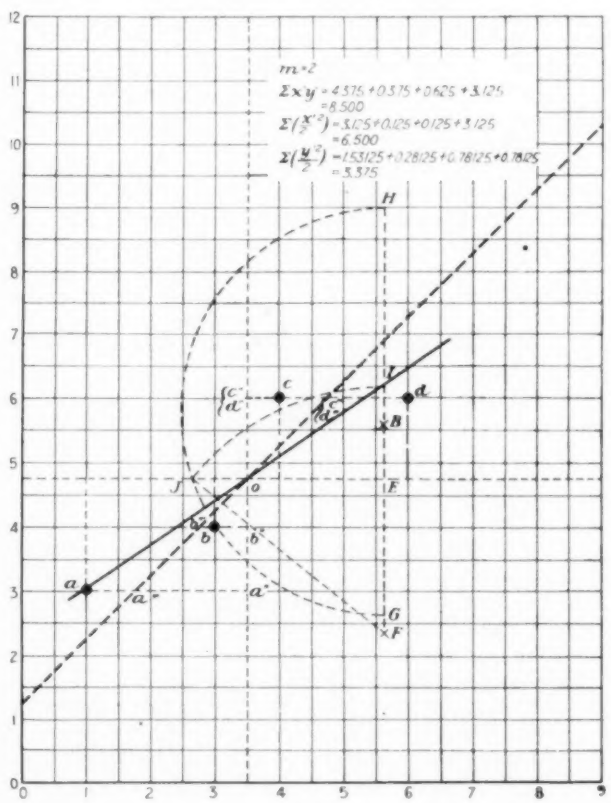

FIG. 2

method of Case 1, on the assumption that the y-values only are in error; draw another line by the same method, assuming that the x-values alone are in error; then draw the final line between these two, inclining it toward one or the other according as the x- or y-values have greater weight. In case the deviations appear to be fairly large, as in Fig. 2, it may be better to use the accurate,

though somewhat longer, process. First, locate the mean point O and transfer the axes as before. Lay off OE on the new x-axis equal to $\Sigma x'y'$, using any convenient unit of measurement; from E lay off EB vertically upward, making it equal to $\Sigma(y'^2/2)$, obtained by tracing the triangles $Oa''a''$, $Ob''b''$, etc.; and from B lay off BF vertically downward, making it equal to $m\Sigma(x'^2/2)$, m being the weight of the x-observations relative to the y-observations. The latter summation is obtained exactly as in Case 1. Prolong the line through F, E, and B and points G and H on it, such that $EG = OE$ and $EH = OE \times m$. Make GH the diameter of a semicircle cutting the new x-axis in J, and swing radius FJ onto line FH. The point I thus located, together with point O, determine the empirical line.

The equation of the line is of course $Y = aX + b$. Exact formulas for a and b are given in the Appendix.

Case 3

Frequently the x-observations increase while the y-observations decrease, suggesting a reciprocal relation and a curve of hyperbolic form. The general hyperbola does not lend itself readily to graphical treatment owing to the large number of constants to be evaluated; but by "conditioning," it is very easy to locate and plot an equilateral hyperbola, having one of the axes as asymptote, and satisfying the least-square criterion. For example, in the direct-current series-motor test plotted in Fig. 3 it may be assumed with reasonable truth that the starting torque is of a much greater order of magnitude than any of the values obtained under running conditions. That being the case, the curve is obtained as follows:

First, draw the ordinates through the plotted points a, b, c, to h, and with the upper left-hand corner of the diagram as a center, draw a quarter-circle large enough so that the tangent to it at the point where the a-ordinate cuts it will extend approximately to the upper right-hand corner of the chart. From the point where this tangent cuts the top line of the diagram, drop an ordinate to a' on the same horizontal with a. In the same manner draw tangents to the quarter-circle where it is intersected by the b-ordinate, c-ordinate, etc., and locate points b', c', etc.

For those ordinates that do not cut the quarter-circle the reverse construction is used; i.e., for the e-ordinate draw mn through its upper end and tangent to the quarter-circle, and then draw an ordinate through the point of tangency m, locating e' on this ordinate on the same horizontal with e. The entire construction of ordinates and tangents can be performed very rapidly with a sharp-cornered draftsman's triangle, as suggested by the dot-dash outline in Fig. 3.

If the hyperbola is a suitable curve for the problem in question, it will be found that the auxiliary points a', b', c', etc. are approximately in line, and this fact may be used as a test for the appropriateness of such a curve.

The next step consists in fitting a straight line rs to the auxiliary points. This is done in precisely the same manner as outlined for straight-line diagrams, and therefore need not be elaborated here. Having located rs, it only remains to set dividers to the respective vertical deviations—i.e., the vertical distances between the auxiliary points and the intersections of their ordinates with rs—and transfer them to the original a, b, c, etc. ordinates. This gives a series of points on the desired curve, which may then be sketched in and completed with a curved rule. This curve, shown by a heavy line in Fig. 3, is the "best" hyperbola with two arbitrary constants that can be fitted to the given data. Its equation is $Y = \dfrac{a}{X} + b$, where a is the slope of the auxiliary line rs multiplied by the square of the radius of the quarter-circle (measured in the same units as X), and b is the y-intercept of the auxiliary line; i.e., in Fig. 3, $a = \dfrac{820}{200} \times 800^2$ and $b = -2260$.

Case 4

The general parabolic or hyperbolic form of curve, with axis of symmetry passing through the origin, is one that frequently lends itself well to the representation of test data. The equation of such a curve is $Y = aX^b$, a and b being either positive or negative, integral, or fractional. If we try to fit a curve that will make the root-mean-square of the y-deviations a minimum, the normal equations are very unwieldy, and a graphical method is apparently out of the question. But by making the well-known transformation to logarithmic coordinates, the equation becomes $\log Y = \log a + b \log X$, and it is a simple enough matter to find a line such that the root-mean-square of the deviations of $\log y$ will be a minimum. This is a mathematical subterfuge that may seem unjustifiable according to the strictest canons of

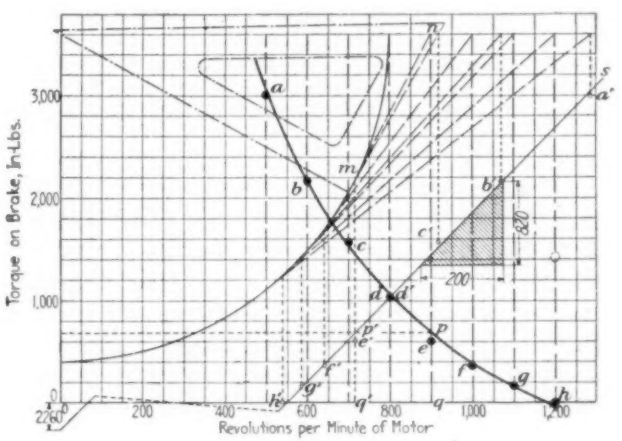

Fig. 3

logic, but it is recommended by statisticians[4] and is certainly acceptable on the ground of simplicity.

The use of logarithmic coordinates is so common in engineering practice that it is hardly necessary to work out a sample problem to illustrate the graphical method. Briefly, the process consists in transferring the observations to full-logarithmic paper, using any convenient combination of scales, fitting a straight line to the points by the method of Case 1 or Case 2, and then, if desired, retransferring to regular coordinates by picking off a sufficient number of points from the straight line to insure a smooth curve on the regular-coordinate paper.

Case 5

A type form very similar to the preceding is the exponential or logarithmic curve $Y = ae^{bX}$ or $Y = a \log X + b$. By plotting the points on semi-logarithmic paper and fitting a straight line by the basic graphical method, a curve is obtained which, for the exponential case, gives least-square values for the deviations from $\log y$, and for the logarithmic equation gives least-square values for the deviations from y.

Case 6

The observed points may frequently indicate a curve which is not symmetrical about the x- and y-axes, or does not pass through the origin, or have the form of a logarithmic or exponential curve. If it appears that it should be concave upward, and rising from left to right, try plotting values of x^2 against y and see if the points lie in a fairly straight line. If they still curve upward,

[4] "Statistical Methods," pp. 290–297.

a larger exponent may be tried. Conversely, if the curvature is downward, a fractional exponent is indicated, and if the curve is to slant downward from left to right, the exponent will be negative. Fig. 4 shows clearly the form of the curves belonging to this general category and the relation between the direction of curvature and the value of the exponent.

In any event the procedure is to choose arbitrarily the value of the exponent n in the equation $Y = aX^n + b$, plot the values of x^n versus y from the observation data, fit a straight line to this plot, read off on this straight line the values of Y that belong with the various x^n-values, and plot these against x to form the final curve. An example will make this clear. Fig. 5-*a* shows by means of solid dots seven observations ranging from $x = 2$, $y = 1$; to $x = 20$, $y = 11$. The general location of these points indicates a positive fractional value for the exponent n: say, $n = 1/2$. The observed values of x are accordingly raised to the one-half power and plotted against the observed values of y, giving the solid dots in Fig. 5-*b*, which lie in a flat S-curve that can readily be correlated with a straight line without excessive deviations. The straight line CD, obtained by the basic method, is drawn in Fig. 5-*b*, and the Y-values pertaining to the plotted $x^{1/2}$-values are shown by small circles. When these have been transferred to Fig. 5-*a*, the locus for the required curve AB

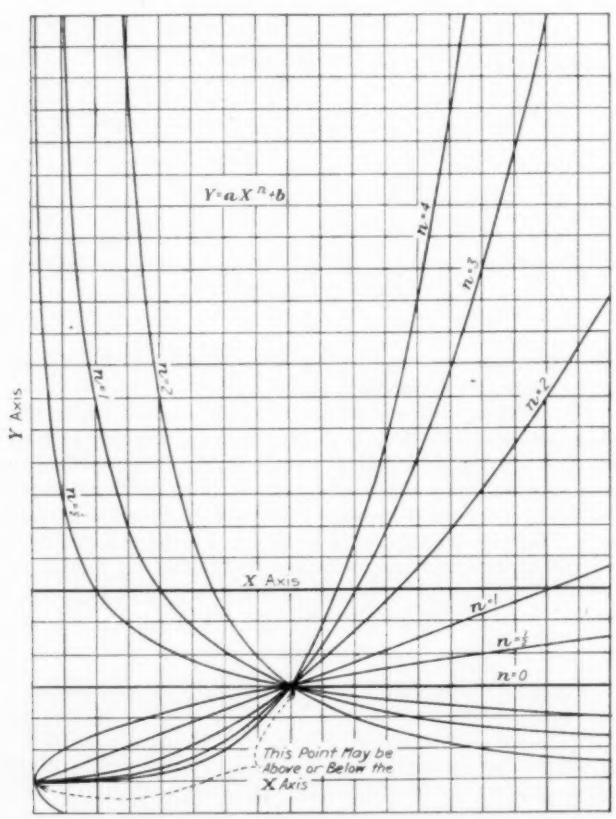

FIG. 4

has been duly obtained. The equation of the curve is $Y = aX^{1/2} + b$, or $a^2X = Y^2 - 2bY + b^2$, in which a is the slope of the straight line CD (with due regard to possible differences in the horizontal and vertical scales) and b is the intercept of CD on the y-axis.

Curve EF in Fig. 5-*a*, which fits the observed points more closely than AB but has certain offsetting disadvantages, will be referred to at the close of the paper.

CASE 7

This curve, the last to be discussed in the present paper, differs in several respects from those that precede it. Hitherto, all the curves have been derived from a basic straight line, fitted to a series of points by what may be termed a standard method. In the case of the sine-cosine curve the normal equations are

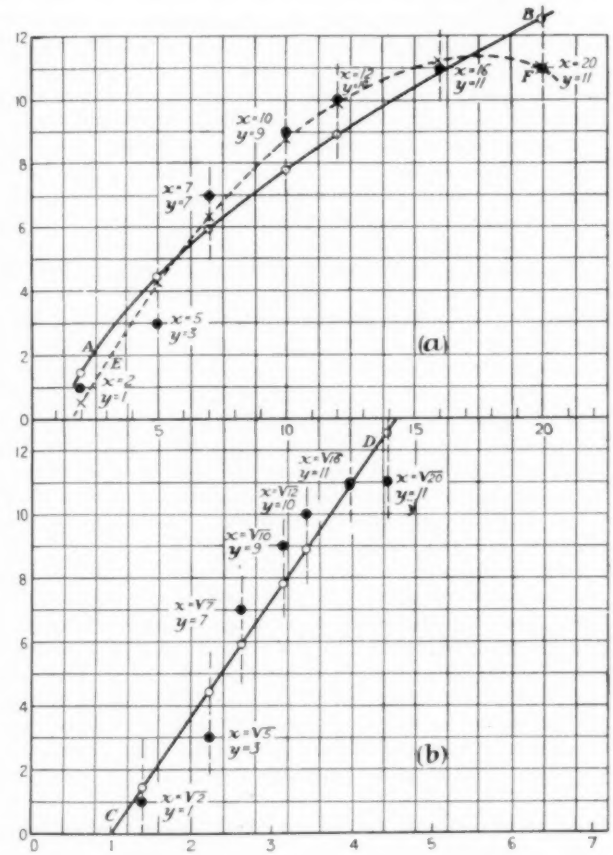

FIG. 5

markedly different; the only similarity lies in the device of shifting the x- and y-axes in order to simplify these equations and in limiting the number of constants in the empirical equation to two. In order to avoid the presence of three or more constants, it is assumed that (*a*) the period or frequency of the wave is known, and that (*b*) the x-axis is so located that the mean of all the y-observations is zero. The unknown constants to be determined are thereby reduced to the amplitude and the phase of the periodic curve.

To locate the new y-axis, the observed data[5] are plotted on transparent tracing vellum, and a double-frequency sine curve of any desired amplitude is laid out in ink or soft pencil on a separate sheet of paper (so that it will be visible through the vellum), using either the table of functions or the standard graphical method for its construction. It should extend for at least $2^1/_4$ wave lengths and have the first $^1/_4$ wave length accurately marked (AB, Fig. 6-*a*). This is then placed under the plot of observed values, making A coincide with the origin of

[5] Data taken from a forest and stream-flow experiment at Wagon Wheel Gap, Colo., by the U. S. Forest Service and Weather Bureau. To make the problem more typical, a limited set of readings were used, running from January, 1911, to September, 1912. Ordinates are monthly mean temperatures; abscissas are months.

coordinates (Fig. 6-*b*); the ordinate passing through each point is noted; and all the ordinates are added algebraically with dividers and the sum laid off vertically at *DE* (upward if positive and downward if negative). Then the tracing vellum is shifted to the left so that *B* coincides with the origin of coordinates (Fig. 6-*c*), and the same process of ordinate marking and summation is performed, giving the horizontal line *DF*. Sometimes, as in Fig. 6-*c*, $DF = 0$. This construction determines the angle *EFD*, the bisector of which gives the angular displacement of the new *y*-axis from the original axis. In Fig. 6-*c* angle *EFD* = 270 deg.; hence, the new *y*-axis, shown in Fig. 6-*c*, is located to the right of the original *y*-axis at a distance $c = \frac{135}{360} \times AC$.

The construction of the final empirical curve is accomplished in two steps: in the first, the amplitude of the sine component is obtained, and in the second, that of the cosine component. The resultant is found by plotting the components and simply adding them graphically, or by adding the two amplitudes vectorially, determining the phase of the resultant, and plotting a single sine curve to fit these conditions.

Fig. 6-*d* illustrates the first step. A sine curve of fundamental frequency and any convenient amplitude is drawn up on a separate sheet and slipped under the transparent plot, making its axis coincide with the new *x*-axis and its origin with the new origin *O* of the plot. A 45-deg. line *GH* is also drawn through *O*. Then ordinates are drawn from each of the plotted points 1, 2, 3, etc., to the sine curve, and from their intersections with this curve are drawn corresponding abscissas to the new *y*-axis. The intersections of these abscissas with *GH* are numbered 1′, 2′, 3′, etc., the primed numbers each being related to the corresponding original numbers. The planimeter is now used to measure and sum up a series of rectangular areas, one for each plotted point, thus: Start tracing at *O*, go down to the abscissa through 1′, over to *GH*, straight up to the new *x*-axis, and back to *O*; repeat for the other points, always starting out on the new *y*-axis and returning to *O* on the new *x*-axis. The final result is laid off vertically from the *x*-axis at a point where the underlying sine curve has its full amplitude, and any convenient scale is used (see *IJ*, Fig. 6-*d*). Then another series of rectangles is summed up, by starting the planimeter at *O*, going down to the abscissa through 1, across to the ordinate through 1′, up to the new *x*-axis, over to *O*, and so on for all the other points. Here again it is necessary to start tracing each rectangle on the new *y*-axis, as a result of which it will be found that some of the rectangles will be traced counterclockwise. It is therefore well to note the reading of the planimeter each time that the tracing point arrives at *O*, so that in case the total area is negative its true value may be found by subtracting the final reading from the maximum scale graduation of the planimeter. In Fig. 6-*d* this final reading is positive and is laid off horizontally as *IK*, to the same scale as *IJ*. Horizontal line *LM*, determined by the two legs of the triangle *IJK* and the point *L* where the sine curve intersects *IJ*, is then the amplitude of the sine component of the final empirical curve.

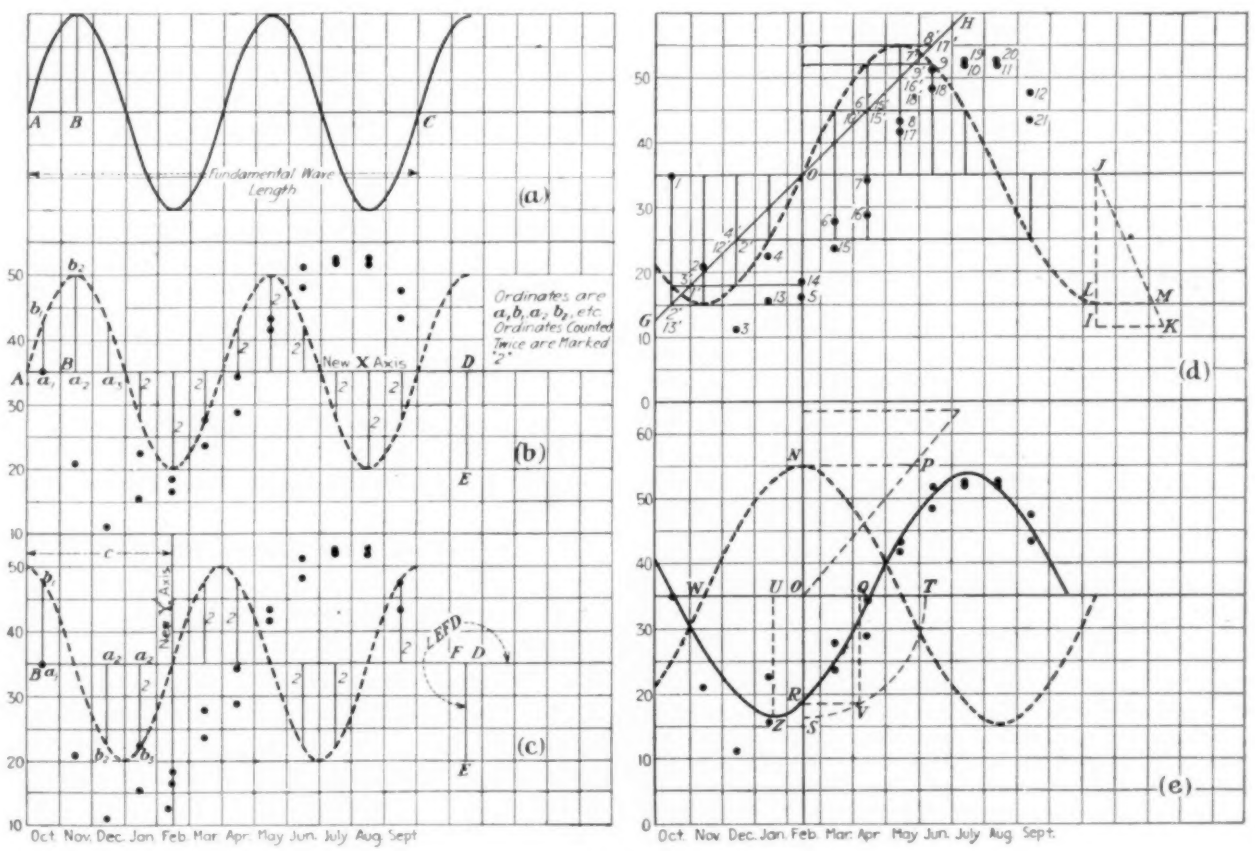

FIG. 6

The cosine component is determined in exactly the same way, except that the underlying curve is moved along so that its highest point coincides with the new *y*-axis (Fig. 6-*e*). The amplitude of this component for the illustrative problem is shown at *NP*; it is negative in sign.

To combine the two components graphically without plotting

either one, lay off $OQ = LM$ and $OR = NP$. Measurements up and to the right of O are positive; down and to the left are negative. Draw arc ST with O as center and OV as radius, measure arc SV with a protractor, lay off UO so that $\frac{UO}{WO} = \frac{\text{arc } SV}{90°}$, and locate Z at the intersection of horizontal and vertical lines through S and U; Z is then the minimum (or maximum) point on the required empirical curve, and since the wave length and axis of the curve are already known, it can be plotted by simple geometrical means.

In conclusion, a few general rules will be given that apply with equal force to all types of curve plotting:

1 Do not extend a curve by extrapolation more than 10 per cent at either end.

2 If observations are of unequal weight, multiply the weights by the least common factor that will make them all integral, and then consider that each point is replaced by several discrete but coincident points, equal in number to the weight of the point in question.

3 When an empirical relation between two sets of observations is derived by applying a known mathematical or physical law, it makes some difference whether the law is applied to each pair of observations individually or to a primary empirical relation between the observed quantities; e.g., the water rate of a steam turbine at different loads is not found by observing loads and corresponding pounds of steam per kilowatt-hour, but by observing loads and total steam consumptions per unit of time. Usually these latter observations are individually divided by the loads, and the resulting points of pounds per kilowatt-hour versus load are used as the basis of an empirical water-rate curve. However, it would be slightly more logical to find an empirical curve for the relation of load to total steam consumption, and then derive the water-rate curve from this primary curve by dividing its ordinates by the corresponding loads.

4 In all the cases described in this paper, except Case 2, it is assumed that the y-observations alone are subject to error. Hence, in plotting observations in which both sets are inexact, those which are most nearly correct should be plotted as abscissas.

5 The number of arbitrary constants in any empirical equation should be as small as possible consistent with good correlation. This somewhat begs the question, since there is no absolute standard of correlation. In the theory of statistics a relative measure of correlation is found by comparing the standard error of the assumed line with that of a horizontal line passing through the mean of the y-values. It may be stated as an unprovable but common-sense principle that the use of more than two constants in the equation is not justified unless they are needed in order to make the "index of correlation,"[6] as it is called, greater than 85 per cent, the maximum value with perfect correlation being 100 per cent. In Fig. 5-*a*, curve AB, representing an equation with two constants, has an index of correlation of 95.45 per cent. Curve EF, with three constants calculated by solving three simultaneous normal equations fits the points slightly better (i. c. = 98.74 per cent), but the peak near the right end suggests a downward trend which is not justified by the observed data. A somewhat rougher approximation, such as is furnished by curve AB, is in reality far more useful.

Appendix

Let

x_1, y_1, x_2, y_2, etc. = coordinates of plotted points

X_1, Y_1, X_2, Y_2, etc. = variables of empirical equations (in general X is independent and Y is dependent)

d_1, d_2, d_3, etc. = deviations of the dependent variable from the empirical curve; i.e., $d = y - Y$ when $x = X$

n = number of related pairs of observations or number of plotted points

x'_1, y'_1, x'_2, y'_2, etc. = coordinates of plotted points with reference to axes passing through the mean of the x and y observations; i.e., $x = x' + \frac{\Sigma x}{n}$, $y = y' + \frac{\Sigma y}{n}$, $\Sigma x' = 0$, $\Sigma y' = 0$

a, b, c, e, etc. = constants in the empirical equation

Σ = summation of a series of similar terms; it affects everything that follows it, up to the next + or − sign; i.e., $\Sigma xy^2 = x_1y_1^2 + x_2y_2^2 + \ldots$, and $(\Sigma xy)^2 = (x_1y_1 + x_2y_2 + \ldots)^2$.

Case 1

To determine a and b in the empirical equation $Y = aX + b$, assuming the x-observations perfect, $x_1 = X_1$, $x_2 = X_2$, etc.

$y_1 - d_1 = aX_1 + b$, hence $d_1 = y_1 - aX_1 - b$ and $d_1^2 = y_1^2 - 2ay_1X_1 + a^2X_1^2 - 2by_1 + 2abX_1 + b^2$

$y_2 - d_2 = aX_2 + b$, $d_2 = y_2 - aX_2 - b$, $d_2^2 = y_2^2 - 2ay_2X_2 + a^2X_2^2 - 2by_2 + 2abX_2 + b^2$

etc. etc. etc.

$$\Sigma d^2 = \Sigma y^2 - 2a\Sigma xy + a^2\Sigma x^2 - 2b\Sigma y + 2ab\Sigma x + nb^2$$

If $\sqrt{\frac{\Sigma d^2}{n}}$ is a minimum, Σd^2 must also be a minimum; hence

$$\frac{\partial}{\partial a}\Sigma d^2 = -2\Sigma xy + 2a\Sigma x^2 + 2b\Sigma x = 0$$

$$\frac{\partial}{\partial b}\Sigma d^2 = -2\Sigma y + 2a\Sigma x + 2nb = 0$$

$$a = \frac{n\Sigma xy - \Sigma x\Sigma y}{n\Sigma x^2 - (\Sigma x)^2} \qquad b = \frac{\Sigma x^2\Sigma y - \Sigma x\Sigma xy}{n\Sigma x^2 - (\Sigma x)^2}$$

$$a = \frac{\Sigma x'y'}{\Sigma x'^2}$$

When $X = \frac{\Sigma x}{n}$, these values of a and b give $Y = \frac{\Sigma y}{n}$.

The line constructed by the graphical method satisfies the foregoing condition for a and passes through the point $X = \frac{\Sigma x}{n}$, $Y = \frac{\Sigma x}{n}$.

Case 2

To determine a and b in the empirical equation $Y = aX + b$, when both x- and y-observations are in error and the x-observations have a weight of m times the y-observations.

Let d_x represent the deviation of an observed point from the empirical line assuming the y value as perfect, and d_y the deviation assuming the x-value as perfect (see Fig. 7). Then, if the x- and y-values are both in error but of equal weight, the total deviation d should equal $d_y \cos\theta$ and also $-d_x \sin\theta$, or $d^2 = -d_xd_y \sin\theta \cos\theta = \frac{d_x^2d_y^2}{d_x^2 + d_y^2}$. But the x-value is m times as accu-

[6] "Statistical Methods," p. 436.

rate as the y-value; hence the square of the deviation should be shifted toward d_y by substituting md_x^2 for dx^2. This makes

$$d^2 = \frac{md_x^2 d_y^2}{md_x^2 + d_y^2} = \frac{md_y^2}{m + d_y^2/d_x^2} = \frac{md_y^2}{m + a^2} = \frac{m(y - ax - b)^2}{m + a^2}$$

$$\Sigma d^2 = \frac{\Sigma y^2 - 2a\Sigma xy + a^2\Sigma x^2 - 2b\Sigma y + 2ab\Sigma x + nb^2}{1 + a^2/m}$$

The minimum value of Σd^2 with respect to a and b is obtained when

$$\frac{\partial}{\partial a}\Sigma d^2 = \frac{(\Sigma y^2 - 2a\Sigma xy + a^2\Sigma x^2 - 2b\Sigma y + 2ab\Sigma x + nb^2)\,2a/m - 2(a\Sigma x^2 - \Sigma xy + b\Sigma x)\,(1 + a^2/m)}{(1 + a^2/m)^2} = 0$$

and

$$\frac{\partial}{\partial b}\Sigma d^2 = \frac{2(a\Sigma x - \Sigma y + nb)}{1 + a^2/m} = 0$$

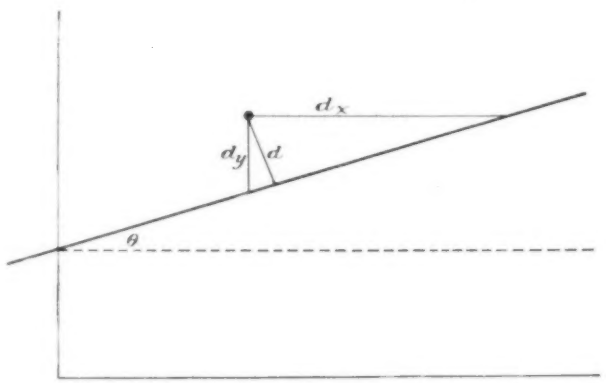

FIG. 7

This gives

$$\frac{a}{m}\Sigma y^2 - 2\frac{ab}{m}\Sigma y + \frac{nab^2}{m} + \Sigma xy - a\Sigma x^2 - b\Sigma x - \frac{a^2}{m}\Sigma xy + \frac{a^2 b}{m}\Sigma x = 0$$

and

$$a\Sigma x - \Sigma y + nb = 0.$$

Therefore

$$b = \frac{\Sigma y - a\Sigma x}{n}$$

and

$$na\Sigma y^2 - a(\Sigma y)^2 + n(m - a^2)\Sigma xy - (m - a^2)\Sigma x\Sigma y + am(\Sigma x)^2 - nam\Sigma x^2 = 0.$$

The last equation, when arranged in the type form of a quadratic, is

$$a^2 - \left[\frac{n\Sigma y^2 - (\Sigma y)^2}{n\Sigma xy - \Sigma x\Sigma y} - \frac{m[n\Sigma x^2 - (\Sigma x)^2]}{n\Sigma xy - \Sigma x\Sigma y}\right]a - m = 0,$$

or

$$a^2 - \frac{(\Sigma y'^2 - m\Sigma x'^2)}{\Sigma x'y'}a - m = 0$$

The solution of this is

$$a = \frac{\Sigma y'^2 - m\Sigma x'^2}{2\Sigma x'y'} \pm \frac{1}{2}\sqrt{\left(\frac{\Sigma y'^2 - m\Sigma x'^2}{\Sigma x'y'}\right)^2 + 4m}$$

Referring now to Fig. 2 and its construction, it will be remembered that

$$EF = \Sigma\left(\frac{y'^2}{2}\right) - m\Sigma\left(\frac{x'^2}{2}\right)$$

Also

$$EJ^2 = EG \times EH = OE \times EH = m(OE)^2 = m(\Sigma x'y')^2$$

$$\text{Therefore } JF = \sqrt{\left[\Sigma\left(\frac{y'^2}{2}\right) - m\Sigma\left(\frac{x'^2}{2}\right)\right]^2 + m(\Sigma x'y')^2}$$

and $EI = JF - EF$

$$= \frac{\Sigma x'y'}{2}\sqrt{\left[\frac{\Sigma y'^2 - m\Sigma x'^2}{\Sigma x'y'}\right]^2 + 4m} - \frac{\Sigma y'^2 - m\Sigma x'^2}{2}$$

The slope of the constructed line is

$$\frac{EI}{OE} = -\frac{\Sigma y'^2 - m\Sigma x'^2}{2\Sigma x'y'} + \frac{1}{2}\sqrt{\left[\frac{\Sigma y'^2 - m\Sigma x'^2}{\Sigma x'y'}\right]^2 + 4m}$$

but this is identical with the expression for a above; hence the line has the correct slope. Moreover, the value of b by construction is $\frac{\Sigma y}{n} - a\frac{\Sigma x}{n}$, which agrees with the required value of b given above.

CASE 3

To determine a and b in the empirical equation $Y = \frac{a}{X} + b$.

In Fig. 3 let x_1 = abscissa of c, u_1 = abscissa of c', and r = radius of quadrant. Then, from similar right triangles, $\frac{x_1}{r} = \frac{r}{u_1}$ and $x_1 = \frac{r^2}{u_1}$.

$$y_1 - d_1 = \frac{a}{x_1} + b = \frac{au_1}{r^2} + b$$

and similarly for y_2, y_3, etc.,

$$\Sigma d^2 = \Sigma y^2 - \frac{2a}{r^2}\Sigma uy + \frac{a^2}{r^4}\Sigma u^2 - 2b\Sigma y + \frac{2ab}{r^2}\Sigma u + nb^2$$

$$\frac{\partial}{\partial a}\Sigma d^2 = -\frac{2}{r^2}\Sigma uy + \frac{2a}{r^4}\Sigma u^2 + \frac{2b}{r^2}\Sigma u = 0$$

$$\frac{\partial}{\partial b}\Sigma d^2 = -2\Sigma y + \frac{2a}{r^2}\Sigma u + 2nb = 0$$

$$a = r^2\frac{\Sigma u'y'}{\Sigma u'^2} \qquad b = \frac{\Sigma u^2\Sigma y - \Sigma u\Sigma uy}{n\Sigma u^2 - (\Sigma u)^2}$$

To prove that the curve in Fig. 3 correctly represents the equation, select any point where the curve cuts an ordinate of one of the observed points, such as p, the corresponding point on the auxiliary line being p'. Then, by construction, $pq = p'q'$, and $op' = \frac{r^2}{op}$. Also, the auxiliary line was so constructed that $p'q' = \left(\frac{\Sigma u'y'}{\Sigma u'^2}\right)u' + \frac{\Sigma y}{n}$

$$= \left(\frac{\Sigma u'y'}{\Sigma u'^2}\right)\left(\frac{r^2}{op} - \frac{\Sigma u}{n}\right) + \frac{\Sigma y}{n}$$

$$= \frac{r^2 \dfrac{\Sigma u'y'}{\Sigma u'^2}}{op} + \frac{\Sigma u^2 \Sigma y - \Sigma u \Sigma uy}{n\Sigma u^2 - (\Sigma u)^2}$$

Substituting $Y = pq$ for $p'q'$, and X for op, and inserting a and b in place of their equivalents, this equation becomes identical with the type form at the head of the paragraph; hence the construction is correct.

Case 7

To determine a and b in the empirical equation $Y = a \sin \omega X + b \cos \omega X$, it being conditioned that $\Sigma y = 0$ and $\omega\left(\text{or } \frac{2\pi}{\omega}\right)$ is known.

Let x_1, x_2, x_3, etc., be redefined as the abscissas of the plotted points relative to the new y-axis, the abscissa of this axis relative to the original y-axis being c.

Let f = amplitude of double-frequency sine curve used in construction.

Let g = amplitude of fundamental frequency sine curve used in construction.

Then, by construction (Figs. 6-*b* and 6-*c*),

$$\frac{\dfrac{c}{2\pi}}{\omega} = \frac{1}{2} \times \frac{\angle EFD}{2\pi}$$

$$\omega c = \frac{\angle EFD}{2} = \frac{1}{2} \text{arc tan} \frac{DE}{DF} = \frac{1}{2} \text{arc tan} \frac{\Sigma f \sin 2\omega x}{\Sigma f \cos 2\omega x}$$

$$\tan 2\,\omega c = \frac{\Sigma \sin 2\omega x}{\Sigma \cos 2\omega x}, \quad \sin 2\,\omega c \Sigma \cos 2\,\omega x = \cos 2\,\omega c \Sigma \sin 2\omega x$$

$$\Sigma \sin 2\,\omega(x - c) = \Sigma \sin 2\,\omega x' = 0$$

According to the theory of least squares

$$d_1 = a \sin \omega x_1 + b \cos \omega x_1 - y_1, \text{ etc.}$$

$$d_n = a \sin \omega x_n + b \cos \omega x_n - y_n$$

$$d^2{}_n = a^2 \sin^2 \omega x_n + 2ab \sin \omega x_n \cos \omega x_n + b^2 \cos^2 \omega x_n - 2ay_n \sin \omega x_n - 2by_n \cos \omega x_n + y_n{}^2$$

$$\frac{\partial}{\partial a} \Sigma d^2 = 2a\Sigma \sin^2 \omega x + 2b\Sigma \sin \omega x \cos \omega x - 2\Sigma y \sin \omega x = 0$$

$$\frac{\partial}{\partial b} \Sigma d^2 = 2b\Sigma \cos^2 \omega x + 2a\Sigma \sin \omega x \cos \omega x - 2\Sigma y \cos \omega x = 0$$

$$a = \frac{\Sigma y \sin \omega x - b\Sigma \tfrac{1}{2} \sin 2\omega x}{\Sigma \sin^2 \omega x} \qquad b = \frac{\Sigma y \cos \omega x - a\Sigma \tfrac{1}{2} \sin 2\omega x}{\Sigma \cos^2 \omega x}$$

Since the empirical curve is determined solely by the y-deviations of the observation points and does not depend on the location of the axes of coordinates, the y-axis may be shifted arbitrarily to the right or left. Assume that it is moved to the right (Fig. 6-*d*) so that the new abscissas x' are related to the old ones x by the equation $x' = x - c$. Then the new values of a and b are given by the equations

$$a = \frac{\Sigma y \sin \omega x' - b\Sigma \tfrac{1}{2} \sin 2\omega x'}{\Sigma \sin^2 \omega x'} \qquad b = \frac{\Sigma y \cos \omega x' - a\Sigma \tfrac{1}{2} \sin 2\omega x'}{\Sigma \cos^2 \omega x'}$$

As proved in the foregoing, the second term in the numerator of each of these expressions equals zero. According to the construction used in Fig. 6-*d*, $LM = \frac{IK}{IJ} g = \frac{\Sigma y\,(g \sin \omega x')}{\Sigma\,(g \sin \omega x')^2} g = \frac{\Sigma y \sin \omega x'}{\Sigma \sin^2 \omega x'} = a$; likewise, $NP = b$.

Discussion

Carroll F. Merriam.[7] There is an important application for least squares in studies upon which are based important contracts. Slight differences in the location of the "best line" may make differences in the terms of these contracts amounting to considerable sums of money, and if the location be left to judgment it would give rise to disputes. Therefore any simplification of this problem and the enabling of it to be more commonly used should prove of assistance to engineers handling work of this kind.

Although analytical methods involve complicated computations, the development of the modern electric-driven computing machine makes possible a quick and easy solution, especially if the machine has a sufficient number of banks of keys to enable the products x^2 and $x'y'$ to be multiplied simultaneously and totaled at the same time. The graphical method has little if any advantage when mechanical means of calculating are available.

In all seven of the cases mentioned, it has been assumed that the best line would have a comparatively simple equation. Although this assumption may be of great aid in deriving formulas from experimental data, there are many engineering problems in which no attempt is made to derive such a formula, and, furthermore, this assumption may be misleading. We must not lose sight of the fact that we have information frequently, other than the mere coordinates of the points. Attention should be given to the location of the axes and the probable relation between the variables as evident from the nature of the problem. Failure to observe these may easily lead to false conclusions.

We may take as an example Fig. 1. To one unfamiliar with engineering, it would appear that the straight line is claimed to be the best representation of the relation between the two variables and that inasmuch as efficiency is increased with decreasing rate of firing from 120 lb. of dry coal per sq. ft. per hr. to one-third of this rate, it can be expected that maximum efficiency will be reached when the rate of firing is zero. It is perfectly evident from the nature of the case that this is not true.

We know that the curve must end at a value of x equal to the stand-by losses and that at this point y will equal zero. This fact is just as important as the location of any of the eight points, but it has been ignored necessarily by assuming the best line to be straight. Furthermore, no attempt has been made to locate the probable maximum value for efficiency, even though this may be of prime importance in such a series of tests.

These experimental results can be replotted by using the vertical scale for the product of the original x and y values. Inasmuch as the coal burned times efficiency equals the coal usefully burned, it will be apparent that the losses, which would then be represented by the distance that each point falls below a 45-deg. line, appear to be made up of certain constant losses plus others which are approximately proportional to some power of the rate of firing. It will be seen, furthermore, that five of the points lie very distinctly along such a curve, whereas point d is out of line with the others and therefore extremely doubtful. One would certainly be justified in at least heavily discounting the value of point d, if not in eliminating it altogether. This fact is by no means so clearly evident from Fig. 1. Points g and h may be considered to have about equal values in determining the trend of the curve for the high rates.

[7] Pennsylvania Water & Power Company, Baltimore, Md. Mem. A.S.M.E.

In many engineering problems it is not wise to trust the location of an important curve either to a draftsman or to mathematical analysis. There is need for engineering judgment and skill. For example, it is seldom justifiable to make sudden changes in the general trend of the curve to accommodate apparently wild points, yet there are cases where sudden turns have been shown to be inherent to the nature of the work. On the other hand, it is easy to become misled by opinions formed in advance regarding the shape to be taken by a curve, and great care should be taken to guard against this kind of mistake.

The method of least squares can be applied graphically to test the merits of several proposed locations for the most probable curve passing through a group of points. The plotted points should be connected to any curve to be tested by vertical lines. With the length of these lines as radii, circles are described using the points themselves as centers. The tracing point of the planimeter is started at a distinctly marked point on the curve, anywhere to the left of the left-hand point. The curve should be followed to the right to the foot of the vertical line drawn from the first point, and then around the circle clockwise, returning again to this point and proceeding along the curve to the second vertical line, and so on.

After following around the last circle, the starting point is reached by returning along the curve, and the total area of the circles are read on the dial of the planimeter. Assuming that all curves tested are consistent in shape with the nature of the data, the one which shows the smallest area included in the circles may be considered to be the best representation of the probable relation between the two variables.

The foregoing applies to the case where it is assumed that there is no error in x, but in case both x and y are assumed to be subject to error, slanting lines can be substituted for the vertical lines, these lines being inclined in proportion to the probable error in each of the two directions.

T. H. Gronwall.[8] In a paper of this kind, the question of greatest interest to the engineer is that of the speed and accuracy with which the methods proposed can be applied to practical problems. It may be stated that, at present, graphical methods are generally held inferior in both respects to the numerical ones, except possibly in some quite special cases of the application of graphical statics. Professor Whitaker, who established the first laboratory of applied mathematics in any English-speaking country at the University of Edinburgh in 1913, says in the preface to his "Calculus of Observations:" "When the Edinburgh laboratory was established in 1913, a trial was made, as far as possible, of every method which had been proposed for the solution of the problems under consideration, and many of these methods were graphical. During the ten years which have elapsed since then, the graphical methods have almost all been abandoned, as their inferiority has become evident, and at the present time the work of the laboratory is almost exclusively arithmetical."

The same kind of evidence of the superiority of the numerical methods may be gathered by a perusal of the volumes of the German "Zeitschrift for angewandse Mathematik und Mechanik," and the experience of the writer has been the same, with regard to both engineering and purely scientific problems. With the increasing use of calculating machines, this superiority of the numerical methods will be more and more pronounced. In the paper under discussion, the graphical construction of reciprocals in case 3, Fig. 3, for instance, is decidedly slower than reading them off from a table of reciprocals, and the construction in case 7, while quite interesting from a theoretical point of view, is exceedingly complicated.

Another consideration is that if one does not use these intricate graphical processes constantly, one generally finds that when the occasion to use them arises, one has forgotten how to do it and has to read up on them again. On the contrary, the simple mathematics underlying the numerical processes is easily retained in the memory.

Criticism may also be directed against the application of the method of least squares itself to problems of the type used as illustrations in the paper. It is not often that one can assert with any degree of plausibility that the Gaussian law holds for the errors of observation in engineering data, and hence the applicability of the method of least squares is very limited. Even where it is applicable, a rough and ready determination of the constants involved will frequently be as acceptable from a practical point of view as the least-square determination, and accomplished with much less labor. The writer has encountered many instances of this kind.

G. B. Karelitz.[9] The paper presents an opportunity to discuss in general the comparative value of graphical, mechanical, and numerical integration. A number of years ago the writer had an opportunity to investigate the accuracy of area determination by planimeters. It was found that in order to obtain an accuracy of 1 per cent the boundary of the area must be traced at least twice. An objection to mechanical computation is the ease with which an error can be made in tracing the triangles; one of these may be traced only once, while another three times instead of two. And when an error is made there is no means to locate it; the calculation must be repeated; it is therefore necessary to read the dial of the planimeter after each triangle is traced.

Now, in cases where a large number of determinations is to be made, such as the mentioned several hundred steam diagrams, or in shipbuilding computations where from 100 to 200 integrals of waterlines and cross-sections are to be found, the mechanical integrator is very serviceable. In mechanical engineering the accuracy generally needed is comparatively not high, and simple numerical computation proves to be the most reasonable method for evaluation of integrals. The method of least squares may be used advantageously only in separated occasions, the arithmetical average of values observed being a sufficient approximation in most cases.

Another general remark which the writer would like to make has no direct bearing on the paper itself. It has been quite customary to interpret a set of experimental data by an analytical formula. This procedure is rather dangerous; the formula may be reprinted several times, the range of the experiments not being mentioned, and unknowingly the results of the experiment in question will be extrapolated without any justification. Anybody can quote a number of examples to corroborate this statement. Only when a certain law governing the shape of the curve is known, the constants and coefficients being determined by experiment, is there reason to express test results by analytical formulas. In transactions of the last year or two one may find a number of papers giving such unjustified formulas having practically no meaning. Introducing a general practice to present experimental data by a curve or by a table, or to define clearly the range of validity of a formula, should one be used, would be of much value.

A. E. R. de Jonge.[10] I think that Mr. Waters is to be congratulated on drawing the attention of engineers in general to the method of least squares and on giving a simple and efficient method which will allow us to solve problems of this kind quickly on the drawing board.

[8] Department of Physics, Columbia University, New York, N. Y.

[9] Research Engineer, Westinghouse Elec. and Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

[10] New York Edison Co., New York, N. Y. Mem. A.S.M.E.

The question which Prof. Whitaker in England raises, that graphical methods are not as accurate as are analytical or computing methods, is of course quite true when it is necessary to apply them with great accuracy; but in practically all cases of average engineering problems this great accuracy is neither necessary nor wanted. I must say I disagree with Professor Whitaker completely in his statement that graphical methods are easily forgotten. I think it is very much easier to remember a process like the one given by the author than to remember a formula, and, as the speaker before outlined, there are limitations to formulas.

Formulas are so often used without accurate knowledge by the person who uses them, of how they have been derived and what limitations are involved; and I must say that I honestly believe that the method which Mr. Waters has outlined is as good as any that may be given in this particular case.

I was originally a naval architect, and in that science the question of integration enters as an everyday problem. We have to find integrals, but we never do it by computation. We always do it graphically, either purely graphically by a simple method of geometrical construction, or by the assistance of an instrument, either the integraph, the integrator, or at least the planimeter.

I think that the use of graphical methods can be recommended, as far as engineering problems are concerned.

The question of using analytical methods or graphical methods is, to my mind, largely a question of personal inclination and ability. Some people like the analytical way of dealing with problems and others the geometrical way, and it is largely a question of the person who uses the method to choose which one suits him best.

I have especially in mind the question of graphic statics. In graphic statics there is nowadays such a tremendous lot of work being done with analytical methods which could so profitably be replaced by a much simpler graphical method. I mention only the question of the elasticity ellipse, which is practically unknown in this country and practically unknown on the other side, too, except in Switzerland, where it originated, has been developed, and used to a very large extent. Professor Culmann is the originator and has developed the method, and after his death Dr. W. Ritter has perfected the method in such a way as to be incomparably simpler than all analytical methods. I say this unreservedly and it is a great pity that these methods are not known either in this country or in England.

I would like to advocate that whenever curves are being given the points from which the curves are derived should be marked on the diagram. It is unfortunately true that many, many curves have been published which do not represent values correctly. The omission of the points does not give one a chance of checking up the actual value of the curve or the actual average which the curve represents. It would be very much more valuable if all those curves and data diagrams which are being published would indicate definitely those points from which they are derived and if this would be made a general practice by members of this Society.

Author's Closure

Mr. Merriam has called attention to the comparatively simple equation for each of the seven cases illustrated in the paper. It was not the author's intention to emphasize equations, but rather the curves which are the real object in any graphical representation of data. However, since the point has been raised, he would state that the equations *are* simple, and for two reasons: (1) The planimeter is admirably suited for performing the operation $a_1b_1 + a_2b_2 + a_3b_3 + \ldots + a_nb_n$ at one setting, as required when two constants are to be determined; but when more than two constants are involved, the products are of higher degree, and consecutive multiplication and addition are not so easy. Incidentally, the standard computing machine would also present difficulties at this point. (2) Simple equations show the trend of the plotted points adequately, without forcing a proximity of the curve to doubtful points.

Fig. 1 illustrates this feature very well. The straight-line relationship between efficiency and rate of firing is of course unreasonable when extrapolated to the y-axis, yet it was quite properly used by the author of the book from which the plotted points were taken (the data of the figure are not original with the present paper) to derive further relations in locomotive-boiler operation of marked importance and value. It would have been quite possible to plot efficiency times rate of firing versus rate of firing as Mr. Merriam suggests, but neither this relationship nor the probable value of the maximum efficiency was considered to be essential.

It is absolutely certain that judgment and common sense must be applied in curve plotting. If points or regions of discontinuity are known to exist, from experience with the tests and observations, they must of course be recognized, the plotted points separated into groups, and individual curves drawn through each group. Skill must also be used in the discarding or weighting of "wild" points. The graphical method is only a technique—a kind of tool; and common sense is necessary in using it just as in applying any other technique to the solution of an engineering problem.

Mr. Merriam's method of testing a curve by tracing circles around the plotted points is interesting and theoretically correct, as far as it goes. Its evident drawback lies in the fact that it satisfies a necessary but not a sufficient condition for proof that a given curve is the best line, as judged by the least-square criterion.

Mr. Karelitz has presented some interesting observations on the relative accuracy of graphical and other methods of integration. It is not at all clear to the author why the sources of inaccuracy mentioned, such as tracing triangles the wrong number of times, are not equally possible when performing the equivalent operation by machine. Furthermore, it is stated that arithmetical averages of observed values are good enough in most cases. How, then, is a straight line, much less a curve, to be located by arithmetical averages? There is an infinite number of straight lines that may be drawn through a field of plotted points, any one of which will have the sum of the deviations equal to zero, but only one of these lines will be the right one.

The criticism that Mr. Gronwall made represents pretty generally the point of view of statisticians, both in this country and abroad. In all of the books on statistics that I have consulted I find that arithmetical methods are explained at great length, and many chapters are devoted to exposition of the best system for tabulating the figures, setting down the products and sums, and giving hints as to how to avoid errors, all of which points to the conclusion that the arithmetical method is not quite as simple as it is claimed to be.

It would seem that the preference of method is largely a matter of the point of view of the user. One designer, in obtaining the size of a machine part, may figure it out by formula; another may use a chart or nomogram of some sort; a third may use both methods, checking one against the other. Personally, I should not like to say dogmatically that any one of these designers uses the best method. My experience with engineering offices in industry has been that graphical systems are frequently preferred; the average engineer can grasp the real meaning of a set of observations by a glance at a graphical chart much better than from a table of figures, and, that being the case, he is more prone to favor graphical methods in any application than he is to favor arithmetical methods.

APM-51-19

Flow Characteristics of Submerged Jets

By M. J. Zucrow,[1] Lafayette, Ind.

In this paper, which deals with submerged square-edged and chamfered short tubes or jets, the author shows by dimensional analysis and corroboratory experiment that the coefficient of discharge for geometrically similar jets is a function of the rate of discharge, the fluidity of the liquid, and the jet diameter. The effect of changing the angle of chamfer was studied as well as the influence of the variations in the length-diameter ratio on the discharge characteristic.

THIS paper deals with the discharge characteristics of submerged square-edged and chamfered short tubes or jets which were calibrated with chemically pure benzol. The diameters of the jets varied from 0.020 to 0.088 in., and the ratio of the length L to the diameter D ranged from 0.318 to 10.57.

By means of dimensional reasoning the conditions for similarity in the motions of liquids through geometrically similar jets are established, and the results checked experimentally. It is shown that the coefficient of discharge C, for geometrically similar jets, is a function of the dimensionless product $w\phi r$, where w is the rate of discharge (gravimetric), ϕ the fluidity of the liquid, and r the reciprocal of the jet diameter in inches.

The effect of changing the angle of chamfer α at the entrance to jets having the same L/D ratio was studied; two chamfer depths were used, namely, 0.008 and 0.040 in. To determine the influence of variations in L/D on the discharge characteristics several square-edged tubes that had the same diameter (0.0326 in.) but different ratios of L/D were calibrated.

Dimensional Treatment of Flow Through a Jet. According to the ordinary laws of hydraulics the flow of liquids through jets and orifices is given by Torricelli's equation as

$$Q = Ca\sqrt{2gh} \quad \ldots\ldots [1]$$

where

Q = volumetric rate of discharge,
C = coefficient of discharge and
a = area of the orifice, or jet, and
h = head expressed in terms of the flowing liquid.

Experiments have demonstrated that C varies with the rate of discharge and with the liquid flowing, and for a particular jet it is affected by certain definite physical quantities, represented by the functional relationship

$$C = f(v,d,\rho,\mu) \quad \ldots\ldots [2]$$

where v is the actual mean velocity of the fluid, defined by the equation $Q = av$, d is the diameter of the jet, ρ is the density, and μ the viscosity. By means of dimensional reasoning it is possible to express dimensionally the foregoing relationship of physical quantities as the product of powers of the fundamental quantities, mass, length, and time.[2] Since C is a pure number, it has no dimensions, and [2] expressed dimensionally becomes

$$O = L^aT^{-a} \cdot L^b \cdot M^cL^{-3c} \cdot ML^{-1}T^{-1} \quad \ldots\ldots [3]$$

The values of the exponents are found to be

$$a = -1,\ b = -1,\ c = -1$$

and

$$C = f\frac{vd\rho}{\mu} \quad \ldots\ldots [4]$$

By a simple transformation it is possible to put [4] in the more convenient form

$$C = f(w\phi r) \quad \ldots\ldots [5]$$

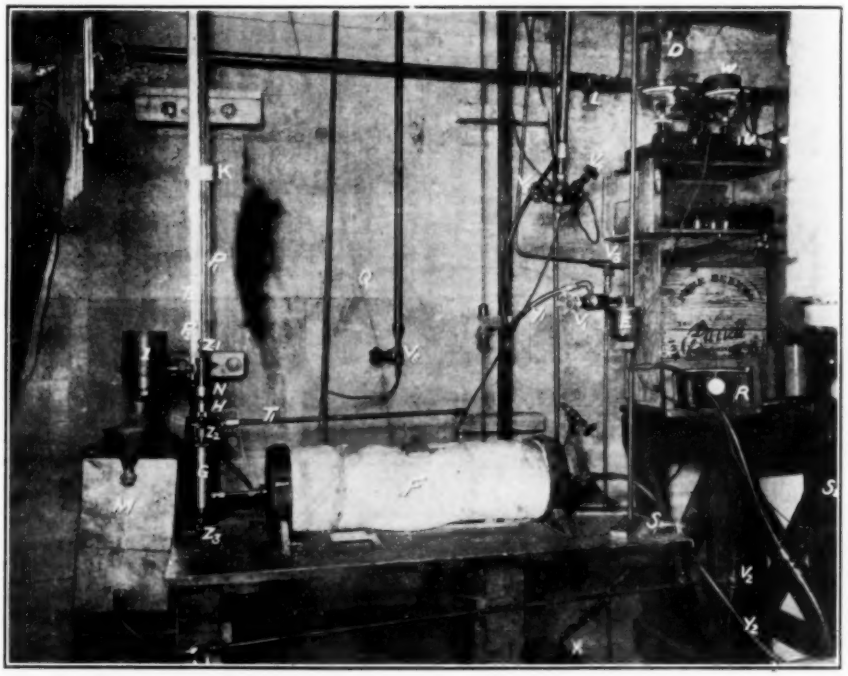

Fig. 1 View of Test Plant

where w = actual rate of discharge (gravimetric)
r = reciprocal of the diameter = $1/d$
ϕ = fluidity of the liquid = $1/\mu$

Since $w\phi r$ is non-dimensional, either English or metric units may be used in its evaluation.

The validity of [5] depends entirely upon the truth of the assumption that v, d, ρ, and μ are the only variables entering into the problem.

Equation [5] tells us that, if C is plotted as a function of $w\phi r$, the resulting curve gives information regarding the effects of temperature and fluid changes upon C from experiments using one liquid and an adequate range of heads. The curve so obtained for a given jet can be regarded as its characteristic curve, and should hold true for all geometrically similar jets.

Description of Apparatus

The test plant is shown in Fig. 1, and the arrangement of the parts is indicated schematically in Fig. 2. The plant embraces the following main components:

1 Jet chamber (*H*)
2 Weir (*I*)
3 Filter (*G*)
4 Heater (*F*)
5 Piezometers (P_1) and (P_2)
6 Float chamber (*E*)
7 Fuel-weighing and electrical apparatus.

Only the last item need be described in detail.

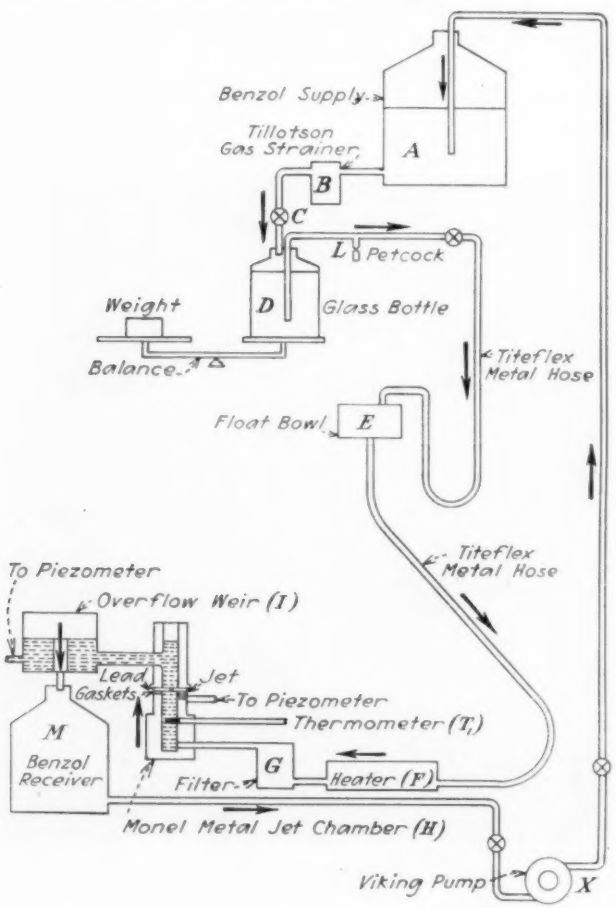

Fig. 2 Arrangement of Apparatus in Test Plant

Fuel-Weighing and Electrical Apparatus. The benzol is piped from the tank *A*, Fig. 2, into the glass bottle *D* located on the left-hand pan of the balance, and shown in the upper right-hand corner of Fig. 1. To give the balance freedom of motion the benzol is siphoned from the bottle to the carbureter float chamber *E*, used to maintain a constant static head upon the jet. The balance is sensitive to less than one-tenth of a gram, and is equipped with a contact wire dipping into the mercury cup *U*. The latter completes an electric circuit when a balance is reached between the scale pans. The completion of this circuit operates the relay *R*, which is used for starting and stopping the decimal-faced stop watch shown in the picture.

The connections from the siphon to the float chamber and from the latter to the heater are made of Titeflex flexible metal tubing. The petcock *L*, shown in the upper part of Fig. 1, is used for priming the siphon.

Course of Flow. Referring to Figs. 1 and 2, the benzol flows from the supply tank *A*, through the Tillotson gas strainer *B*, past the gate valve V_4, into the glass bottle *D*. From here the liquid is siphoned into the float chamber *E*; it then flows through the heater and filter to the jet chamber *H*, upward through the jet into the weir *I*, which maintains a constant submergence of approximately 4 in. upon the jet. The liquid discharged from the weir is caught by the receiver *M*, from where it is returned to the supply tank *A* by means of the motor-driven Viking pump *X*.

Outline of Investigation

The investigation subdivided itself into three subordinate series of experiments.

1—*Geometrically Similar Jets.* This part of the investigation consisted of the calibration of eight different jets having substantially the same *L/D* ratio. The jets were machined in pairs so that there were four different diameters; i.e., each pair had the same diameter. The dimensions and identification numbers of these jets are given in Table 1.

TABLE 1 GEOMETRICALLY SIMILAR JETS

Jet No.	Diameter (*D*) In.	Diameter (*D*) Cm.	Length (*L*) In.	*L/D*
1[1]	0.0882	0.224	0.0289	0.328
1[2]	0.0879	0.224	0.0290	0.330
3[1]	0.0593	0.151	0.0195	0.329
3[2]	0.0593	0.151	0.0195	0.329
4[1]	0.0318	0.0808	0.0101	0.318
4[2]	0.0317	0.0805	0.0106	0.334

5[2]	0.0204	0.0518	0.0069	0.338

The object in making and calibrating two like jets of each diameter was to determine if any desired jet could be reproduced if necessary; further to use the data obtained with one jet as a check on the results obtained with the other.

2—*Chamfered Jets.* To obtain the information pertaining to this phase of the research, ten different jets having substantially the same lengths and diameters were used. One of these, No. 27, was square-edged, the others were chamfered with different included angles. Four of these were chamfered to a depth of 0.008 in., and five to a depth of 0.040 in. The dimensions of these jets are given in Tables 2 and 3.

14	0.0324	0.0823	0.3427	10.570

Properties of Liquid. Commercial chemically pure benzol was used throughout the investigation. The physical properties of this benzol were determined by the Bureau of Standards and are presented in Fig. 3.

Note on Temperature Control. Since plotting C as a function of $w\phi r$ takes into account the effects of temperature changes, no attempt was made to control the temperature of the liquid during the experiments; the temperature variation during any one set of experiments was small in every case, rarely exceeding more than 3 deg. cent.

Presentation and Discussion of Results

Geometrically Similar Jets. Figs. 4, 5, and 6 summarize the investigation with square-edged jets having the same L/D. In Fig. 4 the observed net head h is plotted as ordinate against the rate of discharge W as abscissa. The reason for using W as the independent variable instead of h is to enable the assembling of the complete data on one sheet. Each of the four curves presents the data obtained at substantially constant temperature, with a pair of jets having the same diameter and practically the same length. Of the eight jets, seven have substantially the same L/D ratio, about 0.333; the remaining jet (No. 4^1) has an L/D ratio of 0.318.

The plotted results for each jet of a pair having the same dimensions fall on one curve. This not only confirms the accuracy of the data, but also indicates that it is possible to produce duplicate jets.

Fig. 5 shows the coefficient of discharge C as a function of h. This is the usual method employed for presenting the results of hydraulic experiments.

It is apparent that four different curves, one corresponding to each jet diameter, are required to describe the results. It is seen that when h and L/D are both constant, the coefficient of discharge decreases as the jet diameter is increased. Further, in the case of such short jets, the value of C increases as h decreases. This result is true in a general way of all the jets, but the limits between which C varies narrow as the jet diameter increases. This is readily seen from the curve for jets Nos. 1^1 and 1^2. For these jets C varies from a minimum of 0.620 to a maximum of 0.690, the corresponding values of h being 19 and 3. C does not vary noticeably at the higher heads, the large changes in its value occurring at the lower heads. There appears to be a definite head below which C increases rapidly; this head is different for each pair of jets and decreases with the increase in diameter.

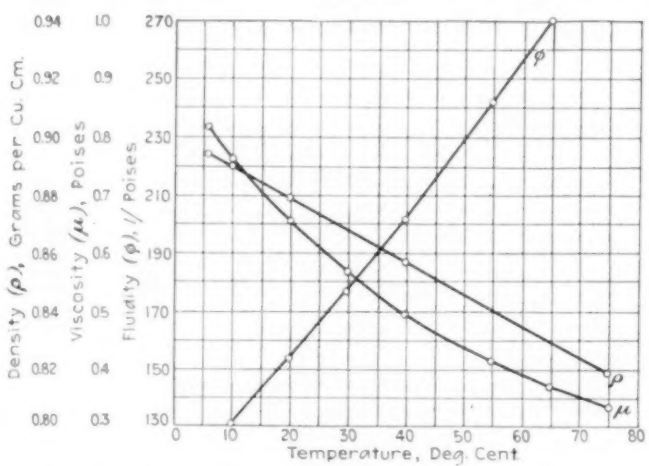

Fig. 3 Physical Properties of Chemically Pure Benzol

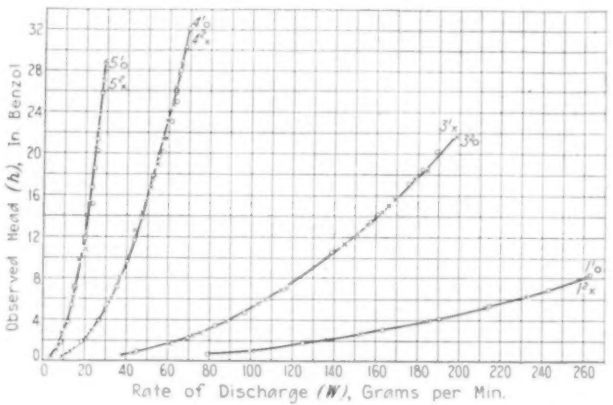

Fig. 4 Submerged Square-Edged Jets, Benzol Flowing. Observed Head Plotted Against Rate of Discharge

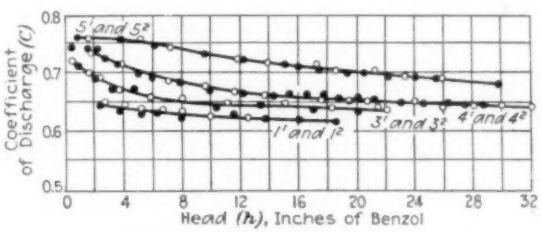

Fig. 5 Submerged Square-Edged Jets, Benzol Flowing. Coefficient of Discharge Plotted Against Head. L/D Substantially Constant

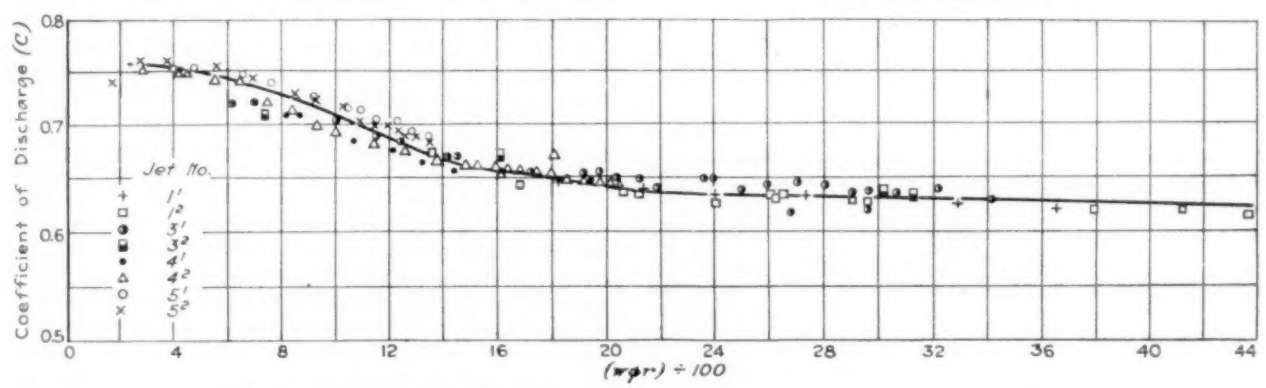

Fig. 6 Submerged Square-Edged Jets, Benzol Flowing. Coefficient of Discharge Plotted Against $w\phi r/100$

The plotting of C against h, as in Fig. 5, presents the results so that they can be readily applied in practice. But from an experimental point of view the mode of presentation has certain disadvantages. To obtain the necessary information a large number of jets must be calibrated, and the temperature must be maintained substantially constant through the tests. Furthermore, if the effect of changing the liquids discharged by the jets is to be studied, the investigation must be repeated for each liquid having a kinematic viscosity different from that used in the original calibration of the jets.

[(*a*) Characteristic curve of Zenith jet No. 110. (*b*) Characteristic curves of Amac jet No. 27 and orifice 1.463 mm. diam. (Orifice curve from results of W. N. Bond.)]

Fig. 6 shows C as a function of the non-dimensional group of variables $w\phi r$. It is apparent that, within the limits of experimental error, the points for all of the jets fall upon a single curve. The curve therefore applies to a single jet, or to any one of a group of square-edged jets with the same L/D.

Before discussing this curve in detail, it should be pointed out that one of the features of this method of presenting the results is the readiness with which it reveals small errors in measurement. For example, if an error of minus 1 per cent is made in measuring the diameter of a jet, two consequences result. First, the coefficient of discharge is increased about 2 per cent. Secondly, the value of $w\phi r$ is increased 1 per cent, which brings the plotted point into the region where the values of C are decreasing. Thus the point is moved upward and to the right, and plotted further off the curve than is the case where C is plotted against h. This may be the reason why the points for jets Nos. 5[1] and 5[2] lie slightly above all the others.

Referring to Fig. 6, we see that as $w\phi r$ is increased, C decreases, but reaches an almost steady value when $w\phi r$ is greater than 2000. The widest variations in C occur within the region containing value of $w\phi r$ less than 1800. If the curve is considered as applying to a single jet, the shape signifies that as the effect of viscosity diminishes (that is, as the fluidity increases) the condition of flow approaches that for a perfect liquid, and C tends to remain constant. The portion of the curve which includes the low values of $w\phi r$ corresponds to a condition of flow where the effect of viscosity is dominant, and probably represents a state of motion which is different from that prevailing where $w\phi r$ has large values. These results are in agreement with those obtained by Bond and by Finlayson (see Fig. 7). Their results, determined independently, were obtained by varying the viscosity of the liquid discharging through a single jet.

The results herein presented, and those of previous investigations, demonstrate conclusively that for similarity in the motions of different liquids through jets, the only condition necessary for geometric similarity is that L/D should be the same for each jet. Consequently, the curve shown in Fig. 6 is equally true for gasoline, water, or any liquid, and for all jets having $L/D = 0.333$. It should be remembered, however, that the viscosity of the liquid must be independent of the rate of shear; a condition which may not exist for heavy oils such as that used by Davidson[3] and oils at low temperatures.[4]

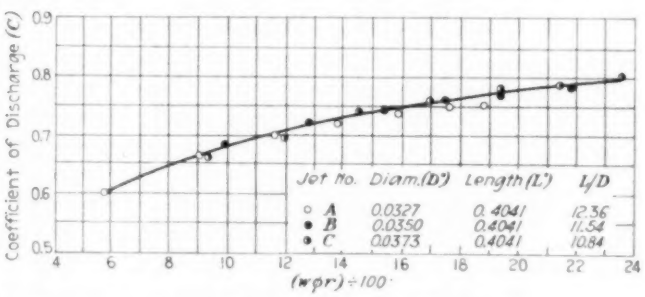

FIG. 8 SUBMERGED CHAMFERED JETS, WATER FLOWING. COEFFICIENT OF DISCHARGE PLOTTED AGAINST $w\phi r/100$

(Obtained by recomputing data of P. S. Tice, N.A.C.A. Report No. 49.)

The results just discussed certainly apply to short jets, but are they equally valid for longer jets? To obtain the answer to this question some of the experimental results, obtained by P. S. Tice[5] with chamfered jets having nearly the same L/D, and discharging distilled water, were recomputed. The recomputed data are shown plotted dimensionally in Fig. 8. Although these jets do not have exactly the same L/D and the depth of chamfer is not proportional to the jet dimensions, these small deviations in geometric similarity produce no material effect; the points for the three jets lie on one curve well within the limits of allowable error. The shape of the curve, however, is quite different from that obtained with the short jets of Fig. 6, for in the case of these chamfered jets C increases as $w\phi r$ is increased.

The work of Bond, Finlayson, Tice (recomputed), together with the experiments of the author, demonstrate that the characteristic curve obtained by plotting C against $w\phi r$ is valid for all liquids flowing through a jet, and for all jets which are geometrically similar to it, within allowable limits.

[5] N.A.C.A. Report No. 49.

The foregoing discussion shows that a complete analysis of the flow of liquids through jets can be made with a minimum of experimental work if dimensional plotting is used. For all that is required is experiments with a single typical jet to determine its characteristic curve, one liquid, and an adequate range of heads. From the characteristic curve, the effect of changing the liquid, the rate of discharge, and the temperature can be calculated.

Effect of L/D—Square-Edged Jets. For this part of the investigation eight different square-edged jets were calibrated. The results are shown in Fig. 9. Of the eight, seven had substantially the same diameter, 0.0326 in., and one jet, No. 4², was slightly smaller, with a diameter of 0.0317 in. The dimensions of the jets are given in Table 4.

The two series of points for jet No. 14 refer to two different sets of experiments conducted with this jet to determine the quality of the edges at the entrance and exit of the jet. The

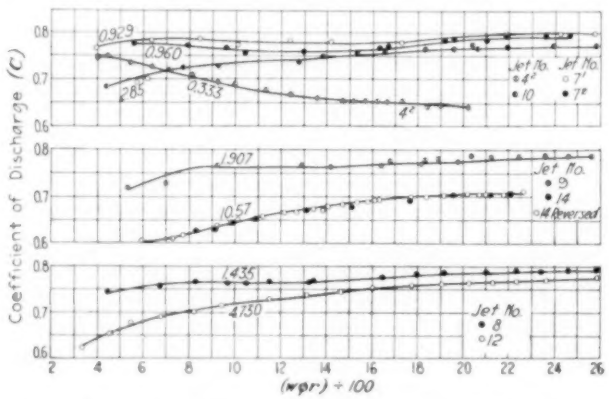

FIG. 9 CHARACTERISTIC CURVES OF SQUARE-EDGED JETS
(L/D varying from 0.333 to 10.57. Numbers refer to values of L/D.)

(Obtained by recomputing data of P. S. Tice.)

side which pointed upstream during the first experiment was facing downstream in the second, so that the exit edge was used for the entrance to the passage. The points referring to this condition correspond to the points labeled "Jet No. 14 Reversed" in Fig. 9. The close agreement between the points indicates that the quality of both edges was about the same, and that if there was any taper or roughness in the passage, it was not of a serious nature.

An examination of Fig. 9 shows that varying L/D exerts a great influence upon the flow conditions within the jets. When L/D is 0.333, the high values of C occur at small values of $w\phi r$ between 200 and 500, and as $w\phi r$ is increased to about 1400 the value of C diminishes, but from this point on C remains practically constant. Increasing L/D to 0.929 completely changes the shape of the characteristic curve. The values of C corresponding to values of $w\phi r$ less than 350 are lower than those for $L/D = 0.333$; but in the region of high values of $w\phi r$ the values of C are much higher than they are for the thinner jet. Thus, when $w\phi r$ is 2000, $C = 0.642$ for $L/D = 0.333$,

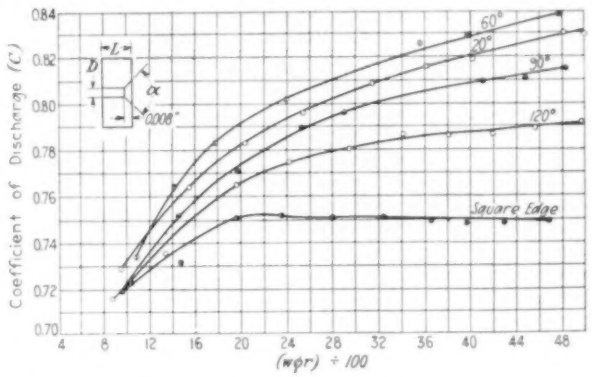

FIG. 11 EFFECT OF SMALL CHAMFER ON UPSTREAM EDGE
(Numbers refer to included angle of chamfer.)

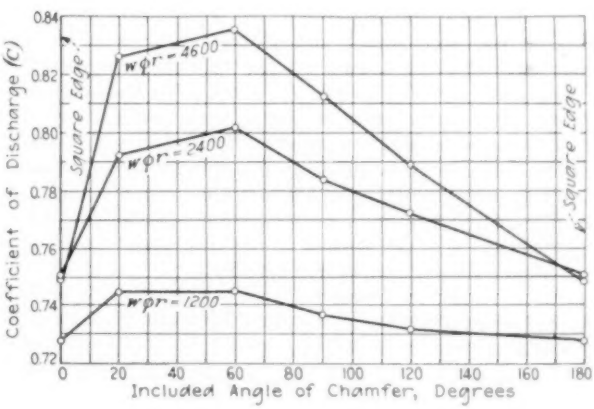

FIG. 12 EFFECT OF CHAMFER
(Depth = 0.008 in.; $L/D = 3.55$.)

and $C = 0.792$ for $L/D = 0.929$. It is also evident that, when $L/D = 0.929$, the variation in C for all values of $w\phi r$ between 700 and 2700 is slightly less than 1 per cent.

A small increase in L/D from 0.929 to 0.960 does not have an appreciable effect upon the shape of the characteristic curve, but the values of C are slightly diminished for the entire range of values for $w\phi r$. As L/D is further increased the values of C corresponding to low values of $w\phi r$ decrease more rapidly than those corresponding to the higher values. For example, consider an increase in L/D from 0.929 to 4.73. When $w\phi r$ is 400, C for the short jet is 0.767 and is only 0.643 for the longer jet, a decrease of 16.2 per cent. When $w\phi r$ is 2600, the corresponding values of C for the short and long jets are 0.789 and 0.770, or C is diminished only 3.5 per cent. At $w\phi r = 600$ the decrease in C is 11.7 per cent.

A comparison between the curves for $L/D = 0.929$ and $L/D = 10.57$ shows that, when $w\phi r = 600$, the decrease in C due to lengthening the jet is 22 per cent. Thus it appears that the increasing L/D decreases the values of C for all values of $w\phi r$, and that the greatest effects occur at the low values of $w\phi r$. It is also evident that the range of values for which C remains substantially constant is reduced, and is only reached with very high values of $w\phi r$.

Effect of Changing Temperatures. The effect of changing the temperature of the liquid is to change its viscosity and density. A rise in temperature increases ϕ, and decreases ρ.

It has been demonstrated that C is a function of v, d, ρ, and μ, and that no other physical properties need be considered. Consequently the effect of increasing or decreasing the temperature

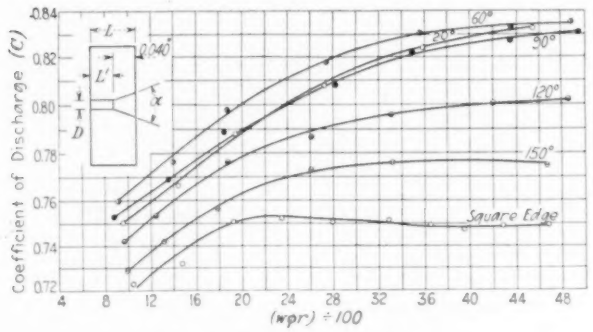

FIG. 13 EFFECT OF CHAMFER
(Depth = 0.04 in.; numbers refer to included angle of chamfer.)

is merely to change the values of $w\phi r$, but the change should have no influence upon the shape of the characteristic curve.

To investigate this proposition, the temperature data given by Tice was recomputed and plotted dimensionally. Tice obtained his data by flowing gasoline through a jet 0.0344 in. in diameter with L/D equal to 11.83. He obtained three different curves, one corresponding to each temperature. The results of the recomputation are shown in Fig. 10, and it is seen that the three curves combine into a single curve, demonstrating that, if an adequate range of heads is used in calibrating a jet, the effect of temperature upon its discharge coefficients can be predicted, and it is unnecessary to perform special experiments to determine the influence of that variable.

Effect of Angle of Chamfer. This investigation is divided into a study of the effect of changing the included angle when the depth of chamfer is 0.008 in., and when the depth is 0.04 in. For simplicity the first set of experiments are termed "small-chamfer" experiments and the second "deep-chamfer" experiments.

Small-Chamfer Experiments. The results of this investigation are presented in Figs. 11 and 12. Fig. 11 shows C as a function of $w\phi r$ for a square-edged jet, and also for four jets having the same total L/D but included chamfer angles α of 20, 60, 90, and 120 deg. The results, as previously shown, apply to all jets which are geometrically similar.

It is evident from Fig. 11 that a small chamfer on the upstream edge of the passage greatly increases the values of C. For example, for the square-edged jet $C = 0.79$ when $w\phi r = 4600$, and for the 60-deg.-chamfered jet, the corresponding value of C is 0.836.

To determine the angle of chamfer which consistently gives the highest values of C, C is plotted as a function of the chamfer angle α for three constant values of $w\phi r$ (see Fig. 12). It is apparent that the maximum values of C occur when α is between 20 and 60 deg. Owing to the number of points being insufficient for an exact determination of this particular angle, the plotted points are connected by straight lines and not by a smooth curve. The graphs show that for low values of $w\phi r$, that is, with viscous liquids or low rates of discharge, chamfering the entrance to the jet has but a small effect upon the value of C; apparently any angle of chamfer gives substantially the same results. In the case of less viscous liquids, or higher rates of flow, a decided gain in the value of C is possible if the angle of chamfer is properly selected.

Deep-Chamfer Experiments. The results are presented in Figs. 13 and 14. In a general way, they are similar to those obtained with the small chamfer. Comparing Figs. 11 and 13 we see that with a deep chamfer the values of C are not as sensitive to small variations in the values of α between 20 and 90 deg., when $w\phi r$ is large, but that C is more sensitive to changes in α when $w\phi r$ is small. The small difference in the results with the deep and small chamfer may in part be attributed to the lack of geometric similarity between the two sets of jets.

The experiments with chamfered jets demonstrate that a slight or deep chamfer on the upstream edge of the passage gives higher values of C than are possible with square-edged jets having the same L/D. By selecting suitable values of α a widely varying range of values of C can be obtained.

CONCLUSIONS

The following conclusions regarding the discharge characteristics of submerged jets are drawn from this investigation:

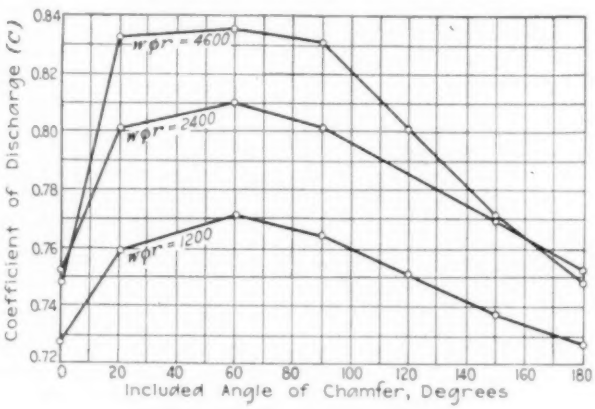

FIG. 14 EFFECT OF CHAMFER
(Depth = 0.04 in.; $L/D = 3.55$.)

1 If C is plotted against $w\phi r$ from data obtained with one liquid, one jet, and an adequate range of heads, the resulting characteristic curve is valid for all jets which are geometrically similar.

2 For square-edged jets and for chamfered jets geometric similarity is obtained when the ratio L/D is the same as that for the calibrated jet.

3 The characteristic curve is valid for any liquid flowing through the jet, and can be used to predict the effect of changing liquids.

4 The characteristic curve takes into account the effects which temperature produces upon the condition of flow.

5 The values of C for square-edged short tubes (L/D less than 1.5) are not very sensitive to changes in liquid, temperature, or rate of discharge, especially for values of $w\phi r$ greater than 600.

6 The length of the jet, the condition of the upstream edge of the passage, the angle of chamfer, and the depth of chamfer have marked influences upon the characteristic curves of jets.

7 Increasing the length of square-edged jets destroys the tendency to constancy of C, especially at low values of $w\phi r$.

8 Chamfering the upstream edge of the passage increases the values of C throughout the entire range of values of $w\phi r$, especially at the higher values.

9 Chamfered jets with an included angle of 20 to 60 deg. have the highest attainable values of C.

10 Increasing the depth of chamfer from 0.008 in. to 0.040 in. slightly increases the values of C.

11 The values of C for chamfered jets are more sensitive to changes in the liquid, temperature, and the rate of discharge, than is the case for square-edged jets with the same total L/D.

APM-51-20

A New High-Speed Fan

By CARL J. FECHHEIMER,[1] EAST PITTSBURGH, PA.

The author describes a centrifugal fan of novel construction for use on steam-turbine-driven generators. In the impeller, straight blades of sheet metal are bulged with respect to a plane passing through the longitudinal axis, and are riveted to the supporting rings. Further to reduce stresses, the blades are made of duralumin, having low density and good physical properties. A partition ring lowers the stresses still more. An analysis of the stresses set up in operation is given, as well as test data of an experimental fan built to deliver 50,000 cu. ft. of air per minute and having a peripheral velocity of 25,500 ft. per min. at 1800 r.p.m. The experimental fan was run up to 83 per cent overspeed.

AS THE sizes of steam-turbine-driven generators have increased, it has become difficult to make internal centrifugal fans wide enough to handle the large volumes of air and at the same time to keep the stresses low enough. The normal peripheral velocity is of the order of 25,000 ft. per min., and the rotors are guaranteed to operate at overspeeds of 20 per cent. The internal diameter cannot be decreased, because there must be sufficient space between the shaft and the fan to admit the air without prohibitively high loss at entrance.

In order that reasonably high fan efficiencies may be obtained, the blades should be inclined backward, and for many applications straight blades, set at about 25 deg. to a tangent at the inner periphery, give good performance.[2] In comparison with the centrifugal forces of the metal parts, the forces due to differences of air pressures and air velocities are negligible. The centrifugal forces acting upon flat blades are then as indicated in Fig. 1, all forces being along radial lines. The components normal to the plane of the blade are the ones requiring consideration.

Viewed from above, the blade and acting normal components are as shown in Fig. 2. These forces produce bending moments in the flat blade, as indicated in Fig. 3. Here $\frac{\text{C.F.}}{2}\cos\alpha$ is the summation of the components of centrifugal forces normal to the blade, for half the blade width; M is the bending moment; and f_s is the shearing force (usually on rivets) needed to balance the centrifugal components. Other things being equal, the bending moment increases as the square of the width, and the stress decreases only as the first power of the blade thickness. For wide fans the blade thickness for safe stresses becomes prohibitive. Several means for overcoming the difficulty suggest themselves: namely, use of partitions so as to reduce the width per blade;[3] use of light-weight material for the blades; and use of curved instead of flat blades. In this paper a description of a high-speed fan is given in which all three of these ideas are incorporated. The blades are curved, but not in a way that is usual in fan- or pump-impeller construction. Each blade is curved with respect to a plane passing through the longitudinal axis.

The forces C.F. cos α in Fig. 2 tend to bend the blade forward, and as soon as the deflection thereby produced becomes appreciable, end thrusts on the supporting rings ensue which tend to draw those rings toward each other. For lower-stressed blades the blade deflection is so small that what small end thrust is produced is counterbalanced by compression in parts of the blades themselves. But for the wide, high-speed fans the end thrust is too great, and increases the blade deflection. Consequently, the tow supporting rings are drawn toward each other and the fan is liable to collapse. The end thrust can obviously be balanced by compression struts, but they interfere with the air flow and complicate the construction.

Suppose that instead of making the blade flat, it be given an initial bulge. It is then possible to reduce the bending moment

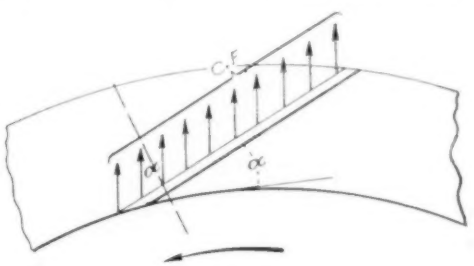

FIG. 1

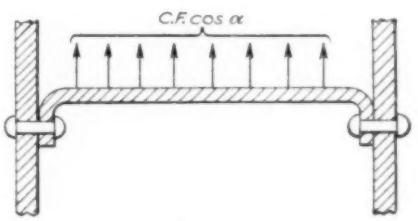

FIG. 2

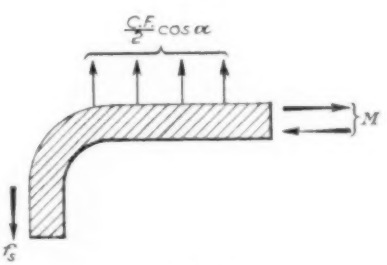

FIG. 3

to a negligible amount. This is the same idea that is embodied in many analogous applications, such as in boiler heads, arches, suspension-bridge cables, etc. If in Fig. 3 the bulge be forward, the resultant forces will be like those indicated in Fig. 4. The bending moment is now replaced by the tensile force f_t in the blade, which in turn is balanced by an end thrust F_t acting against the supporting ring. By properly designing the curvature of the blade, the bending moment is substantially eliminated.

If all the blades be curved forward as in Fig. 4, in order to balance the end thrusts it is necessary to supply axial struts, or their equivalent, as indicated in Fig. 5. However, it is easy to accomplish this in another way and without providing the compression struts.

If the blades are bent initially in the reverse direction, as in Fig. 6, the stress in the blade is changed from tension to compres-

[1] Electrical Development Section Engineer, Westinghouse Electric & Mfg. Co. Mem. A.S.M.E.

[2] See "Performance of Centrifugal Fans for Electrical Machinery," by Carl J. Fechheimer, Trans. A.S.M.E., vol. 46 (1924), p. 287.

[3] A partition is a ring placed equidistant between the two main supporting rings to which the blades are fastened. R_2 in Fig. 12 is such a partition, R_1 and R_3 being the main supporting rings. Obviously, more than one partition may be used to reduce the bending moment in the blades.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

sion, and the end thrust is the reverse of that shown in Fig. 4. It is then quite a simple matter so to construct a fan that the total number of blades is even, and to have the same number of forward-curved (tension) blades as backward-curved (compression) blades, alternating the tension and compression blades. The alternate outward and inward forces on the supporting rings (F_t and F_c in Figs. 4 and 6) balance each other, and no axial struts or bolts are needed.

As in the case of a suspended cord with a uniformly distributed load, the ideal curve should be a catenary. Or, as is well known,

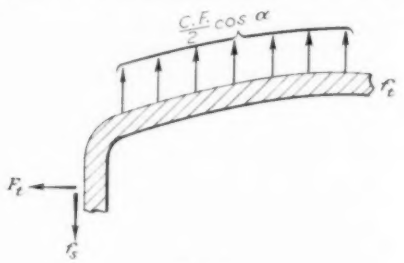

FIG. 4

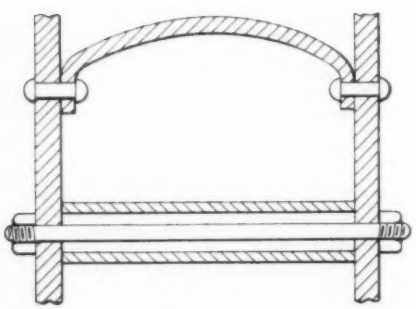

FIG. 5

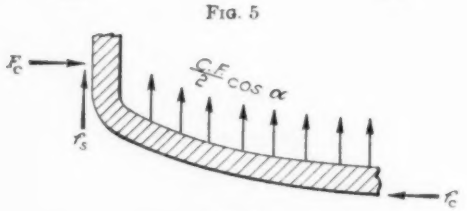

FIG. 6

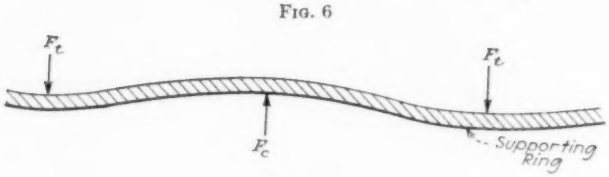

FIG. 7

if instead of uniform distribution along the blade the distribution of centrifugal forces normal to the axis be uniform, the ideal curve is a parabola. It may readily be shown that if the initial bulge is small, an arc of a circle is so close to either a catenary or a parabola that it may readily be used instead. The dies used in the manufacture of the blades are considerably simplified by bending them to an arc of a circle, and consequently that construction was adopted.

It will be noted that the alternate outward and inward forces on the supporting rings produce a bending moment therein. The conditions are like those in a continuous girder, as indicated in Fig. 7. There are various ways of securing an ample factor of safety from the standpoint of stresses due to this bending moment. These may be enumerated as follows:

1 Increase in number of blades, thereby reducing the distance between the points of application of the forces, which reduces the bending moment
2 Increase in section modulus of the supporting ring
3 Use of steel of great strength
4 Decreases in forces F_t and F_c. This may be accomplished in a number of ways:
   (*a*) By means of a partition which makes the axial width of the individual blade half as great
   (*b*) By reducing the thickness of the blades
   (*c*) By use of low-density material in the blades
   (*d*) By increase in initial bulge of the blades.

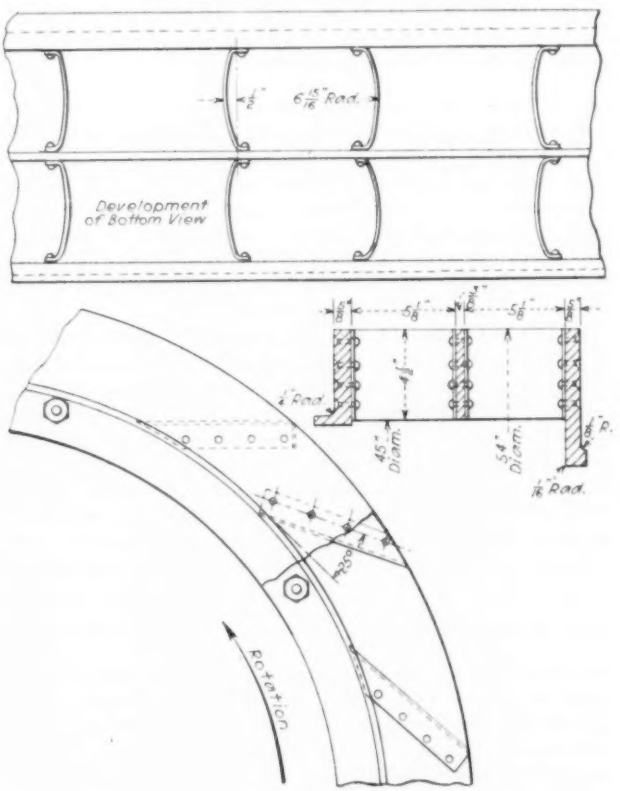

FIG. 8 PROPORTIONS OF EXPERIMENTAL FAN IMPELLER SHOWN IN FIG. 9

The manner in which these points were embodied in the design will now be elaborated upon. They refer to an experimental fan capable of delivering 50,000 cu. ft. per min., and having a peripheral velocity of 25,500 ft. per min., at 1800 r.p.m. Several generators are now operating with internal fans of this design.

1 The number of blades chosen was 18. In so far as performance from the air-flow standpoint is concerned, there is little difference for any number between 12 and 24. With 18 blades, and other proportions as chosen, the calculated stresses in the rings were satisfactory.

2 The supporting ring at the end adjacent to the rotor body is prevented from deflecting much by being backed by the rotor end plate, and by being of sufficient thickness. At the other end either an angle or channel section can be used, and then either one or both projecting parts at the inner or (and) outer diameter act, in conjunction with suitable stationary parts, effectively to seal against air leakage.

3 By using chrome-nickel steel in the supporting rings, the stresses are minimized, even with comparatively thin rings.

4 (*a*) Calculations indicated that for the width of fan needed it would still be advisable to put in one partition, although it might have been possible to employ one span only. (*b*) The blade thickness was made only 0.125 in., which was ample to secure a rigid structure. (*c*) All forces were greatly reduced by the substitution of duralumin for steel in the blades. This material, when suitably heat treated, has about the same physical properties as steel, but only about 36 per cent of its density. (*d*) The initial bulge of the blades was moderate, 0.5 in. for 5.125 in. span. The use of duralumin made for safe operation even with this small initial deflection.

At first glance it might appear that the stresses could readily be calculated with accuracy. But, as is frequently the case in composite structures, an analysis of the stress relations is not a simple problem, and some of the complications are due to incremental stresses arising from elastic deformations. Thus the side thrusts on the supporting rings permit of an incremental bulge of the tension blades, and a decrease of the bulge of the compression blades. Such incremental deflections decrease the tension-blade end thrusts, and increase those for the compression blades. Thus incremental bending gives unequal end thrusts, and the blade must have sufficient thickness to carry this as a bending stress. That is, there is a certain blade thickness below which buckling will occur in the compression blades. The deflections of the rings themselves admit of still further changes in the deflection of the blades, and so on. The resultant series is rapidly converging and the stresses are not much higher than those computed without allowing for incremental deflections, particularly with careful selection of proportions of the supporting rings, number of blades, etc. But from the calculation standpoint the problem becomes complicated, and it was therefore decided to construct an experimental fan. From the results of tests on the fan it will be seen that the construction is sound. In fact, the fan proved to be even better than was anticipated. The proportions of this fan are given in Fig. 8, and in Fig. 9 the completed fan is shown.

The backward-curved blades, as is usual in members under compression, are subject to buckling, and in the design it is important so to proportion those parts as to allow for an ample factor of safety. This was another reason why the partition was used, as without it the other proportions would have had to have been considerably modified to make the fan safe.

The results of calculation of some of the more important stresses are given in Table 1. They are given at 20 per cent overspeed (2160 r.p.m.) and at the maximum speed obtained in test (3300 r.p.m. = 0.83 per cent overspeed). The stresses at the higher speed were taken as $(3300/2160)^2 \times$ stresses at 2160 r.p.m. That is, no corrections were made for elastic nor for plastic deformations.

TABLE 1 CALCULATED STRESSES, POUNDS PER SQUARE INCH[1]

Location	Speed 2160 r.p.m.	Speed 3300 r.p.m.
Tension in blades (forward-curved blades)	1,780	4,150
Ring stress at inner radius, not allowing for blade thrust	25,700	60,000
Ring stress at outer radius, not allowing for blade thrust	27,000	63,000
Ring stress allowing for external loading	43,100	100,000
Bending in compression blades with incremental deflection and compression stress	6,010	14,000
Bending at corners near rivets of tension blades	24,000	56,000
Tension in rivet body	6,330	14,800
Shear of rivet heads	4,000	9,300
Shear of rivet body	4,500	10,400

[1] For calculating the bending in the rings due to the end thrusts, no allowance was made for the stiffening due to their L-shape. Consequently the calculated ring stresses which allow for end thrusts are high. They are about right where no end thrust is considered.

The factor of safety for a blade in compression against buckling is 10.2 at 2160 r.p.m.

The calculation of the bending at the corners of the tension blades requires some assumptions to be made, as the lever arm is uncertain. The figure given in Table 1 for 2160 r.p.m. is closer to the proportional limit or to the yield point of the material than any other, but if the yield point is passed, plastic deformation of the duralumin reduces the stresses.

In order to reduce the power required to drive the fan, a special set-up was made, in which the ingoing-air volume was reduced to a minimum by means of a wheel which revolved with the rest of the fan and cleared the rotating flange by only $^1/_8$ in. Even so, the power consumption was considerable, and the reason that higher speeds were not obtained was because the driving belt slipped, and the driving motor was overloaded. The set-up for the test is as shown in Figs. 10 and 11. The blower was placed in the frame of a turbine generator which was lined with heavy

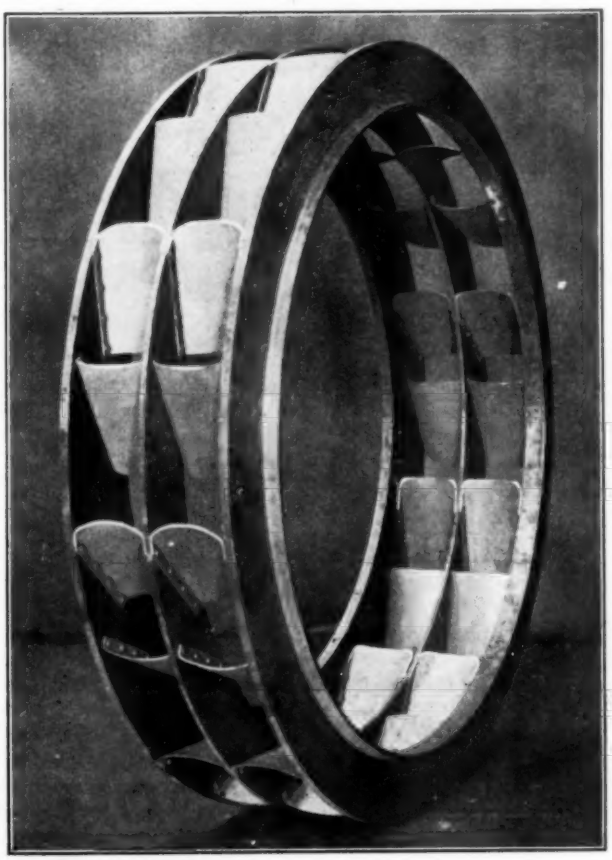

FIG. 9 VIEW OF EXPERIMENTAL FAN IMPELLER

timbers for safety in the event that the blower should fail at some high speed. The tests consisted of running at consecutively increasing speeds, starting with 1600 r.p.m., holding the speed for 10 min. at each speed, and shutting down between runs to take measurements. These measurements consisted in taking observations on a Berry strain gage[4] of (1) distances along the rings, (2) axial distances between rings, and (3) chordal distances between adjacent blades. As the air and fan got warm, and as the

[4] The unit for this gage is 0.0002 in., thereby detecting very small changes over a total Berry strain-gage length of $5^1/_8$ in. (the width of a blade). This corresponds to a strain of $(0.0002/5.125) = 39/10^6$ inches per inch. The stress for unit change then is: $(39/10^6)E$, where E is the modulus of elasticity. Taking E to be 30×10^6 as for steel, the stress for unit change is 1170 lb. per sq. in. For duralumin with a modulus of about 10×10^6, it is 390 lb. per sq. in., thus indicating the accuracy with which the measurements were made.

temperatures caused expansions, thereby affecting the strain-gage readings, the temperatures were also taken, and suitable corrections made therefore in the strain-gage readings. The blower was run at 2700 r.p.m. for one hour, to note the effect of longer time, and the final speed was 3300 r.p.m., for 10 min., after which, owing to the overload on the driving motor and belt, the tests were discontinued. There was no failure at the last-named speed, which corresponds to 83 per cent overspeed of the generator

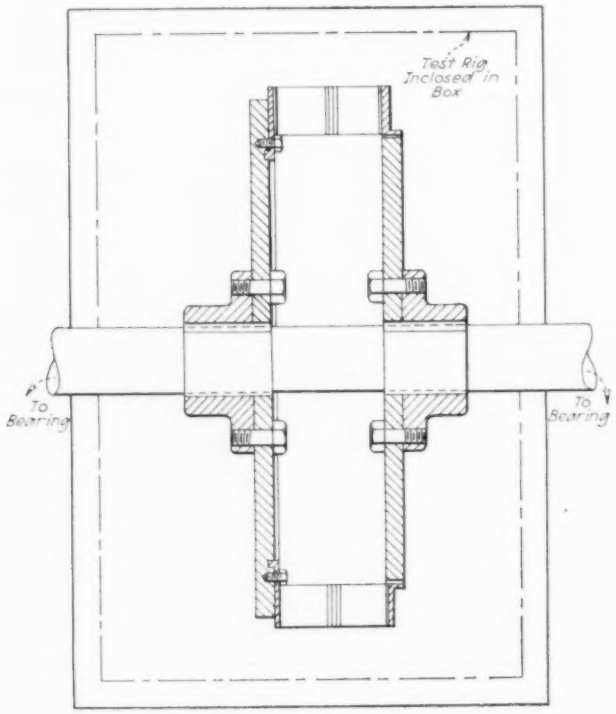

FIG. 10 SET-UP FOR TEST

and to a peripheral velocity of 46,700 ft. per min. (8.85 miles per min.).

The results of the tests indicated that there were no permanent sets in the rings such as was originally thought might take place (as indicated exaggerated in Fig. 7). What the strain-gage measurements did show was that the distance between the outside ring and the middle supporting ring increased slightly, and the distance between the inner ring and the one normally attached to the rotor end plate decreased a little. The measurements between adjacent blades corroborate these results. The first signs of permanent set occurred at 2300 r.p.m., i.e., above the overspeed usually specified.

An explanation of these deformations is offered herewith. Ring R_1 (Fig. 12) remains fixed. Ring R_2 is free to move, and it is substantially equally loaded on either side. R_3 is loaded on one side only, and largely owing to the non-uniformity of the section—the extension was at the outer diameter only—this ring was distorted as shown exaggerated by dotted lines. Had the section used been a channel instead of an angle, this distortion would have been nearly eliminated. It should be noted that the permanent sets were in the blades and were sufficient to hold the rings in the position shown, even after the fan was shut down. After having been run at high speed, the elongated outer parts of the blades meet opposing forces in the inner blades, causing the latter to compress a little, as was found from the Berry gage readings. It was noteworthy that at no speed was there a wavy deformation of the supporting rings, as the calculations had led the author to believe might take place. If there were such tendencies to deform, the elasticity of the ring caused it to resume its form before it was shut down.

In the last column in Table 1 are given the calculated stresses at the maximum speed attained. In Table 2 are given the physical properties of the materials as determined from measurements on suitable test bars taken from the ring forgings or blade sheet.

TABLE 2 PHYSICAL PROPERTIES OF MATERIALS USED IN RINGS AND BLADES

	Proportional limit[1]	Yield point	Ultimate tensile strength	Per cent elongation in 2 in.	Per cent reduction in area
Chrome-nickel steel in rings	...	88,000 to 91,000	122,000 to 124,500	22 to 25.2	61.8 to 63.8
Heat-treated duralumin in blades	17,500 to 18,000	34,270 to 34,800	54,100	18	26.4

[1] Proportional limit taken as the end of the straight-line part of the stress-strain diagram. Yield point taken as 0.2 per cent of the plastic deformation of duralumin.

If the calculations were correct, it will be seen that the bending stress at the corners of the tension blades at 2300 r.p.m. was 27,000 lb. per sq. in., or above the proportional limit but below the

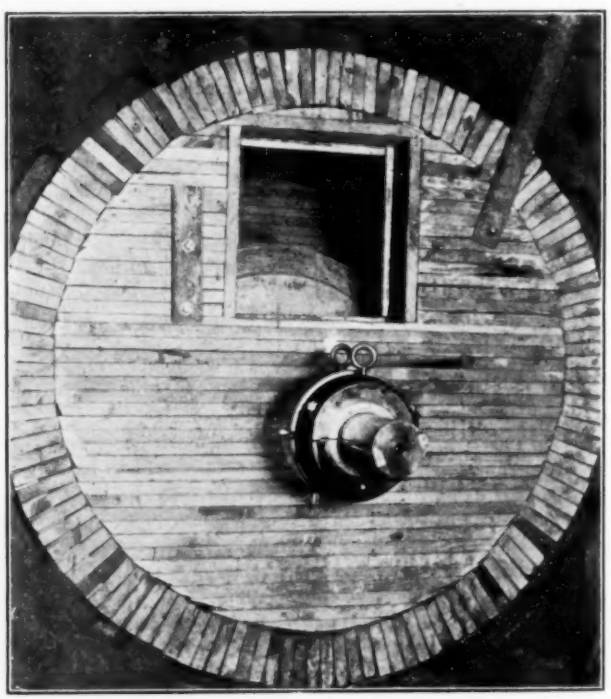

FIG. 11 SET-UP FOR TEST

yield point. Also, according to calculations the yield point of the chrome-nickel steel was passed shortly before the maximum speed of 3300 r.p.m. was reached.

Subsequent to making these tests, the duralumin blades were removed, and steel blades 0.156 in. thick, instead of 0.125 in. for duralumin, were substituted. The superiority of heat-treated duralumin was thereby proved. Permanent sets appeared at 1700 r.p.m., and at 2300 r.p.m. the vibration became so great, due to distortions, that tests at higher speeds were abandoned.

In Table 3 are given comparisons of bending stresses in flat blades for a fan 5.125 in. wide between rings and running at 2160 r.p.m. The blades were considered to be beams with fixed ends, giving two-thirds the stress that would obtain with a beam with free ends. With this assumption, the maximum stress occurs

near the corners of the blade, but the blade is highly stressed at the middle, too. At the corners, plastic deformation reduces the stresses beyond the elastic limit. This undoubtedly took place at the corners of the curved-blade fan, and yet failure was avoided, even though at the final speed at which the fan was run the calculated stress at the corners was more than double what it was at the speed corresponding to the yield-point stresses.

TABLE 3 BENDING STRESSES IN FLAT BLADES (LB. PER SQ. IN.)

Material	Thickness = 0.125 in.	Thickness = 0.1875 in.
Duralumin	28,400	19,000
Steel	79,500	53,000

As previously pointed out, the objection to the flat blades is that once they start to deform, the whole fan may collapse. With the curved blades, the highest blade stress occurs at the bend near the rivets, and plastic flow and permanent sets follow, but failure does not ensue.

Small models of the experimental fan with arched blades and of one with flat blades were run in the same test rig to determine their performances. The differences for the two in the pressure-volume and efficiency curves were negligible, being so small as to be within the range of experimental error.

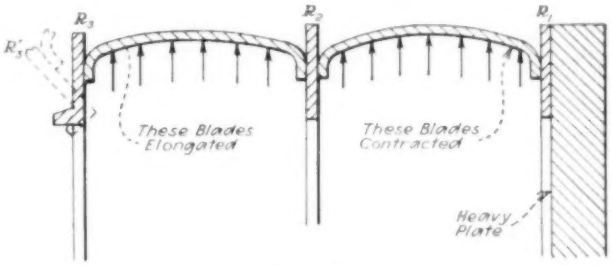

FIG. 12

During this investigation, Messrs. S. Timoshenko, G. W. Penney, and J. DenHartog advised regarding method of calculating stresses. M. Stone conducted the tests, and placed the results in report form. The work of these men was much appreciated, and the value of their work is hereby acknowledged.

APM-51-21

Vibration Damping, Including the Case of Solid Friction

By A. L. KIMBALL,[1] SCHENECTADY, N. Y.

The idea of logarithmic vibration decrement is briefly reviewed and several ways of expressing it and finding it are given.

The simple case of a vibrating reed is treated, three kinds of damping being considered—(1) an external liquid damping, (2) a liquid viscosity damping within the spring, (3) solid damping within the spring whereby the dissipation per cycle is independent of frequency but depends upon amplitude squared. For an experimental study and discussion of this type of damping see "Internal Friction in Solids," by A. L. Kimball and D. E. Lovell.[2]

These cases are discussed both for free vibrations and sustained vibrations.

A method is given for analyzing solid damping vibration problems which is of general application to all cases of vibration that can be treated on the assumption of an ideal viscosity damping. This method is used by Ormondroyd and Den Hartog in the closure to the discussion of their paper[3] *entitled "The Theory of the Dynamic Vibration Absorber."*

The discussion of vibration damping given herewith presents methods used by the writer for several years past in vibration work.

Logarithmic Decrement

By way of introduction the idea of logarithmic decrement will be briefly reviewed, as a clear understanding of it is of basic importance for the appreciation of what is to follow. Consider a damped vibration as given by the following equation and shown in Fig. 1:

$$y = y_0 e^{-\alpha t} \cos \omega t \qquad [1]$$

The logarithmic decrement δ is defined as the natural logarithm of the ratio of any two successive amplitudes of a vibration whose amplitude decreases exponentially, such as that given by Equation [1].

Expressing mathematically,

$$\delta = \log \frac{y_0}{y_1} = \log \frac{y}{ye^{-\alpha T}} = \log e^{\alpha T} = \alpha T \qquad [2]$$

where T is the period of a complete vibration.

Another useful way of expressing δ is derived by making use of the logarithmic series

$$\log x = x - 1 - \tfrac{1}{2}(x-1)^2 + \cdots \qquad [3]$$

For any amplitude y

$$\delta = \log \left(\frac{y + \Delta y}{y} \right)$$

(see Equation [2]), where Δy represents the decrease of y per cycle as shown in Fig. 1. Substituting in [3]

$$\delta = \frac{\Delta y}{y} \qquad [4]$$

where all terms of the series except the first are dropped since they are relatively small in most cases of vibration damping met with in practice.

The latter expression for δ is very useful because by means of it δ can be found at once by a simple measurement from a graph (or a photograph) of the damped vibration like that given in Fig. 1.

When δ is known, the amount of energy dissipated per cycle, ΔW, can be found as follows:

The total vibrational energy W, at some time t, equals ky^2

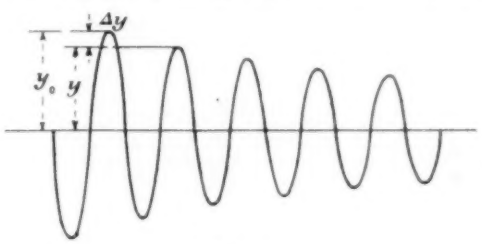

Fig. 1

since it equals the maximum potential energy of the system. The total vibrational energy one cycle later equals

$$k(y - \Delta y)^2 = W - \Delta W$$

Subtracting the latter from the former to find ΔW

$$\Delta W = k(y^2 - y^2 + 2y\,\Delta y - \Delta y^2) = 2ky\,\Delta y$$

where $-\Delta y^2$ is dropped as being negligible. Therefore,

$$\frac{\Delta W}{W} = \frac{2ky\,\Delta y}{ky^2} = 2\frac{\Delta y}{y} = 2\delta$$

$$\Delta W = 2W\delta \qquad [5]$$

In words, this equation says that the energy dissipation per cycle of a vibration whose amplitude decreases exponentially with time is equal to the total energy of the vibration at the time in question multiplied by twice the logarithmic decrement.

Any elastic vibration with any form of decrement has a definite instantaneous logarithmic decrement at each point. Expression [5] is expressed in terms of the logarithmic decrement as found from some point on a decrement curve of such a vibration. No matter what be the shape or the mode of vibration of the body, this relation is applicable. Although not mathematically exact, it is very useful in work involving vibration damping.

It is seen that three different expressions for the logarithmic decrement δ are given under expressions [2], [4], and [5].

The best way to appreciate the physical meaning of δ is through expression [4] as applied to the graph of Fig. 1. When once δ is known for any amplitude, for a vibrating system, the rate of energy dissipation through friction is at once obtained through [5], and if the decrement is constant, the resonance vibration amplitudes can also be found (see Table 2).

Three Cases of Vibration Damping

The vibratory motion of a reed carrying a mass m, such as that

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

shown in Fig. 2, may be found from the well-known differential equation:

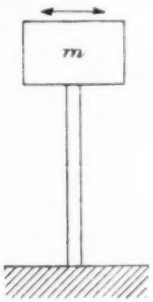

FIG. 2

$$m\frac{d^2y}{dt^2} + b\frac{dy}{dt} + cy = 0 \quad \ldots\ldots [6]$$

where m = mass carried by reed
b = a damping factor
c = elastic constant of reed
= elastic force exerted by reed when m is displaced unit distance from its rest position
y = displacement of m from its rest position at time t.

The solution of this equation is

$$y = y_0 e^{-\frac{bt}{2m}} \cos \omega_0 t \quad \ldots\ldots [7]$$

where

$$\omega_0 = \sqrt{\omega_c^2 - \frac{b^2}{4m^2}} \quad \ldots\ldots [8]$$

in which

$$\omega_c = \sqrt{\frac{c}{m}}$$

Equation [7] is seen to be the same as [1] when

$$\alpha = \frac{b}{2m}$$

Case I. *The damping such that b is independent of c and m.*

An example of such a system is one in which the damping is produced by the motion of the mass m in an ideal viscous liquid, neglecting any damping action within the reed itself. In this case b is assumed independent of c and m. However, the vibration frequency of the reed may be changed through the variation of c or m.

In this case from [1], [2], and [7]

$$\delta = \alpha T = \frac{bT}{2m} \quad \ldots\ldots [9]$$

From [8], the period of vibration

$$T = \frac{2\pi}{\omega_0} = \frac{2\pi}{\sqrt{\omega_c^2 - \frac{b^2}{4m^2}}} \quad \ldots\ldots [10]$$

Substituting [10] in [9]

$$\delta = \frac{\pi b}{m\sqrt{\omega_c^2 - \frac{b^2}{4m^2}}} \quad \ldots\ldots [11]$$

When α is relatively small, the second term under the radical is neglected and

$$\delta = \frac{\pi b}{m\omega_c} = \frac{\pi b}{\sqrt{mc}} \quad \ldots\ldots [12]$$

since $\omega_c = \sqrt{\frac{c}{m}}$

Case II. *Damping produced by friction within reed obeying the liquid viscosity law.*

In this case b is a parameter depending upon the form and properties of material of the elastic support, as expressed by Equation [18].

The calculation of an expression for δ in this case is best made from Equation [5] after evaluating ΔW and W.

Consider a unit volume of the solid as shown in Fig. 3.

Let the friction component of force per unit velocity of strain in the direction shown by the arrows be equal to η. This is, in

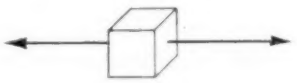

FIG. 3

fact, what is sometimes called the *coefficient of normal viscosity.*

Thus if ϵ = strain per unit length, the viscosity force produced upon the faces of the unit cube during elongation or compression is

$$\eta\frac{d\epsilon}{dt} \quad \ldots\ldots [13]$$

If

$$\epsilon = \epsilon_m \sin \omega t, \quad d\epsilon = \epsilon_m \cos \omega t d(\omega t)$$

where ϵ_m = half amplitude of the strain. Therefore, the damping force $= \eta\epsilon_m\omega \cos \omega t$

Now work per cycle per unit volume is

$$\Delta W_1 = \int \text{force} \times d\epsilon$$

taken over one cycle, therefore

$$\Delta W_1 = 2\int_0^{\pi} \eta\epsilon_m^2\omega \cos^2 \omega t d(\omega t) = \pi\eta\epsilon_m^2\omega \quad \ldots\ldots [14]$$

ΔW = total dissipation per cycle in entire volume of the material of the vibrating body

$$= \int\int\int \pi\eta\epsilon_m^2\omega dV \quad \ldots\ldots [15]$$

where V is the volume.

The total vibrational energy may be expressed in terms of the elastic potential energy of maximum strain

$$W = \int\int\int \tfrac{1}{2}\epsilon_m^2 E dV \quad \ldots\ldots [16]$$

Substituting [15] and [16] in Equation [5] and solving for δ

$$\delta = \frac{\pi\eta\omega_c \int\int\int \epsilon_m^2 dV}{E\int\int\int \epsilon_m^2 dV} = \frac{\pi\eta\omega_c}{E} \quad \ldots\ldots [17]$$

where ω is replaced by ω_c characteristic of a free vibration. Since the volume boundary is the same in the two cases, the integrals cancel. From [12] and [17],

$$b = \frac{\delta m\omega_c}{\pi} = \frac{\eta m\omega_c^2}{E} = \frac{\eta c}{E} \quad \ldots\ldots [18]$$

where in [17] ω_c is replaced by $\omega_c = \sqrt{\frac{c}{m}}$ as an approximation.

Case III. *Solid damping where dissipation per cycle is independent of the frequency.*

In accordance with previous work done by the writer[2] it will be assumed, as a good approximation, that loss per unit volume per

cycle $= \xi\sigma_m^2$, where σ_m is the maximum stress at the point considered,

$$= \xi\epsilon_m^2 E^2 \quad [19]$$

Then

$$\Delta W = \int\int\int \xi\epsilon_m^2 E^2 dV$$

and as before W is given by [16]. Substituting in [5] as before and canceling the integrals

$$\delta = \xi E \quad [20]$$

From [9],

$$b = \frac{m\omega_c \xi E}{\pi} = \frac{\xi E\sqrt{mc}}{\pi} \quad [21]$$

Comparison of the Three Cases

Table 1 shows the values of b and δ for the three cases arranged for comparison.

TABLE 1

		δ, log decrement	b, damping factor
I	Damping with b depending on external viscous friction only	$\frac{\pi b}{\sqrt{mc}}$	b independent of m and of properties of material of rod
II	Liquid damping (often wrongly applied to solids)	$\frac{\pi\eta\omega_c}{E}$	$\frac{\eta c}{E}$
III	Solid damping (correct law of solid damping)	ξE	$\frac{\xi E\sqrt{mc}}{\pi}$

In case I, although b is independent of the frequency of the vibration, the decrement δ decreases either with an increase of the mass m carried by the reed or its stiffness c.

In case II, b is proportional to the stiffness c but independent of m. The decrement δ increases with the frequency of the vibration.

In case III, the damping factor b depends upon both m and c. The decrement δ is *independent of frequency*, the loss per cycle being also independent of the frequency.

In this table, the values given for b apply, of course, only to a vibrating system with a concentrated mass m like that of Fig. 2. The value of δ under case I applies only to a system of one degree of freedom.

In cases II and III, however, the expression given for δ holds for any type of vibration or any vibrating system whatsoever which derives its elasticity and dissipation from one material such as a given type of steel. For instance, if a vibrating bar is substituted in place of the system shown in the figure, the expressions for δ under II and III still hold. The mathematical derivations given from Equations [13] to [17] are the same in this case as before.

The important difference between the δ of case II and that of case III (true solid damping) is that in the former it depends upon the vibration frequency, and is proportional to it; in the latter it is a constant for all frequencies.

Remarks on Method of Analysis

At first thought, it seems surprising that solid damping, where apparently the liquid viscosity law does not apply, should be handled by an equation of the form [6] whose damping term $b\frac{dy}{dt}$ gives a force depending upon velocity, like that produced by liquid viscosity.

The solution of this equation gives an exponential amplitude decrement curve from which it follows that a constant log amplitude decrement is obtained. Now the requirement for an exponential amplitude decrement of a vibration is simply that the dissipation per cycle be proportional to the amplitude squared. This condition is fulfilled in all three of the cases discussed, so that the amplitude decrement curve of Equation [6] applies in all three cases, provided the damping factor b is looked upon as a parameter and evaluated as previously illustrated for the special case considered.

The exact form of the vibration curve, however, aside from amplitude decrement, *does* depend upon the shape of the hysteresis loop. Equation [1] applies at all instants only when the hysteresis loop is of elliptical form. A vibration arising from some other form of hysteresis loop can be exactly represented by replacing the single cosine factor by the correct harmonic series.

Application to the Case of Sustained Vibrations

For a case of a sustained vibration, produced by a sinusoidal force $F\cos\omega t$, the differential equation of the system of Fig. 1 takes the form

$$m\frac{d^2y}{dt^2} + b\frac{dy}{dt} + cy = F\cos\omega t \quad [22]$$

This equation is the same as [6] except for the right-hand term. The solution of this equation is well known to be

$$y = y_o e^{-\frac{bt}{2m}}\cos\omega_o t + \frac{F\cos(\omega t + \beta)}{\sqrt{(c - m\omega^2)^2 + b^2\omega^2}} \quad [23]$$

where

$$\omega_o = \sqrt{\omega_c^2 - \frac{b^2}{4m^2}} \qquad \text{see Equation [8]}$$

and where

$$\tan\beta = \frac{b\omega}{c - m\omega^2} \quad [24]$$

Equation [23] contains two terms, the first the transient term which dies out with time, and the second a sustained-vibration term which remains. The first is the solution of Equation [6] which has been discussed already. In what follows, only the last term will be considered, and from it a study of the variation of amplitude with the frequency of the applied stimulus will be made for the three types of damping discussed previously for the system shown in Fig. 2.

Case I: b independent of m and of properties of the material of the rod.

$$y_m = \frac{F}{c\sqrt{\left(1 - \frac{\omega^2}{\omega_c^2}\right)^2 + \frac{b^2\omega^2}{c^2}}} \quad [25]$$

where y_m = maximum value of y for a given ω and $\omega_c = \sqrt{\frac{c}{m}}$ as in Equation [8].

When $\omega = \omega_c$, and when b is small, y_m has very nearly its maximum possible value, and the system is in resonance.

Case II. In this case for any unit volume the elastic stress is $E\epsilon$ and the frictional stress $\eta\frac{d\epsilon}{dt}$, Equation [13]. They are both sinusoidal and 90 deg. apart in phase. The ratio of the amplitude of the frictional stress to that of the elastic stress is seen to be independent of amplitude and thus equal to the same constant for every point in the vibrating elastic material. It follows that the ratio of the amplitude of the frictional term $b\frac{dy}{dt}$ to the elastic term cy for the entire vibrating body, as given by Equation [22], must also be equal to this constant. Expressing mathematically,

$$\frac{\eta\left(\frac{d\epsilon}{dt}\right)_m}{E\epsilon_m} = \frac{b\left(\frac{dy}{dt}\right)_m}{cy_m}$$

but since the vibration is sinusoidal and isochronous for every unit volume

$$\frac{\left(\frac{d\epsilon}{dt}\right)_m}{\epsilon_m} = \frac{\left(\frac{dy}{dt}\right)_m}{y_m} \text{ so that } b = \frac{\eta c}{E}$$

This is seen to agree with the value of b from Table 1 for this case. Substituting in Equation [25],

$$y_m = \frac{F}{c\sqrt{\left(1 - \frac{\omega^2}{\omega_c{}^2}\right)^2 + \frac{\eta^2\omega^2}{E}}} \quad \ldots\ldots [26]$$

This equation is seen to differ from [25] only by the const. $\frac{\eta^2}{E^2}$ which replaces $\frac{b^2}{c^2}$. Thus, the amplitude curve as a function of frequency of stimulus is of the same form in the two cases. This is what would be expected because in both case I and case II the damping is viscous in character, the friction being proportional to the displacement velocity.

Case III. In this case also the frictional force component per unit area can be expressed as $\eta \frac{d\epsilon}{dt}$ assuming, as before mentioned, that the actual hysteresis loop of solid friction is replaced by one of equal area but of elliptical form, as required by this relation for a sinusoidal vibration. The coefficient η will then be a parameter depending upon other physical quantities. It may be evaluated by equating the work per cycle arising from this frictional force (see Equation [14]) to that obtained by experiment for solid friction (see Equation [19]).

This gives

$$\eta\pi\epsilon^2{}_m\omega = \xi E^2\epsilon^2{}_m$$

therefore

$$\eta = \frac{\xi E^2}{\pi\omega} \quad \ldots\ldots [27]$$

Comparing the frictional and elastic terms for a unit volume with those for the entire body as under case II,

$$\frac{b}{\eta} = \frac{b\pi\omega}{\xi E^2} = \frac{c}{E}; \; b = \frac{\xi E c}{\pi\omega}$$

This also agrees with the value of b under case III of Table 1 except that in that case ω was given the value $\omega_c = \sqrt{\frac{c}{m}}$ characteristic of a free vibration.

Substituting in Equation [25],

$$y_m = \frac{F}{c\sqrt{\left(1 - \frac{\omega^2}{\omega_c{}^2}\right)^2 + \frac{\xi^2 E^2}{\pi^2}}} \quad \ldots\ldots [28]$$

The three values of y_m given by Equations [25], [26], and [28] corresponding to the three kinds of damping apply, of course, only to the particular case of the vibrating system of Fig. 1, whose motion is found from the Equations [6] and [22].

At resonance where $\omega = \omega_c$, at which frequency the amplitude is limited by the frictional resistance only, it is evident that for the same magnitude of the decrement δ, the amplitude must be the same in all three cases. This is shown to be the case in Table 2, where the values of δ are taken from Table 1.

TABLE 2

Case of damping	y for $\omega = \omega_c$	δ	y_m for $\omega = \omega_c$ in terms of δ
I	$\frac{F}{b\omega_c}$	$\frac{\pi b}{\sqrt{mc}}$	$\frac{\pi F}{c\delta}$
II	$\frac{FE}{c\eta\omega_c}$	$\frac{\pi\eta\omega_c}{E}$	$\frac{\pi F}{c\delta}$
III	$\frac{\pi F}{c\xi E}$	ξE	$\frac{\pi F}{c\delta}$

General Case of Solid Damping

Since the solid damping of case III is the type usually met with in actual cases where springs are used, this latter is of particular interest and importance. The method of solving the reed vibration problem for solid damping is general for this type of damping. Any such problem can be expressed mathematically by replacing η, the friction coefficient, as defined by Equation [13] for viscous friction, by its value for solid friction just derived under case III, Equation [27], namely

$$\eta = \frac{\xi E^2}{\pi\omega}$$

Thus all problems in elastic vibration which can be solved for cases involving an ideal viscous friction within the elastic material are also susceptible of solution for the case of solid friction, where dissipation per cycle is independent of frequency, but depends upon amplitude squared such that $\Delta W_1 = \xi\sigma_m{}^2$, where ΔW_1 is the frictional loss per unit volume per cycle.

The logarithmic decrement for all such vibrations is independent of the frequency, and is equal to ξE (see Equation [20]).

Discussion

R. H. Canfield.[4] In this paper we have a very useful comparison of different possible types of solid friction as regards the dying out of free vibrations. It should be emphasized that the application of the differential Equation [6] to the problem of Case III, Solid Damping Where Dissipation per Cycle is Independent of the Frequency, is, as he says, an approximation. The present writer has already[5] carried out the solution of this problem for the case of forced vibrations of constant amplitude in a rigorous form, but assuming a parallelogram form of hysteresis curve, without the use of a differential equation. The law of internal friction here specified is that which Mr. Kimball was instrumental in establishing as the general law for solid friction. Experiments by the present writer[5] indicate that the exact law is not quite as simple as the above. In fact, the loss per unit volume per stress cycle seems to be represented somewhat more accurately by the expression $\xi f(f - f_0)$ than by ξf^2, which is the author's original equation. In this case f_0 is a small "threshold stress" below which the internal friction is negligibly small. The threshold f_0 may be of the order of zero or range as high as 4000 lb. per sq. in., the larger values being found in freshly overstrained material.

J. P. Den Hartog.[6] The paper deals with the vibrations of a cantilever beam (Fig. 2) with different kinds of damping, of such a nature that the motion can be expressed by Equation [6] or [22]. In this connection the title of the paper might give rise to the misunderstanding that this method also covers cases where the damping is caused by solid friction between dry surfaces, like leaf springs, certain types of automobile snubbers,

[4] Associate Physicist, Naval Research Laboratory, Anacostia, D. C.

[5] *Physical Review*, vol. 32, no. 3, September, 1928, pp. 520–530.

[6] Research Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

etc. This is apparently not so, since the damping force in these cases is practically independent of the velocity dy/dt. Let us consider the three cases where the damping force is (*a*) independent of dy/dt, (*b*) proportional to it, and (*c*) proportional to its square, and let us assume that the shape of the vibration is approximately sinusoidal. Then for all three cases the relation:

$$\Delta W = 2\,ky\,\Delta y \quad \ldots\ldots\ldots\ldots\ldots\ldots [29]$$

appearing three lines above Equation [5] is true. For a constant damping force F the work dissipated per cycle is $\Delta W = 4\,Fy$, i.e., proportional to the amplitude. With a damping proportional to the amplitude the dissipation is proportional to the square of the amplitude and in case (*c*) it is proportional to the cube of the amplitude. Substituting in [29], it is seen that in the three cases we have:

(*a*) Δy is a constant
(*b*) Δy is proportional to y
(*c*) Δy is proportional to y^2.

Integrating these relations, the amplitude decrement curves of the three cases are found to be:

(*a*) A straight line
(*b*) A logarithmic curve
(*c*) A hyperbola.

The author has very clearly presented three manifestations of our second case. In the classical supposition that the factor b of Equation [22] is a constant of the system (as in the authors' first two cases), it is seen that the dissipated energy per cycle is proportional to the frequency ω. For if we have a sinusoidal vibration of a given amplitude the velocity will go up with the frequency; the damping force $b\,dy/dt$ is also proportional to the frequency; and since the path is constant, namely, the amplitude, the dissipation or work is proportional to the frequency.

Now it has been found experimentally by the author and others that for internal friction in shafts the dissipation is constant and independent of the frequency. This can obviously be incorporated in [22] by replacing the constant damping coefficient b by b_1/ω, where b_1 is an absolute constant for the system. The value of this constant has been calculated by an integration process by the author, giving the result $b_1 = \xi Ec/\pi$.

Therefore the differential Equation [22] for case III of the paper becomes:

$$m\frac{d^2y}{dt^2} + \frac{b_1}{\omega}\frac{dy}{dt} + cy = F\cos\omega t \quad \ldots\ldots\ldots\ldots [30]$$

As the author remarks in his closing paragraph, this result can be applied also to cases of more than one degree of freedom. In fact, in the closure to the discussion of a paper by J. Ormondroyd and myself, we have applied it to the particular two-degrees-of-freedom problem of the dynamic vibration absorber.[7]

C. Richard Soderberg.[8] It is possible to show in a simple manner that the effect of internal friction in solids is identical to that of viscous friction, regardless of the form of the hysteresis loop, as long as the strain variation can be considered sinusoidal. In other words, as long as the friction forces are not large enough to distort the form of the motion, their effect upon the amplitude of motion is equivalent to the effect of viscous friction.

Consider an elementary cube of the material subjected to a single component of strain ϵ, corresponding to a stress σ. If the strain is varied through complete cycles until a steady state is reached, the stress-strain curve will exhibit the ordinary hysteresis loop. When the strain is increasing there will exist, in addition to the elastic stress ϵE, a positive friction stress; when the strain is decreasing the friction stress will be negative. At the piont of reversal the friction stress will be zero. We may write, therefore, as an extension of Hooke's law

$$\sigma = \epsilon E + f(\epsilon) \quad \ldots\ldots\ldots\ldots\ldots [31]$$

where $f(\epsilon)$ is the friction stress.

Let Θ be a parameter varying directly with time, and let the strain variation be sinusoidal, so that

$$\epsilon = \epsilon_m \sin\Theta \quad \ldots\ldots\ldots\ldots\ldots [32]$$

where ϵ_m is the maximum strain. The friction stress $f(\epsilon)$ is obviously a periodic function in Θ, going through zero when $\Theta = \frac{\pi}{2}, 3\frac{\pi}{2}$, etc. Without restricting the form of $f(\epsilon)$ we may write it in a Fourier series

$$f(\epsilon) = a_1\sin\Theta + a_2\sin 2\Theta + \ldots + b_1\cos\Theta + b_2\cos 2\Theta + \ldots\ldots\ldots\ldots [33]$$

The work done in one cycle (the area of the hysteresis loop) is found to be

$$\Delta W = \int_c \sigma\,d\epsilon = \int_0^{2\pi} (\epsilon E + f(\epsilon))\,\epsilon_m\cos\Theta\,d\Theta = \pi\epsilon_m b_1 \ldots [34]$$

all integrals, except the first from the cosine series, vanishing. Thus, only the fundamental of the function $f(\epsilon_m \sin\Theta)$ influences the motion. Naturally this will hold only as long as the variation in Θ of ϵ is strictly sinusoidal.

Since the maximum potential energy in the element is

$$W = \frac{1}{2}E\epsilon_m^2 \quad \ldots\ldots\ldots\ldots\ldots [35]$$

we obtain for the logarithmic decrement of the motion

$$\delta = \frac{\Delta\epsilon_m}{\epsilon_m} = \frac{1}{2}\frac{\Delta W}{W} = \frac{\pi b_1}{\epsilon_m E} \quad \ldots\ldots\ldots\ldots [36]$$

It is obvious from this that the practical measurement of internal friction involves a measurement of the constant b_1. The experimental results available so far, of which those obtained by Mr. Kimball are the most important, indicate that b_1 is a function of the maximum strain ϵ_m, but is independent of the rate of stress reversal. The following cases may be considered of greatest interest.

(*a*) If b_1 is *independent of the maximum strain* ϵ_m, the logarithmic decrement will decrease with ϵ_m, and the actual decrement will be constant. Free vibrations will attenuate along a straight line. This may be characterized as a typical *coulomb friction*.

(*b*) If b_1 is *proportional to the maximum strain* ϵ_m, the logarithmic decrement will be constant. This case is equivalent to *viscous friction*. The area of the hysteresis loop is proportional to the square of the maximum strain.

In both of these cases Hooke's law can be written in the form

$$\sigma = E\epsilon + \frac{\Gamma}{\omega}\frac{d\epsilon}{dt} \quad \ldots\ldots\ldots\ldots\ldots [37]$$

if the parameter Θ is written as ωt. Γ is a *modulus of friction* expressed in the same units as E. In the first case Γ is inversely proportional to the maximum strain; in the second case it is a true constant. Here it is possible to treat the friction as a true

[7] Trans. A.S.M.E., vol. 50 (1928), paper no. APM-50-7.
[8] Västeras, Sweden, Assoc-Mem. A.S.M.E.

viscous friction, provided that the motion can be considered sinusoidal.

The same result is brought forward by the author by another method, and it is not claimed that the above treatment is more fundamental. It is felt, however, that the limitation with regard to the form of the strain variation needs special emphasis.

Another consequence of the above discussion is that any experiment on internal friction in solids, which measures the friction forces (or the logarithmic decrement) under sinusoidal stress variation, will convey no information with regard to the actual form of the hysteresis loop. The only element that will appear in the results is an elliptical hysteresis loop equivalent in effect to the actual one. Regardless of the value of the excellent work done on this subject, by the author of this paper as well as by others, we shall not penetrate into the true nature of this phenomenon until this deficiency in the methods of measurement has been eliminated.

M. STONE.[9] The author in his present paper has reviewed our ideas on vibration damping in a manner that makes the problem simple and of facile grasp. The realization that the results of his own experiments and those of others, yielding the fact that damping in solids is independent of frequency and proportional to the square of the amplitude, point to the conventional type of differential equation of motion

$$Mx'' + Cx' + kx = 0$$

is something that we should not be surprised to find. In fact, any type of vibration damping, in which the energy-loss per cycle is proportional to the square of the amplitude of vibration,

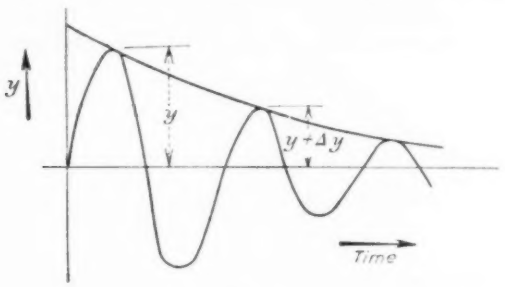

FIG. 4

can be expressed accurately in an equation of the above type. This proceeds from the discussion below.

First, let us consider the idea of logarithmic decrement more closely (Fig. 4). The author, in his second paragraph, defines it for vibrations whose amplitudes decrease exponentially; however, it should not be limited to only such motions, but to any type of decaying vibration. Thus, to use the author's notation,

$$\delta = \log\left(\frac{y}{y + \Delta y}\right) \quad \text{[38]}$$

Now, if we remain in the elastic region, i.e., where the energy at any time is proportional to the amplitude squared ($W = ky^2$), we may continue, writing

$$\psi = \frac{\Delta W}{W} = \frac{ky^2 - k(y + \Delta y)^2}{ky^2} = 1 - \left[\frac{(y + \Delta y)^2}{y}\right] \quad \text{[39]}$$

Now from [38]

$$e^{\delta} = e^{\log\left(\frac{y}{y + \Delta y}\right)} = \frac{y}{y + \Delta y}$$

or

$$\frac{y + \Delta y}{y} = e^{-\delta}$$

and $\left[\frac{(y + \Delta y)^2}{y}\right] = e^{-2\delta}$ and substituting in [39],

$$\psi = 1 - e^{-2\delta}$$

and expanding $e^{-2\delta}$ into its infinite series, we get

$$\psi = 1 - \left[1 - 2\delta + \frac{4\delta^2}{2!} - \frac{8\delta^3}{3!} + \cdots\right]$$

$$= 2\delta - 2\delta^2 + \frac{4}{3}\delta^3$$

and since δ is small, we neglect higher orders, arriving at $\psi = 2\delta$, which is the same as the author's Equation [5], and which he correctly states as being approximate, but which the writer wishes to point out is a relation holding for all types of vibration decay.

Hence, we can get the value of δ from a consideration of ψ, and quickly characterize the type of motion. In addition to the three types of damping discussed in the paper, the writer would like to add parallel developments of Coulomb damping, velocity-squared damping, and shear damping, all of which occur frequently in engineering applications. In each case we are interested in the energy loss per cycle.

Solid Damping: (experimental):

$$\Delta W = \xi x_{\max.}^2 = \xi \epsilon_m^2 E^2 \text{ (independent of } \omega)$$

Velocity Damping: $m\ddot{x} + b\dot{x} + kx = 0$

$$\Delta W = \oint (b\dot{x})dx \text{ where } x = x_m \sin \omega t$$

$$\dot{x} = x_m \omega \cos \omega t$$

$$dx = x_m \cos \omega t d(\omega t)$$

$$\text{Thus } \Delta W = 2\int_0^{\pi} b x_m^2 \omega \cos^2 \omega t d(\omega t) = \pi b \omega x_m^2$$

Liquid Damping: Viscosity force $= \eta \frac{d\epsilon}{dt}$ per unit volume

$$\Delta W = \oint \left(\eta \frac{d\epsilon}{dt}\right) d\epsilon \qquad \epsilon = \epsilon_m \sin \omega t$$

$$\dot{\epsilon} = \epsilon_m \omega \cos \omega t$$

$$d\epsilon = \epsilon_m \cos \omega t d(\omega t)$$

$$\Delta W = 2\int \eta \epsilon_m^2 \omega \cos^2 \omega t \, d(\omega t) = \pi \eta \omega \epsilon_m^2$$

Coulomb Damping: $m\ddot{x} + kx \pm F = 0$

$$\Delta W = \oint F \, dx \qquad x = x_m \sin \omega t$$

$$dx = x_m \cos \omega t d(\omega t)$$

$$\Delta W = 4\int^{\pi/2} F x_m \cos \omega t d(\omega t) = 4 F x_m$$

(Velocity)² Damping: $m\ddot{x} + kx \pm \beta(\dot{x})^2 = 0$

$$\Delta W = \oint \beta \left(\frac{dx}{dt}\right)^2 dx \qquad x = x_m \sin \omega t$$

$$\ddot{x} = x_m \omega \cos \omega t$$

$$dx = x_m \cos \omega t \, d(\omega t)$$

[9] Research Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

$$\Delta W = 4\int_0^{\pi/2} \beta x_m^3 \omega^2 \cos^3 \omega t d(\omega t) = \frac{8}{3}\beta x_m^3 \omega^2$$

Shear Damping (Fig. 5):

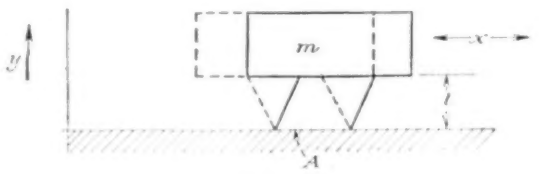

FIG. 5

$$m\frac{d^2x}{dt^2} + F + kx = 0$$

where F = frictional resistance due to shear action in elastic material, such as a rubber pad supporting an electric motor. This type of action is called "tangential viscosity," and is defined

$$F = \lambda \frac{dv}{dy}$$

where v is the velocity in x-direction of a particle under shear action, and λ is the coefficient of tangential viscosity. This type of damping occurs as the damping action of oil films in bearings, etc. Thus

$$F = \int\int \lambda \frac{dv}{dy}\, d(\text{area})$$

Now $v = cy$ and $\dot{x} = cl$ or $c = \dot{x}/l$

$$\text{and } v = \frac{x}{l}\, y$$

$$\text{and } \frac{dv}{dy} = \frac{x}{l}$$

$$\text{Thus} \qquad F = \frac{\lambda}{l}\frac{dx}{dt}\int\int d(\text{area}) = \frac{\lambda}{l}\frac{dx}{dt}A = \frac{\lambda A}{l}\frac{dx}{dt}$$

$$\text{and} \qquad \Delta W = \frac{\lambda A}{l}\oint\left(\frac{dx}{dt}\right)dx = \pi\frac{\lambda A}{l}\omega x_m^2$$

Now in order to get the δ's for each type of damping, we must write down the vibration energy in each case:

Solid Damping:

$$W = \frac{1}{2}kx_m^2 = \frac{1}{2}E\epsilon_m^2$$

and

$$\delta = \frac{\psi}{2} = \frac{\xi E^2 \epsilon_m^2}{E\epsilon_m^2} = \xi E$$

Velocity Damping:

$$\delta = \frac{\pi b\omega x_m^2}{kx_m^2} = \frac{\pi b\omega}{k} = \frac{\pi b}{\sqrt{mk}}$$

Liquid Damping:

$$\delta = \frac{\pi\eta\omega\epsilon_m^2}{E\epsilon_m^2} = \frac{\pi\eta\omega}{E}$$

These are given by the author, and the writer only repeats to preserve the continuity to the next.

Coulomb Damping:

$$\delta = \frac{4Fx_m}{kx_m^2} = \frac{4F}{kx_m}$$

Now since $\delta \approx -\dfrac{\Delta x_m}{x_m}$ for small damping as the author has shown, then

$$-\frac{\Delta x_m}{x_m} = \frac{4F}{kx_m}$$

and we get that

$$\Delta x_m = -\frac{4F}{k}$$

or see that the damping is linear (Fig. 6) and not exponential—an observed fact.

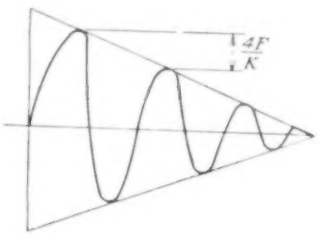

FIG. 6

Velocity² Damping:

$$\delta = \frac{8/3\beta x_m^3\omega^2}{kx_m^2} = \frac{8\beta\omega^2}{3k}x_m$$

Shear Damping:

$$\delta = \frac{\pi\dfrac{\lambda A}{l}\omega x_m^2}{kx_m^2} \text{ where } k = \frac{GA}{l}$$

$$= \frac{\pi\lambda\dfrac{A}{l}\omega x_m^2}{\dfrac{GA}{l}x_m^2} = \frac{\pi\lambda\omega}{G}$$

It will be seen from the above that in all the cases except Coulomb and velocity-squared damping the logarithmic decrement is independent of amplitude, which means an exponential decrease of amplitude with time—and thus the case of motion with solid damping can be represented by the conventional motion equations.

The case of Coulomb damping gives a logarithmic decrement inversely proportional to amplitude, resulting in a linear decrease in amplitude. This type of friction occurs in brake shoes, etc.—wherever solid dry surfaces rub together.

In the case of velocity-squared damping, we obtain δ proportional to the amplitude—and such a fact has been observed in the experiments of Honda and Konno[10] and Iokibe and Sakai.[11] They, however, wishing to adhere to the idea of constant δ, have attributed their linearity between δ and x_m due to too large amplitudes (although they do not go beyond the elastic range), while damping of the sort described above might well explain this consistent observation on many metals.

In the author's own experiments on copper δ,[12] there is a

[10] *Phil. Mag.*, vol. 42 (1921), p. 115.

[11] *Phil. Mag.*, vol. 42 (1921), p. 397.

[12] "Internal Friction in Solids." Trans. A.S.M.E., vol. 48 (1926), p. 450.

very decided increase in δ with amplitude—practically in a straight line. It seems that steels do not exhibit any appreciable change—the brasses, copper, nickel, lead, etc., showing the linear relation to a more or less definite degree, however.

This type of damping yields a decrease in amplitude according to a rectangular hyperbola, and is much faster for the larger amplitudes, for we have

$$\delta = \frac{\Delta x_m}{x_m} = \frac{8\beta\omega^2}{3k} x_m = Cx_m$$

or

$$-\Delta x_m = Cx_m^2$$

Now $-\Delta x_m$ is proportional to $\frac{dy}{dt}$, where y is taken as the envelope of the x_m's and

$$\frac{dy}{dt} = -\alpha y^2$$

or $$-\frac{1}{\alpha}\int\frac{dy}{y^2} = \int dt \text{ or } \frac{1}{\alpha y} = t + \gamma$$

or $$\alpha y t + \alpha\gamma y = 1$$

or $$y = \frac{1}{\alpha(\gamma + t)}$$

which is a displaced rectangular hyperbola (Fig. 12).

Now we must evaluate α and γ in terms of C and various observed characteristics of the observed curve of vibration decay. Now

$$y_t = \frac{1}{\alpha(\gamma + t)}$$

$$y_{(t+T)} = \frac{1}{\alpha(\gamma + t + T)}$$

$$\text{and } \frac{1}{y_t} - \frac{1}{y_{(t+T)}} = \alpha(\gamma + t) - \alpha(\gamma + t + T) = -\alpha T$$

or $$\frac{y_{(t+T)} - y_t}{(y_t)(y_t + T)} = -\frac{\Delta x_m}{x_m^2} = -\alpha T = C$$

and $$\frac{y(t)}{y(t+T)} = \frac{(\gamma + t + T)}{(\gamma + t)} = 1 + \frac{T}{\gamma + t}$$

from which two equations both α and γ may be determined. They are also given geometrically as shown in Fig. 7. The

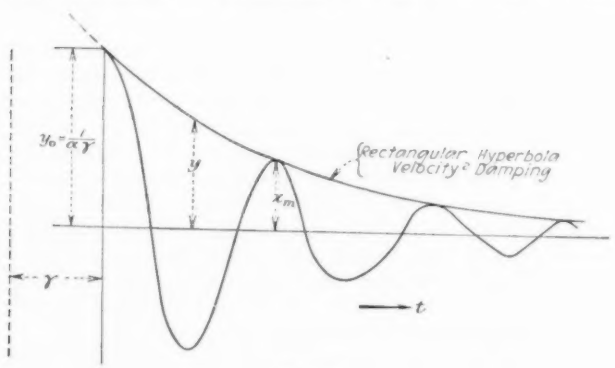

FIG. 7

best test as to the character of the curve, however, is to plot δ vs. x_m, when attempting to differentiate between exponential and hyperbolic damping.

Another observation, of an experimental nature, to discover such damping is to observe the curve of energy loss vs. x_m. For the case of velocity-squared damping, we should expect a cubic relation

$$\Delta W = kx^3$$

Many tests have been made, namely, by Rowett, etc., who have obtained exponents 2.3 and 2.6, showing that the actual damping is of the type

$$F = c\left(\frac{dx}{dt}\right)^k \text{ where } 1 < k < 2$$

The fact that many experimenters have found the energy loss to be practically independent of frequency can be explained by the mechanism of velocity damping, provided the specific resistance be considered proportional to $1/\omega$—and for velocity-squared damping, by considering the specific resistance proportional to $1/\omega^2$. These are hypotheses, but they have a considerable degree of substantiation in Quimby's tests,[13] where he found considerably lower values of specific resistance, working at very high frequencies.

From the consideration of normal viscosity damping, the value of δ arrived at is

$$\delta = \frac{\pi\eta\omega}{E} \text{ or } \frac{\eta}{E} = \frac{\delta}{\pi\omega}$$

It will be observed that the value of δ arrived at when considering tangential viscosity or shear damping is

$$\delta = \frac{\pi\lambda\omega}{G} \text{ or } \frac{\lambda}{G} = \frac{\delta}{\pi\omega}$$

From these two expressions, a close similarity is observed. From observed values of λ and η, we find no simple relation; however, if these two constants were in the ratio of G and E, then a general system-vibration decay need not be distinguished as to shear or direct stress damping. In general, however, we must recognize the difference in these actions, and this must needs modify the author's statement that his dampings II and III represent general system damping.

The general subject of vibration damping is one of increasing importance, for in many applications, instead of avoiding resonances, which we cannot always do, we introduce damping devices and count on existing damping (in a quantitative degree) to render the resonances of minimum violence.

The author has done much to clarify our ideas in this problem, in his present paper, and in preceding ones.

E. O. WATERS.[14] A number of A.S.M.E. papers in recent years have treated the subject of vibration from various points of view, and the present paper has a wholesome unifying effect in pointing out the different kinds of damping which might, at first thought, appear to have wholly dissimilar effects on the amplitude, but which actually, as it proves, produce a logarithmic decrement in every case.

It occurs to the writer that there is another kind of damping, which may not have evidenced itself in much of the author's experimental work, but which would seem to be present in a great deal of machinery, namely, vibrating systems in which one or more of the moving elements pass through poorly lubricated bearings or rub against stationary surfaces with solid contact. In such cases there is assumed to be a damping force

[13] S. L. Quimby, *Phys. Rev.*, vol. 25 (1925), p. 528.

[14] Associate Professor of Mechanical Engineering, Sheffield Scientific School, Yale University, New Haven, Conn. Assoc. Mem. A.S.M.E.

which is constant in magnitude, but which changes its sign with the direction of the velocity.

It would seem that such damping would decrease the amplitude at a constant rate, and that, in the absence of an external harmonic force to sustain the vibrations, it would result in zero motion at the end of a finite interval of time, as contrasted with the logarithmic decrement which theoretically does not terminate. Moreover, the final position of the system would not be one of zero displacement.

The equation of motion is

$$m\ddot{y} + cy = -d \text{ when } \dot{y} > 0$$
$$= +d \text{ when } \dot{y} < 0$$

and the solution, evaluating the integration constants by the condition that $y = y_0$ and $\dot{y} = 0$ when $t = 0$, is

$$y = \left[y_0 - (2n-1)\frac{d}{c} \right] \cos wt + \frac{d}{c} \text{ when } n \text{ is odd}$$
$$-\frac{d}{c} \text{ when } n \text{ is even}$$

n being the number of half-oscillations. The decrement per oscillation is $\frac{4d}{c}$; maximum number of half-oscillations is $\frac{cy_0}{2d}$, neglecting the remainder after performing the division; and the maximum duration of vibration is

$$\frac{\pi\sqrt{cm}\ y_0}{2d}$$

neglecting the time after the last point of zero velocity. The amplitude at the end of the nth half-oscillation is

$$\pm\left[y_0 - (2n-1)\frac{d}{c} \right]$$

and the energy dissipated during the nth half-oscillation is

$$2d\left[y_0 - (2n-1)\frac{d}{c} \right]$$

For the case of sustained vibrations, there are certain difficulties due to the discontinuities at each change of d from + to −. The hysteresis loop for this type of vibration is a parallelogram, and probably the best solution is obtained by substituting for it an ellipse of equal area, and using the standard equations presented by the author.

Author's Closure

Regarding the "threshold stress" observed by Dr. Canfield in his investigations, this is of so small a magnitude as to be almost out of the range of the revolving rod experimental method used by the author. This method as used in our experiments is not reliable for maximum fiber stresses much below 4000 lb. per sq. in., except for certain substances of low elastic modulus, like celluloid.

Mr. Stone has presented an interesting comparison of the decrements for different types of vibration damping as calculated from Equation [5]. In reference to Mr. Stone's remark about this relation "which the writer wishes to point out is a relation holding for all types of vibration decay," it was intended to convey this very idea in the first part of the second paragraph after Equation [5]. The author well appreciates that this relation holds for any law of vibration decay. It gives the logarithmic decrement δ at any instant during a vibration decay whether δ be a constant or not. Mr. Stone's comparison shows very well how δ increases with time when the dissipation per cycle is proportional to less than the second power of the amplitude, and how δ decreases with time when the dissipation per cycle is proportional to more than the second power of the amplitude.

As to the lack of equality between δ as obtained from torsional vibrations as compared with vibrations involving bending, it is probably appreciated that this must be due to a lack of isotropy of most materials as to their internal friction coefficients such that the coefficients vary with change of direction of the strain in the material.

Referring to the hyperbolic decrement curve derived by Mr. Stone, the author has used a similar method in deriving time decrement curves which may be of interest.

Let the energy of vibration $W = ay^2$

Let the time rate of energy dissipation $= \frac{dW}{dt} = -by^n$ where y represents vibration amplitude at some point and a and b are constants

From the first equation $\frac{dW}{dt} = 2ay \times \frac{dy}{dt}$

Equating the two values of $\frac{dW}{dt}$ and using the constant c in place of $\frac{a}{2b}$, the differential equation of amplitude decrement becomes

$$\frac{dy}{dt} = -cy^{n-1}$$

Integrating and evaluating the constant of integration we obtain

$$y^{n-2} = \frac{{y_0}^{n-2}}{(n-2)c{y_0}^{n-2}t + 1}$$

where y_0 = the amplitude y when $t = 0$.

For coulomb friction, $n = 1$ which gives

$$y = -ct + y_0$$

which is a straight line.

For $n = 3$

$$y = \frac{y_0}{cy_0t + 1}$$

which is a hyperbola, as obtained by Mr. Stone.

Turning now to sustained vibrations, an illustration will be considered of a case of an infinite number of degrees of freedom; namely, that of a uniform bar transmitting longitudinal waves. The differential equation for this case is

$$\rho\frac{\partial^2 u}{\partial t^2} - \eta\frac{\partial^3 u}{\partial x^2 \partial t} - E\frac{\partial^2 u}{\partial x^2} = 0$$

where ρ = mass per unit volume
η = friction coefficient
u = *total* strain at any point.

The friction term of this equation is derived on the assumption of frictional stresses in the bar given by $\eta\frac{d\epsilon}{dt}$, which is relation [13] of the author's paper. In the latter expression, the linear strain ϵ is identical with $\frac{\partial u}{\partial x}$ of the above equation of the vibrating bar.

The solution of this equation contains the constant η. Sub-

stituting its value as given by Equation [27], gives the solution for the case of "solid friction" where the dissipation is proportional to the square of the stress amplitude. When the dissipation is proportional to the nth power of the stress amplitude, Equation [27] becomes $\eta = \frac{\xi E^n \epsilon_m{}^{n-2}}{\pi\omega}$. If n has any other value than 2, the coefficient η contains ϵ_m which depends upon the variable x; thus it can be treated as a constant only when $n = 2$. For any other case the differential equation becomes non-linear and its solution more difficult.

It is important to note, however, that for a simple system like that given by Equation [22] the coefficient b can be treated as a constant and the solution for a sustained vibration thereby obtained for a frictional loss per cycle, ΔW, which is *any function*, $\phi(y_0)$, of the stress amplitude.

Using the method of Equation [14], the viscous frictional loss per cycle,

$$\Delta W = \pi b y_0{}^2 \omega$$

Equating this to the solid friction loss $\phi(y_0)$

$$b = \frac{\phi(y_0) y_0{}^{-2}}{\pi\omega}$$

where b is independent of either y or t. Solving [22] as it stands and substituting this value of b, y_0 can be obtained as a function of ω.

The discussion of Mr. Soderberg puts the fundamentals of the problem in a clear and interesting way. The exact mechanism of internal friction is still uncertain and much remains to be done on this subject.

AMP-51-22

Practical Determination of Torsional Vibration in an Engine Installation Which May Be Simplified to a Two-Mass System

By FREDERIC P. PORTER,[1] BELOIT, WIS.

This paper gives a practical solution for the torsional vibration in the shafting of a reciprocating-engine installation which may be reduced mathematically to a simple two-mass system. It presents methods for computing the damped vibrations in installations where the damping forces follow various laws. Particular attention is given to such damping forces as are caused by a marine propeller, elastic hysteresis, and a friction damper. The paper is illustrated by examples of computations for certain engine installations that have been investigated.

TORSIONAL vibrations have in the past caused many failures in the shafts and serious interferences in the operation of reciprocating-engine installations. Steam engines were probably the first type of reciprocating engines to experience these difficulties. As far back as 1900, engineers were beginning to recognize the existence of severe torsional vibrations in the shafting of steam-engine installations.

One of the first theoretical treatments on this subject was given in a paper by Frahm published in the *Zeitschrift des Vereines deutscher Ingenieure*, 1902, page 797, and translated in the *Journal of the American Society of Naval Engineers*, August, 1902, page 721. This paper was a very important contribution to the mathematical solution of torsional-vibration problems. It definitely established that torsional vibration was a problem that should not be neglected in marine propelling installations with engines of the reciprocating type.

The type of installation investigated by Frahm was one in which "the distance between the power-generating engine and the power-absorbing propeller is quite a considerable one." In this type of installation both the engine and propeller may be considered as inelastic flywheels connected to each other by the elastic shaft.

In his paper, Frahm gave a method for computing the damped torsional vibrations for the type of elastic systems just mentioned, damped by a single damping force proportional to the velocity. He considered the action of the propeller to be the principal source of damping, and gave a damping coefficient which he determined experimentally on a number of marine installations and model propellers.

Subsequent investigators have treated in various ways different phases of the subject of torsional vibration, notably that phase which deals with the determination of the synchronous frequency or the frequency of free vibration.

Recently the author presented a paper, "The Range and Severity of Torsional Vibration in Diesel Engines" (*Trans. A.S.M.E.*, Paper APM-50-8, 1928), in which he endeavored to give a comprehensive treatment of the subject of torsional vibration of irregular shafts. The material presented there is the result of a study to determine accurately the range of critical vibrations and the speeds at which they occur. The data also give the results of a study on the effect of elastic hysteresis and propeller damping forces in determining the maximum vibration at the various critical speeds. It is illustrated by examples of computations for the shafting of certain Diesel-engine installations that have been investigated. In the development of the mathematical theory given in the aforementioned paper it was the author's aim to present a general theory that could easily be adapted to any irregular shaft of a multicylinder installation.

Often actual engine installations approximate the mathematical system of two concentrated masses connected by an elastic shaft. In such a system the concentrated mass corresponding to the engine is receiving a succession of impulses stimulating vibration, while the other mass, together with the internal molecular friction, or elastic hysteresis of the material of the connecting shaft, is absorbing the energy given the shaft by the stimulating impulses.

It is the object of the present paper to give in detail the mathematical solution of the type of installation just described, with numerical applications of the theory developed, together with certain experimental verifications of the calculated results.

The forces stimulating torsional vibrations in any reciprocating engine installation are due in general to (1) the pressure forces in the working cylinders, (2) inertia forces of the reciprocating parts, (3) gravity forces of the reciprocating parts and unbalanced rotating parts, and (4) uneven absorption of power at the driven machinery.

The damping forces acting are due in general to (1) elastic hysteresis, (2) the driven machinery, such as a marine propeller, generator, hydraulic pump, dynamometer, vibration damper, etc., (3) slight slippage at the union of two parts of the shaft line-up, (4) surface friction between the moving and stationary parts, (5) energy absorbed by the oil film around the bearings of a crankshaft, (6) energy transmitted by side thrust of the crankshaft journals into the frame of the engine, and (7) air friction, etc.

Accuracy in calculating the amplitude of vibration of any vibrating system depends upon an accurate numerical statement of the stimulating forces and damping forces. It is convenient to handle these forces by expressing the turning moments due to each of the sources of stimulating impulses in terms of a Fourier series. The resulting Fourier series of the turning-effort curve acting at any particular section is then obtained by combining the various harmonic components of the same order acting at that section, where "order" means the number of complete cycles of the harmonic per revolution of the shaft.

A two-mass substitution is made for the connecting rod, one a rotating mass concentrated at the crank radius and the other a reciprocating mass acting at the wristpin. The values of these parts are taken inversely proportional to their distance from the center of mass of the rod.

The inertia of the reciprocating mass has approximately the same effect in vibration as a rotating mass concentrated at the crank radius equal to one-half of the reciprocating mass.

The numerical statement of the stimulating forces and damping forces was taken up in detail in the author's previous paper. An outline of the numerical values of these forces will be included at this time.

The harmonic stimulating impulses of the turning-effort curve

[1] Fairbanks, Morse & Co.

due to the usual pressure forces in a four-cycle Diesel-engine cylinder may be obtained from the coefficients given by Prof. Frank M. Lewis in a paper, "Torsional Vibration in the Diesel Engine," *Transactions of the Society of Naval Architects and Marine Engineers*, Vol. 33, 1925, plates 6 to 11, and "Vibration and Engine Balance in Diesel Ships," same publication, Vol. 35, 1927, plates 9 to 12. It is to be noted, however, that the signs of the coefficients of the cosine terms in the paper in Vol. 33 are opposite those given, i.e., the signs of the cosine terms for the orders $^1/_2$, 1, and $1^1/_2$ are positive and for the orders from 2 to 12 are negative.

The harmonic coefficients of the pressure forces of a triple-expansion, four-cylinder steam engine are given later in this paper. Similar coefficients may be obtained from the indicator cards of the pressure forces in any working cylinder by applying methods of harmonic analysis to the corresponding turning effort.

$$K = fS^{\lambda} \quad [2]$$

where S = one-half the stress range
f = hysteresis constant, and
λ = hysteresis exponent.

Lewis states that from experiments of Rowett made on thin-walled mild-steel tubes, stressed alternately in torsion to a point below the elastic limit, that $f = 1.37 \times 10^{-10}$ and $\lambda = 2.3$ in inch, pound, second, units for stresses less than 8000 lb. per sq. in., and for stresses greater than 8000 lb. per sq. in. the value of λ increases rapidly. The author has observed, however, that it is necessary to increase f to 3.29 times this value in order to obtain calculated results that agree with the recorded vibrations. This correction factor has been used in the investigation of a number of installations and has been found in all cases to be fairly reliable.

The harmonic impulses due to the inertia and gravity forces of the reciprocating parts are given in Tables 1 and 2. The inertia force of the connecting rod causes a torque on the shaft that is not given by the two-mass substitution for the rod. The harmonic impulses due to this source are given in Table 3. In these tables, α represents the crank angle from top center, k is the crank-to-connecting-rod ratio, and r is the crank radius.

The turning moment Q due to the unbalanced part of the connecting rod, crankpin, and crankwebs is given by

$$Q = W_u r \sin \alpha \quad [1]$$

where r is the radius to the center of gravity of the weight W_u of the unbalanced parts.

There are as yet very few experimental data on elastic hysteresis. Experiments on the energy absorbed by steel in reversed torsion show that for small ranges of stress it varies as a power of the stress range between the square and the cube. It may be stated per cubic unit by the equation

For a uniform circular shaft, the hysteresis energy loss per unit length will be

$$K = \int_{2r = d_1}^{2r = d_2} 2\pi r f \left(S \frac{2r}{d_2}\right)^{\lambda} dr = \frac{\pi f S^{\lambda} (d_2^{2 + \lambda} - d_1^{2 + \lambda})}{2(2 + \lambda) d_2^{\lambda}} \quad [3]$$

where d_2 and d_1 are the outer and inner diameters of the shaft and S is the maximum fiber stress. Putting the following values into Equation [3]: $S = 16 d_2 M/\pi(d_2^4 - d_1^4)$, $\lambda = 2.3$, and $f = 4.51 \times 10^{-10}$, where f is 3.29 times the value given by Lewis, the hysteresis loss for the length l of a uniform circular shaft is given by

$$K = \frac{69.7(d_2^{4.3} - d_1^{4.3})}{10^{10}(d_2^4 - d_1^4)^{2.3}} l M^{2.3} \quad [4]$$

where M is constant over the length l.

A marine propeller in vibration is affected in two ways by the surrounding water. The motion of the propeller is resisted

by a force proportional to the angular velocity, and the effective inertia of the propeller is increased by the water carried along with it. The factor for the increase in propeller inertia due to entrained water given by Frahm is between 20 to 32 per cent, with an average increase of about 25 per cent.

If, for a constant speed of advance, Q is the torque of the propeller and A its angular velocity in radians per second, the damping factor ρ may be obtained from the equation

$$\rho = \frac{dQ}{dA} \quad [5]$$

The damping factor given by Frahm[2] was $k = rW_m/v_m$. If R is the crank radius, the symbols used by Frahm in terms of the symbols used here are $k = \rho/R^2$, $W_m = Q/R$, $v_m = AR$, so that

$$\rho = r\frac{Q}{A} \quad [6]$$

The values of r given by Frahm fall between 3.6 and 4, with an average value of 3.8.

The method given by Lewis for adapting D. W. Taylor's model experiments to determine the propeller damping coefficient ρ is as follows:

Let s equal the nominal slip or slip in still water. Then the pitch of the propeller in feet times $(1 - s) \times$ r.p.m. equals the speed of advance in feet per minute. Thus it is evident that $(1 - s)A$ = constant. Differentiating this gives

$$\frac{ds}{dA} = \frac{1 - s}{A} \quad [7]$$

Therefore

$$\rho = \frac{\partial Q}{\partial A} = \frac{\partial Q}{\partial s}\frac{\partial s}{\partial A} = \frac{1 - s}{A}\frac{\partial Q}{\partial s} = \frac{Q}{A}(1 - s)\frac{\frac{\partial Q}{\partial s}}{Q} \quad [8]$$

The model experiments may then be used since

$$(1 - s)\frac{\frac{\partial Q}{\partial s}}{Q} = (1 - s)\frac{\frac{\partial Q_m}{\partial s}}{Q_m} = f_m \quad [9]$$

[2] *Journal of the American Society of Naval Engineers*, August, 1902, p. 759, Equation 7.

where the subscript m denotes the corresponding properties of the model propeller. Hence

$$\rho = f_m\frac{Q}{A} = \frac{60Q}{2\pi \times \text{r.p.m.}}f_m \quad [10]$$

Values of f_m at the nominal slip corresponding to maximum propeller efficiencies obtained from the model experiments of D. W. Taylor have been computed by the author and are given in Table 4. These nominal slips were from 12 to 17 per cent. The characteristics of the propellers are given in terms of pitch ratio, mean width ratio, projected area divided by the disk area, and blade-thickness ratio. These terms depend on the following definitions.

Diameter of the propeller is the diameter of the circle touching the blade tips.

Pitch ratio is the mean pitch divided by the diameter.

Developed area is the area of the helicoidal surface of the driving faces.

Projected area is the area of the projections of the blade faces upon a transverse plane perpendicular to the axis.

TABLE 4 PROPELLER DAMPING COEFFICIENTS

(Values of f_m at nominal slip corresponding to maximum propeller efficiency obtained from model experiments by D. W. Taylor. Models used were elliptically bladed with 3 blades, 16 in. diameter, 3.2 in. hub diameter, 1/64 in. tip thickness, towed at 5 knots speed of advance.)

Disk area is the area of the circle touching the blade tips.

Mean width ratio is h divided by the diameter, where h is the width of a rectangle whose length is the distance from the tip to the hub and whose area is the developed area of one blade. If D is the diameter of the propeller and d the diameter of the hub,

$$\text{Mean width ratio} = \frac{2 \times \text{developed area}}{3(D - d)D} \quad [11]$$

This formula is for a three-bladed propeller.

Blade-thickness ratio is AC divided by the diameter, where AC is obtained as follows: Let a plane through the axis of the propeller cut the center of a blade. Extend the lines of intersection of the plane with the blade faces to the axis. AC is the distance along the axis between these intersections.

It is noted that the factor f_m in Equation [10] is the same as the factor r in Equation [6] given by Frahm. For the purpose of comparing the numerical values of these factors, the value of f_m has been obtained for thirty-four different propellers given

by C. W. Dyson in "Screw Propellers" (1924), Vol. II, sheets 8 to 11. These values are listed below.

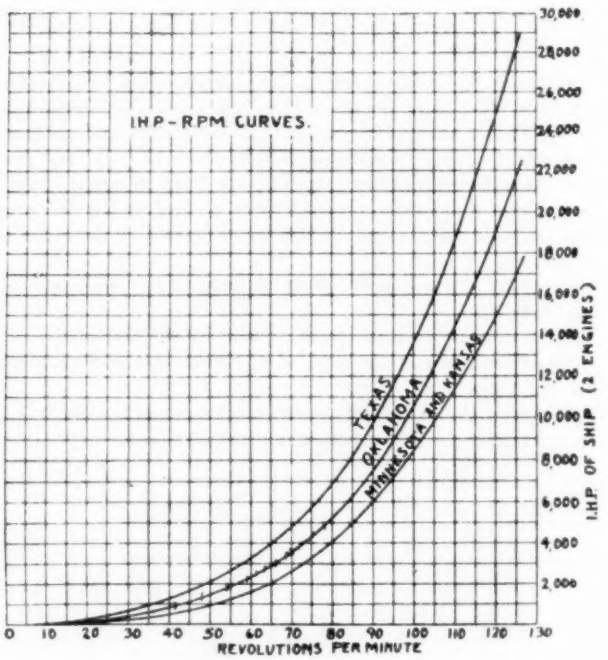

FIG. 1

Ship	f_m	Ship	f_m
Nebraska	3.6	Georgia	3.6
Wisconsin	3.9	Ohio (as adopted)	4.1
Denver	3.9	Kearsarge, Kentucky, and Illinois	3.4
New Orleans	3.9	Missouri	3.4
Albany	3.9	Atlanta	3.9
Montgomery and Detroit	3.7	Chicago	3.6
Marblehead	3.8	Maine (new)	3.6
Chattanooga	3.6	Texas (San Marcos)	3.8
Galveston	3.6	Baltimore and Philadelphia	3.8
Newark	3.5	Olympia	3.8
Alabama	3.9	Arkansas (Ozark)	3.5
Indiana and Massachusetts	3.5	Nevada (Tonopah)	3.5
Charleston (old)	3.6	Wyoming (Cheyenne)	4.1
Boston	3.6	Florida (Tallahassee)	4.1
Oregon	3.8	Connecticut	3.7
Iowa	3.6	Virginia	3.5
Minneapolis:			
Center screw	3.5		
Wing screws	3.4	Sum	125.7
		Average	3.70

The values of f_m for these thirty-four propellers fall between 3.4 and 4.1, and the average value is 3.70. The values given by Frahm for this same factor, i.e., his factor r, was between 3.6 and 4.0, with an average value of 3.8.

Other forms of damping that occur in the driven machinery of particular installations can often be calculated when the characteristics of this machinery are known.

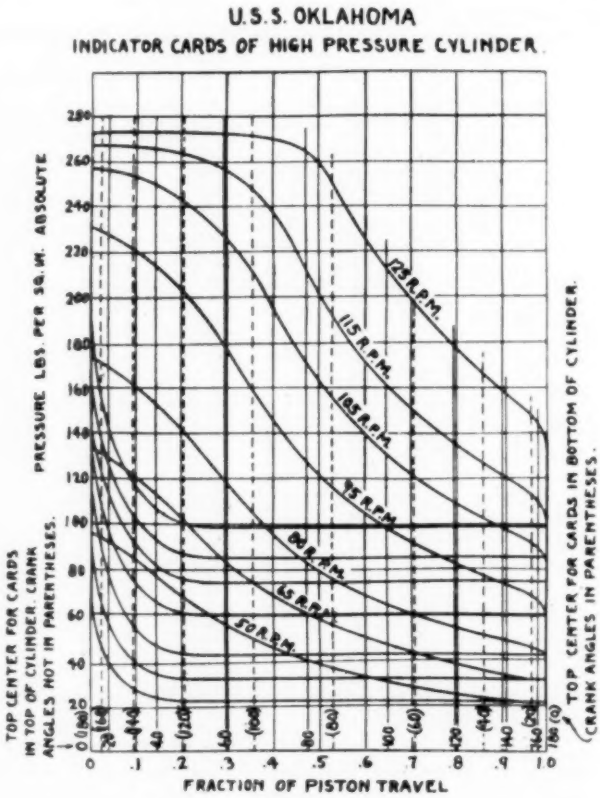
A slight slippage between two of the members of the shaft line-up, such as between bolted flanged couplings, keyed couplings, friction clutch, etc., may be the source of great damping. This source of damping, however, is unreliable and in ordinary cases can be neglected.

The surface friction between the moving and stationary parts of a rotating shaft is nearly independent of the velocity, and therefore has practically no effect on damping the torsional vibrations. Such a friction is balanced by part of the mean torque of the engine.

Other energy losses such as the energy absorbed by the oil film around the bearing of a crankshaft, energy transmitted by side thrust of the crankshaft journals into the frame of the engine, air friction, etc., have a relatively small effect in damping vibrations. Without much error these sources of damping can be neglected.

For numerical illustration, the torsional-vibration investigations made on three steam-engine installations will be described in the following pages. These installations are the main propelling units of the (1) U. S. S. *Oklahoma*, (2) U. S. S. *Texas*, (3) U. S. S. *Minnesota*, and U. S. S. *Kansas*.

Each of these propelling engines is a triple-expansion, four-cylinder steam engine, operating with a maximum boiler pressure of 265 lb. per sq. in. gage. The full-power speed of these engines is 125 r.p.m. The power balance between the cylinders is: high-pressure cylinder, $^1/_3$; intermediate-pressure cylinder, $^1/_3$; and each low-pressure cylinder, $^1/_6$. From forward to aft the cylinders are arranged in the order of: forward low-pressure cylinder (F.L.P.), high-pressure cylinder (H.P.), intermediate-pressure cylinder (I.P.), and after low-pressure cylinder (A.L.P.). The working sequence of the cylinders for a port engine is F.L.P., A.L.P., H.P., I.P., and for a starboard engine



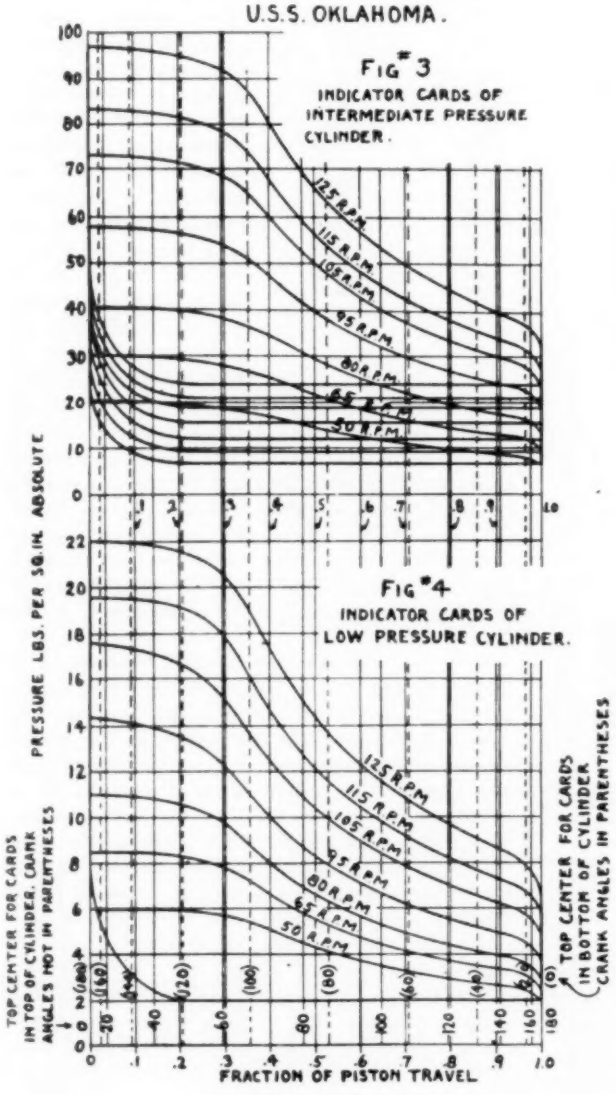


FIG. 2

is F.L.P., I.P., H.P., A.L.P. The crank radius of each is 24 in. and the connecting-rod length is 96 in. The indicated horsepower and revolutions per minute curves are given in Fig. 1. These curves give the total indicated horsepower for the ships, including both the port and starboard propelling units. Other data for these installations are given in Table 5.

I—U. S. S. "Oklahoma," Port Propelling Unit

The impulses causing vibration in this installation due to the turning effort of the pressure forces were obtained from the set of twenty-one indicator cards for the H.P., I.P., and L.P. cylinders shown in Figs. 2, 3, and 4. These cards are based on a set of actual indicator cards taken on the *Oklahoma's* engines. The turning effort corresponding to the pressure forces given

in these cards was analyzed into harmonic components by a schedule method of harmonic analysis. The results thus obtained for the combined effect of the pressures in both the top and the bottom of the various cylinders are given in Figs. 5, 6, and 7. The values (m_i) plotted in these figures give the magnitude of the first eight harmonic components per unit crank radius and unit mean piston area (i.e., mean of top and bottom area of piston). The phase angles of the first six harmonics are also plotted in these figures, and represent the lag of the maximum value of the harmonic behind top center of the piston. These phase angles are given in degrees and represent

FIGS. 3 AND 4

that part of one cycle of the harmonic component referred to, considering one cycle of the harmonic to contain 360 deg.

The resultant effect of all the impulses can now be obtained by assuming that all the impulses act at the center of the engine. This assumption is justified for the vibration in any installation where the amplitude of vibration over the section of the shaft receiving the impulses is nearly constant.

To illustrate the calculations necessary to obtain the resultant harmonic impulses, calculations for these impulses will be described for the first six harmonic components at the engine speed of 80 r.p.m. Let all phase angles be measured from the top center of the F.L.P. cylinder. The cylinders then follow in the order of F.L.P., A.L.P., H.P., I.P. The phase angles for the various orders at the different cylinders are thus increased by the angles given in Table 6.

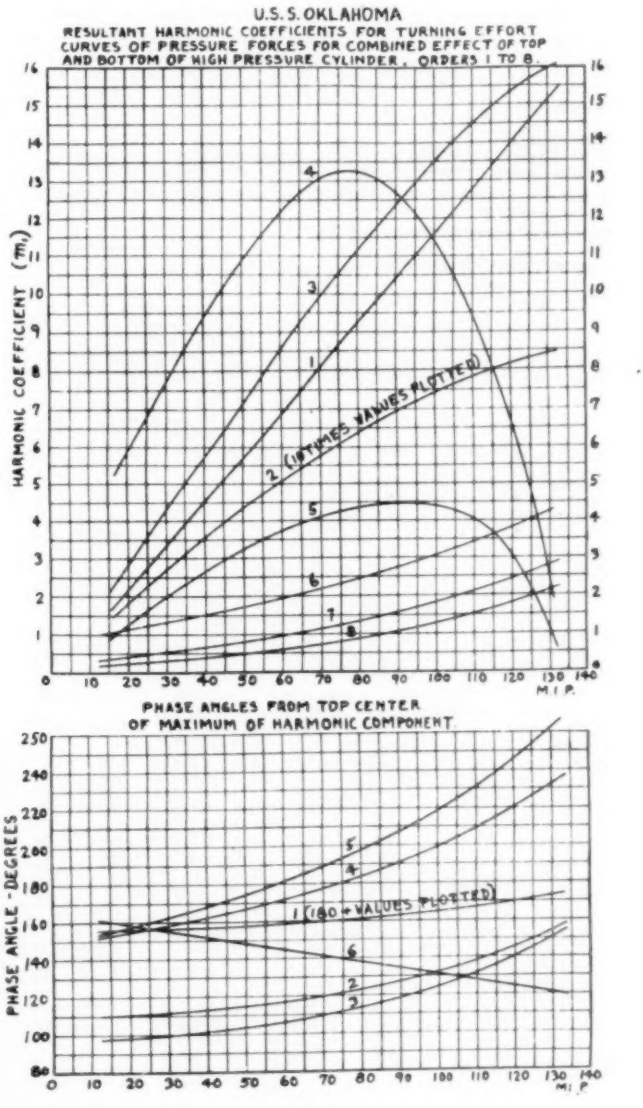

FIG. 5

Fig. 1 gives the i.hp. of the ship at 80 r.p.m. as 5200. Thus the i.hp. for each cylinder at this speed is: H.P., 867; I.P., 867; and L.P., 433; and the corresponding m.i.p. for each cylinder is: H.P., 47.6; I.P., 16.4; L.P., 4.68. The values of m_i and the phase angles for the pressure forces can now be obtained from Figs. 5, 6, and 7. Then multiplying the values of m_i by the mean piston area (mean of top and bottom area of each piston), the impulses due to the pressure forces are obtained. The values obtained in this way are given in Table 7.

The reciprocating part of the connecting rod is $0.4 \times 6470 = 2590$ lb. Thus the total reciprocating weight at the various cylinders is: H.P., 8800; I.P., 11,220; L.P., 11,320. The impulses due to the inertia of the reciprocating weights may be obtained from Table 1. For $r = 24$, r.p.m. $= 80$, these impulses are $104.8\ F_e W_r$.

Reading the values of F_a for the various orders, for a crank-to-connecting-rod ratio of $^1/_4$ from Table 1, the impulses due to this source may be computed. For 80 r.p.m. they are as given in Table 8. The harmonic components in F_a are all sine terms so that the phase angles of the impulses in Table 8 referred to the top center of the F.L.P. cylinder are 90 deg. greater than the phase angles for the various cylinders given in Table 6.

The impulses due to the couple from the connecting rod may be obtained from Table 3. For $h_1 = 38.4$, $h_2 = 57.6$, $H = 43$, $W = 6470$, r.p.m. = 80, these impulses are 424,000 F_c. Reading the values of F_c from Table 3, the impulses due to this source of stimulation at each cylinder are as given in Table 9. The phase angles for these impulses at the various cylinders are 90 deg. greater than those given in Table 6.

The impulses from the gravity forces of the reciprocating masses are given in Table 2. The evaluation of these impulses are given in Table 10. The phase angles for these impulses at the various cylinders are 90 deg. greater than those given in Table 6.

The unbalanced rotating part of the connecting rod is 0.6 × 6470 = 3880 lb. Thus the unbalanced rotating part of one connecting rod, crankpin, and two crankwebs is 3880 + 3760 = 7640 lb. The impulse due to the unbalanced rotating weight is given by Equation [1], so that its value at each cylinder is a 1-order impulse equal to 7640 × 24 = 183,500, having a phase angle at the various cylinders 90 deg. greater than those given for the 1-order in Table 6.

The resultant harmonic impulses acting at the center of the engine can now be obtained by combining the components of the various sources in their proper phase relation. This can be done graphically or analytically. If the latter method is used, the component impulses are multiplied by the sine and cosine of their phase angles. If A is the algebraic sum of all sine products for any order and B is the algebraic sum of all the cosine products, the resultant impulse for this order is $\sqrt{A^2 + B^2}$ and the corresponding phase angle is $\tan^{-1}(A/B)$. If this is done for the components computed above for the engine speed of 80 r.p.m., the resultants given in Table 11 are obtained.

In a similar manner the resultant harmonic impulses acting at the center of the engine can be obtained for any speed. Figs. 8 and 9 give the resultant impulses that have been computed for engine speeds between 40 and 125 r.p.m.

It is observed that the resultant impulse of the 1-order is due mainly to the pressure forces and the gravity forces of the reciprocating masses. The 2-order and 3-order are due mainly to the pressure forces and the inertia forces of the reciprocating masses. The 4-order is due mainly to the pressure forces, but is influenced to some extent by the inertia forces of the reciprocating masses. The effect of the couple from the connecting rod and the gravity forces of the reciprocating masses is seen to be small for the 4-order. It is also observed that the impulses of higher orders than the fourth are due principally to the pressure forces.

The principal damping forces occurring in this installation are due both to the action of the propeller and to elastic hysteresis of the shafting material. The energy absorbed by the elastic hysteresis may be obtained from Equation [4].

The data necessary to obtain the propeller damping coefficient for the *Oklahoma* are as follows:

Diameter	18 ft. 2 in.
Mean pitch	19 ft. 5$^1/_4$ in.
Number of blades	3
Developed area	92.4 sq. ft.
Projected area	77.7 sq. ft.
Pitch ratio	1.070
Mean width ratio	0.242
Projected area ÷ disk area	0.300
Blade-thickness ratio	0.0565

Thus from Table 4, f_m is given as 3.6, making the damping coefficient from Equation [10] equal to

$$\rho = \frac{60 \times 3.6}{2\pi} \frac{Q}{\text{r.p.m.}} = 34.4 \frac{Q}{\text{r.p.m.}} \quad \ldots\ldots [12]$$

in which Q can be obtained from the i.hp. curve in Fig. 1 for a mechanical efficiency of 85 per cent from the equation

$$Q = \frac{33{,}000 \times 12 \times E \times \text{i.hp.}}{2\pi \text{ r.p.m.}} = \frac{63{,}000\, E \times \text{i.hp.}}{\text{r.p.m.}} \quad \ldots [13]$$

where E is mechanical efficiency.

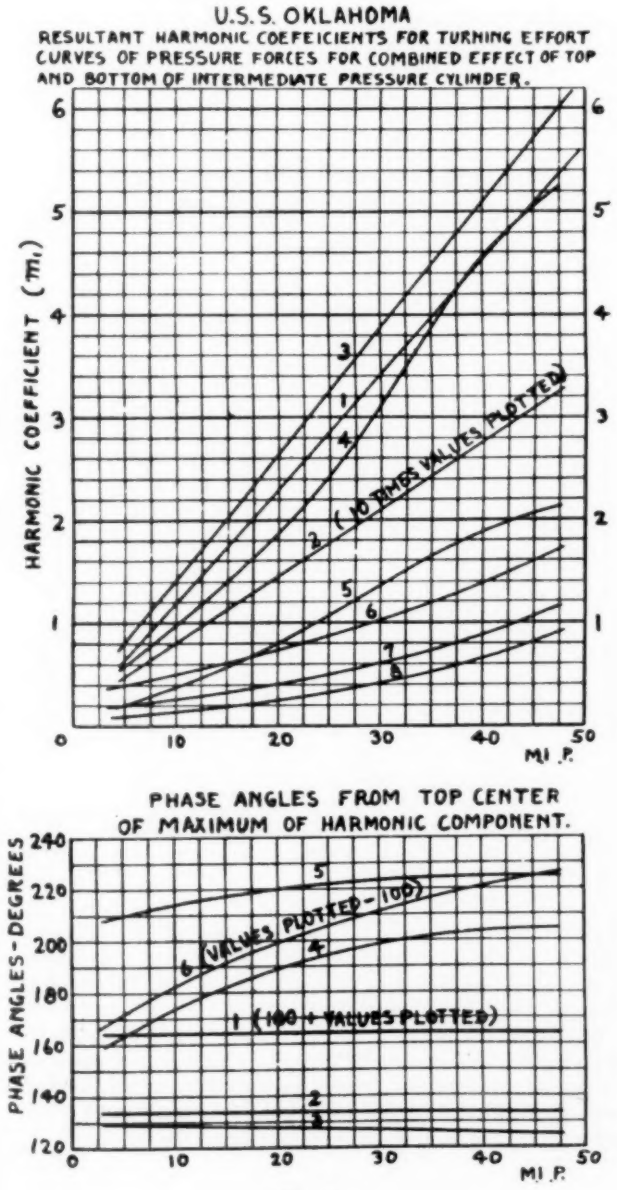

FIG. 6

As stated in Table 5, the stiffness of the shafting between the center of the engine and the center of the propeller is equivalent to 2020 in. of 17.75 in. outside and 8.75 in. inside diameter. This was obtained by calculating the deflection between these sections for a unit twisting moment, and finding the length of 17.75 × 8.75-in.-diameter shafting to give the same deflection. The crankshaft was assumed to have the same elasticity as a shaft of the same length having the journal section. For flanged couplings the shaft on either side was assumed to penetrate part way through the flanges.

The data given above for the *Oklahoma* are sufficient to calculate the amplitude of the first six orders of vibration over the speed range of 40 to 125 r.p.m. It is evident that the installation is approximately equivalent to the mathematical system of two concentrated masses connected by an elastic shaft having mass. If J_1, J_2, and J represent the WR^2 values, or the weight polar moment of inertias of the engine, propeller, and shafting, respectively, and if C represents the stiffness factor or proportional constant between the twisting moment M and the resulting angular deflection θ of the shaft between the center of the engine and the propeller such that $M = C\theta$, then

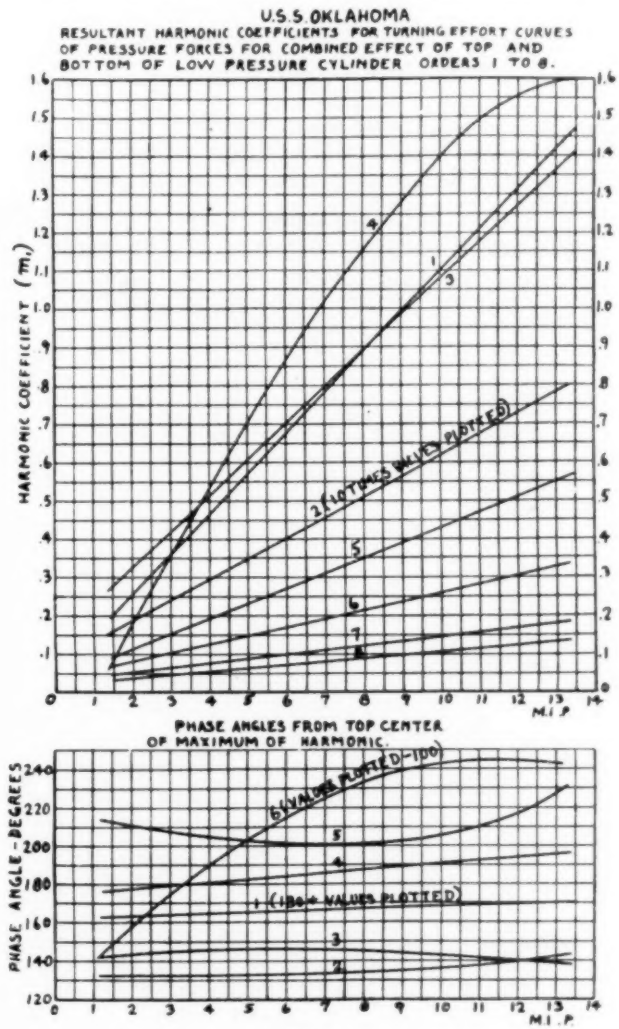

FIG. 7

$$J_1 = 32{,}700{,}000$$
$$J_2 = 66{,}900{,}000$$
$$J = 7{,}110{,}000$$
$$C = 53{,}500{,}000$$

Thus

$$\frac{J_1}{J} = 4.60, \frac{J_2}{J} = 9.41, \text{ and } \phi = \frac{360}{\sqrt{g}} \sqrt{\frac{J}{C}} = 18.33\sqrt{\frac{J}{C}} = 6.68$$

The synchronous frequency for any installation of this type may be obtained by the solution for n in Equations [24] and [39] of the author's previous paper.[3] These equations may be written in the following form:

$$\left.\begin{aligned} \tan\gamma &= \frac{\pi}{180}\frac{J_1}{J}\phi n \\ \tan(\phi n + \gamma) &= -\frac{\pi}{180}\frac{J_2}{J}\phi n \end{aligned}\right\} \quad \ldots\ldots\ldots [16]$$

where γ is a constant of integration in degrees.

It will be noted that there is an infinite number of roots for n as given by these equations. Considering the roots in an increasing order of magnitude, they are the synchronous frequencies of the 1, 2, 3, etc., noded modes of vibrations.

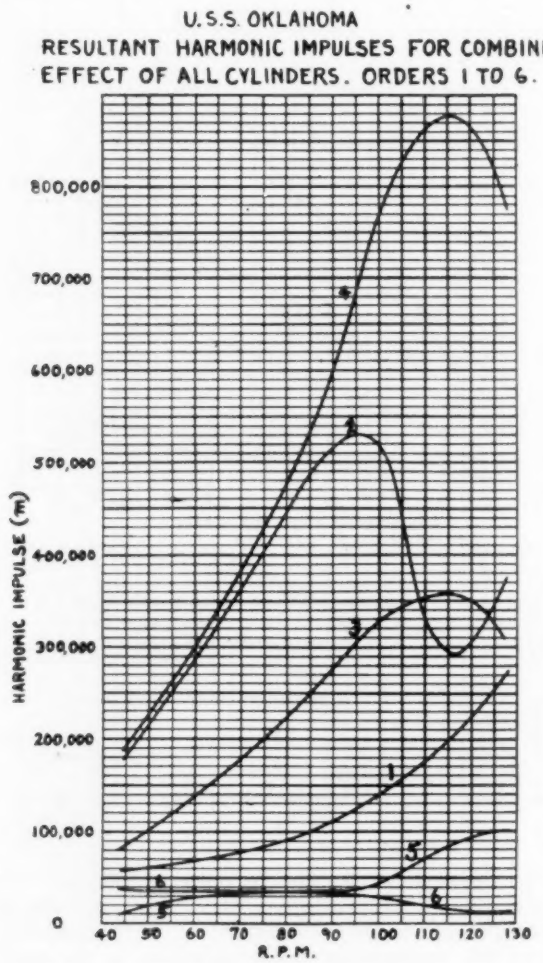

FIG. 8

From the solutions of these equations, a set of curves given in Fig. 10 has been constructed that give ϕn for the one-noded synchronous vibration for various values of J_1/J from 0 to 100 and J_2/J from 0 to ∞. From these curves ϕn can be obtained with a possible error of about one-half of one per cent, from which the value of n for the one-noded synchronous frequency can be computed by dividing by ϕ.

For the case of the installation under consideration, ϕn from the chart in Fig. 10, is 32.0, giving the value of n for the synchronous frequency of the one-noded vibration equal to 32.0/6.68 or 4.79 v.p.s.

When computing the amplitudes for the one-noded vibrations of such a vibrating system, however, where the inertia of the shaft is relatively small in comparison with the inertias of the concentrated masses, it is usually convenient to reduce the system to two concentrated masses connected by an elastic shaft having no mass. This may be done in such a way as to leave the frequency and the location of the node the same as before by using the curves in Figs. 11 and 12.

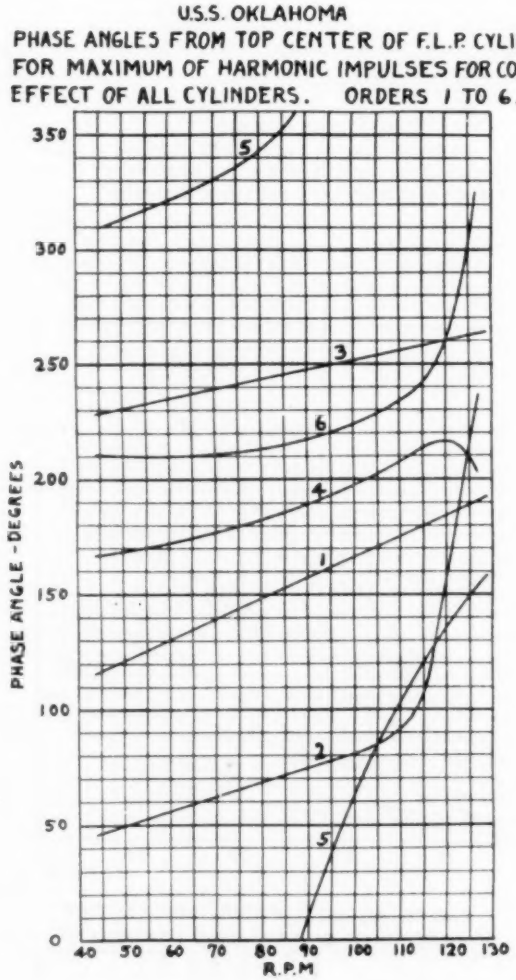

FIG. 9

Fig. 11 gives a factor to obtain the position of the node for the synchronous frequency of the one-noded torsional vibration for any two concentrated masses connected by an elastic shaft having mass from $J_1/J = 0$ to 20 and J_2/J from 0 to 12. The factor plotted in this figure is the absolute value of

$$\frac{x_{nd}}{l} - \frac{x_{cg}}{l}$$

where l = length of the shaft between the concentrated masses
x_{nd} = distance of the node from J_1
x_{cg} = distance of the center of gravity of the inertias from J_1; thus

[3] Loc. cit.

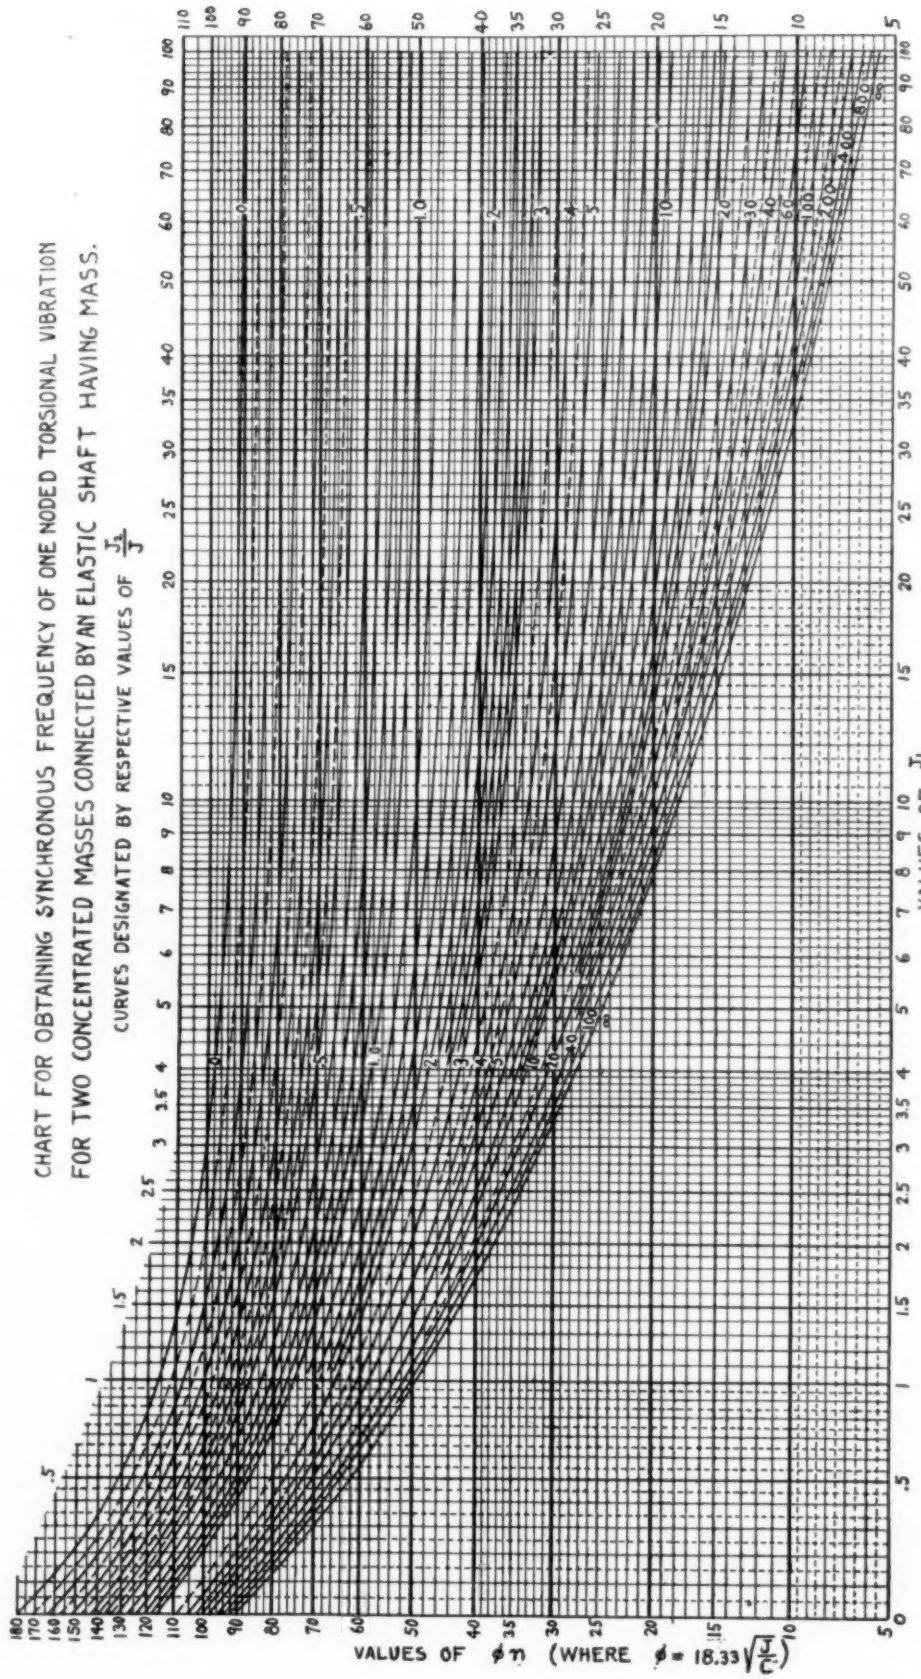

CHART FOR OBTAINING SYNCHRONOUS FREQUENCY OF ONE NODED TORSIONAL VIBRATION
FOR TWO CONCENTRATED MASSES CONNECTED BY AN ELASTIC SHAFT HAVING MASS.
CURVES DESIGNATED BY RESPECTIVE VALUES OF $\frac{J_1}{J}$
VALUES OF $\phi\eta$ (WHERE $\phi = 18.33\sqrt{\frac{K}{C_1}}$)
VALUES OF $\frac{J_1}{J}$

FIG. 10

$$\frac{x_{cg}}{l} = \frac{\frac{J_2}{J} + \frac{1}{2}}{\frac{J_1}{J} + \frac{J_2}{J} + 1} \quad \ldots\ldots [17]$$

The value of x_{nd} was computed from the relation $\frac{\phi n x_{nd}}{l} = 90 - \gamma$, where γ is the same constant as that stated in Equation [16]. This relation follows from Equation [22] of the author's previous paper where to obtain the node, θ is placed equal to zero. The position of the node is obtained from the factor given in Fig. 11 by computing x_{cg}/l from [17] and adding or subtracting $\frac{x_{nd}}{l} - \frac{x_{cg}}{l}$ in such a way as to place the node between the center of gravity of the inertias and the larger concentrated mass.

The synchronous frequency, as given by [18], for a shaft having mass that is fixed at one end and has a concentrated mass at the other can be obtained from Equation [19] by adding a certain fraction of the mass of the shaft to J_1. Let Δ be this fraction of J to be added to J_1. Then the synchronous frequency for the shaft fixed at one end will be given by

$$n = \frac{1}{2\pi}\sqrt{\frac{gC}{J_1 + \Delta J}}$$

Substituting this value of n in Equation [18] and changing the angle $\phi_a n$ to radians, there results

$$\cot \frac{1}{\sqrt{d + \Delta}} = \frac{d}{\sqrt{d + \Delta}} \quad \ldots\ldots [20]$$

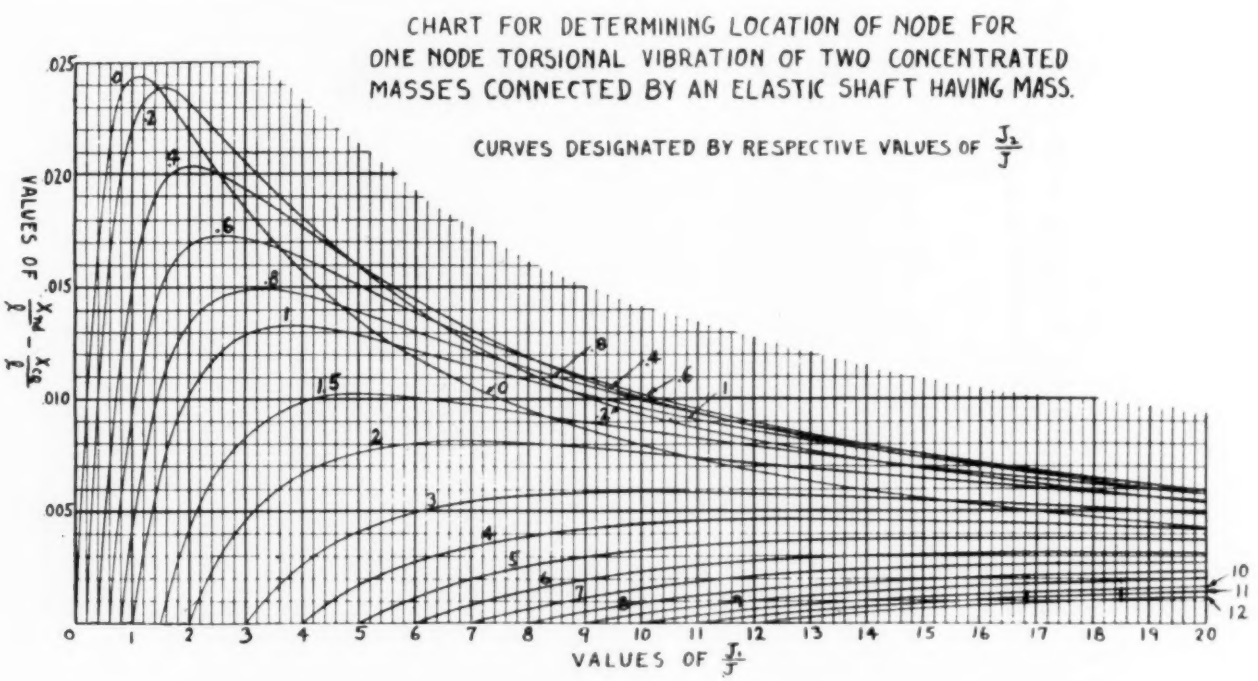

FIG. 11

After the node is determined for the synchronous frequency, the shaft can be considered fixed at the node. The concentrated mass and shaft on either side at this frequency can thus be considered as a vibrating system fixed at one end having a concentrated mass at the other. If ϕ_a is the value of $\frac{360}{\sqrt{g}}\sqrt{\frac{J}{C}}$ for a shaft fixed at one end, and if J_1 is the value of the inertia concentrated at the other, the synchronous frequency follows from [16] by putting $J_2 = \infty$. This gives $\phi_a n + \gamma = 90$, or, eliminating γ, the synchronous frequency follows from

$$\cot \phi_a n = \frac{\pi}{180}\frac{J_1}{J}\phi_a n \quad \ldots\ldots [18]$$

If an elastic shaft without mass is fixed at one end and has a concentrated mass J_1 at the other, the synchronous frequency is given by Equation [42] of Appendix No. 1, by putting $J_2 = \infty$. In this case

$$n = \frac{1}{2\pi}\sqrt{\frac{gC}{J_1}} \quad \ldots\ldots [19]$$

where $d = J_1/J$.

Where there is no concentrated mass at the end, $J_1 = 0$, $d = 0$, and

$$\cot \frac{1}{\sqrt{\Delta}} = 0, \text{ giving } \Delta = \frac{4}{\pi^2} = 0.40528$$

The limit of Δ when the inertia of the shaft is assumed indefinitely small may be obtained as follows:

Equation [20] may be written

$$1 = \frac{d}{\sqrt{d + \Delta}} \tan \frac{1}{\sqrt{d + \Delta}}$$

Expanding the tangent function into an infinite series of increasing powers of the angle, the above relation may be written in the following form:

$$1 = \frac{d}{\sqrt{d + \Delta}}\left(\frac{1}{\sqrt{d + \Delta}} + \frac{1}{3(d + \Delta)^{3/2}} + \frac{2}{15(d + \Delta)^{5/2}} + \ldots\right)$$

which may be changed to

$$\Delta = \frac{d}{3(d + \Delta)} + \frac{2d}{15(d + \Delta)^2} + \ldots$$

If J is taken indefinitely small, d becomes indefinitely large, and $\Delta = 1/3$.

The curves in Fig. 12 give the value of Δ for any value of $J_1/J(=d)$ from 0 to 12.

Hence two concentrated masses connected by a shaft having mass can be reduced to two concentrated masses connected by a shaft having the same elasticity but no mass in such a way as to leave the synchronous frequency and location of the node unchanged, as follows: Determine the location of the node from Fig. 11 and Equation [17]. Find Δ_1 from Fig. 12 for the part of the shaft that is on the same side of the node as J_1, and Δ_2 for the part that is on the same side of the node as J_2. The same frequency and location of the node will then exist for the synchronous vibration of the two masses

$$J_1 + \frac{x_{nd}}{l}\,\Delta_1 J \text{ and } J_2 + \left(1 - \frac{x_{nd}}{l}\right)\Delta_2 J$$

which are connected by a shaft having no mass and the same elasticity as before.

For the installation on the *Oklahoma* Equation [17] gives $\frac{x_{cg}}{l} = 0.660$ and the chart in Fig. 11 gives $\frac{x_{nd}}{l} - \frac{x_{cg}}{l} = 0.004$. Thus $\frac{x_{nd}}{l} = 0.660 + 0.004 = 0.664$. Therefore the inertia of the shaft from J_1 to the node is $0.664\,J$ and from J_2 to the node is $0.336\,J$. This gives $\frac{J_1}{0.664\,J} = 6.92$ and $\frac{J_2}{0.336\,J} = 28.0$ and from the chart in Fig. 12, $\Delta_1 = 0.336$ and $\Delta_2 = 0.334$. Hence $J_1 + \frac{x_{nd}}{l}\,\Delta_1 J = 34{,}300{,}000$ and $J_2 + \left(1 - \frac{x_{nd}}{l}\right)\Delta_2 J = 67{,}700{,}000$.

In this way it is seen that for the one-noded vibration of the installation under consideration, the shaft line-up in vibration is approximately equivalent to the mathematical system of two concentrated masses connected by an elastic shaft having no mass where

$$\begin{aligned} J_1 &= 34{,}300{,}000 \\ J_2 &= 67{,}700{,}000 \\ C &= 53{,}500{,}000 \end{aligned}$$

That this system has the same synchronous frequency as the previous one in which the shaft was considered to have mass may be seen by obtaining its synchronous frequency from Equation [42]; thus

$$n = \frac{1}{2\pi}\sqrt{\frac{386 \times 53.5 \times 102.0}{34.3 \times 67.7}} = \frac{1}{2\pi}\sqrt{907} = 4.79 \text{ v.p.s.}$$

The particular form of torsional vibration that may be expected to cause trouble in an installation of this type is the form that is continually maintained by the stimulating impulses at any constant speed of revolutions. The free or natural vibrations of the system that are caused by suddenly applied or nonperiodic forces rapidly disappear due to the action of the damping forces, if the installation is operated at a constant speed and load for a short time. For this reason the free vibrations may be neglected and consideration need be given only to the forced vibrations of a periodic nature.

The undamped resonance curves of the forced vibration in the installation under consideration may therefore be calculated from Equations [37] to [40]. For example, consider the undamped amplitude of the 4-order vibration at the frequency of $n = 4.65$ v.p.s. The r.p.m. of the shaft corresponding to a 4-order vibration of this frequency is $4.65 \times 60/4$ or 69.75 r.p.m. From expression [30] Appendix No. 1, $\alpha = -0.4178$, $\beta = -0.5677$. Thus $\alpha - \beta = 0.1499$. The value of m for the 4-order at this speed from Fig. 8 is 380,000 with a phase angle from Fig. 9 of 177 deg. Expression [30] then gives $m_0 = 0.4070$. Hence from Equation [39], $a = 0.4070/0.1499 = 2.715$, and from Equation [40], $b = -2.715 \times 0.5677 = -1.542$.

The stress in any uniform section of the shaft due to the deflection Ⓗ degrees of one mass relative to the other is

$$S = \frac{16Md_2}{\pi(d_2^4 - d_1^4)} = \frac{4d_2C\text{Ⓗ}}{45(d_2^4 - d_1^4)} \quad \ldots\ldots\ldots\ldots [21]$$

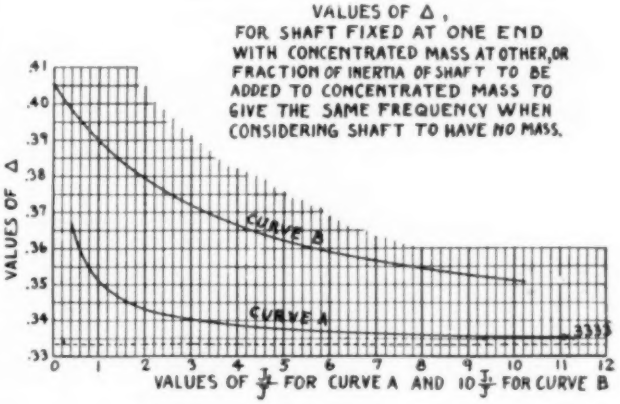

FIG. 12

where d_1 and d_2 are the inner and outer diameters of the section.

The total deflection over the shaft for the example considered is $2.715 + 1.542 = 4.257$, so that the stress in the small section of the shaft (17.5 in. outside and 8.75 in. inside diameter) from Equation [21] is 4050 lb. per sq. in.

The undamped resonance curve for the amplitude of the 4-order vibration at the engine and propeller computed as just described is shown in Fig. 13. The sign of the amplitude a in passing from a little below synchronism to a little above is considered to remain positive and the phase of the vibration to change by 180 deg. The calculated results are also tabulated in Table 12. It is observed that the amplitude of the undamped vibration at synchronism is infinite.

If the principal damping action comes from the propeller the damped resonance curves may be calculated from Equations [31] to [36]. Illustrating this, consider again the 4-order vibration of the installation on the *Oklahoma* at $n = 4.65$ or r.p.m. = 69.75. The value of ρ is given by Equation [12] which depends on Q. The i.hp. for this speed from Fig. 1 is 1808 per engine, so that from Equation [13], $Q = 1{,}390{,}000$. Then Equation [12] gives $\rho = 685{,}000$. From [30], $\rho_1 = 3740$. Therefore Equations [33] to [36] give, $a_N = 2.337$, $b_N = -1.326$, $a_d = 0.4960$, $\omega = 30.6$. These values are illustrated graphically in Fig. 14.

The resonance curve for the 4-order vibration damped only by the action of the propeller computed as just described is shown in Fig. 13 and also in Table 12. The manner in which the curves are plotted gives a picture of the amplitude of vibration at any point of the shaft. If at any speed the shaft is considered as represented by the ordinate in such a way that the engine and propeller are on their respective resonance curves, the amplitude at any intermediate section of the shaft is given at the corresponding point on the ordinate. It may be men-

tioned that although the maximum vibration does not usually occur precisely at synchronism, the difference can hardly be seen in ordinary cases.

The phase angles of the normal phase of the motion and of the resultant motion in degrees of the 4-order cycle behind the maximum value (m) of the impulse is shown in Fig. 13, as is also the phase angle of m behind top center of the F.L.P. cylinder. The phase angle for the vibration behind top center of the F.L.P. cylinder may be obtained by adding the phase angle of the vibration behind m to the phase angle of m behind the F.L.P. cylinder.

If the principal damping action comes both from the propeller

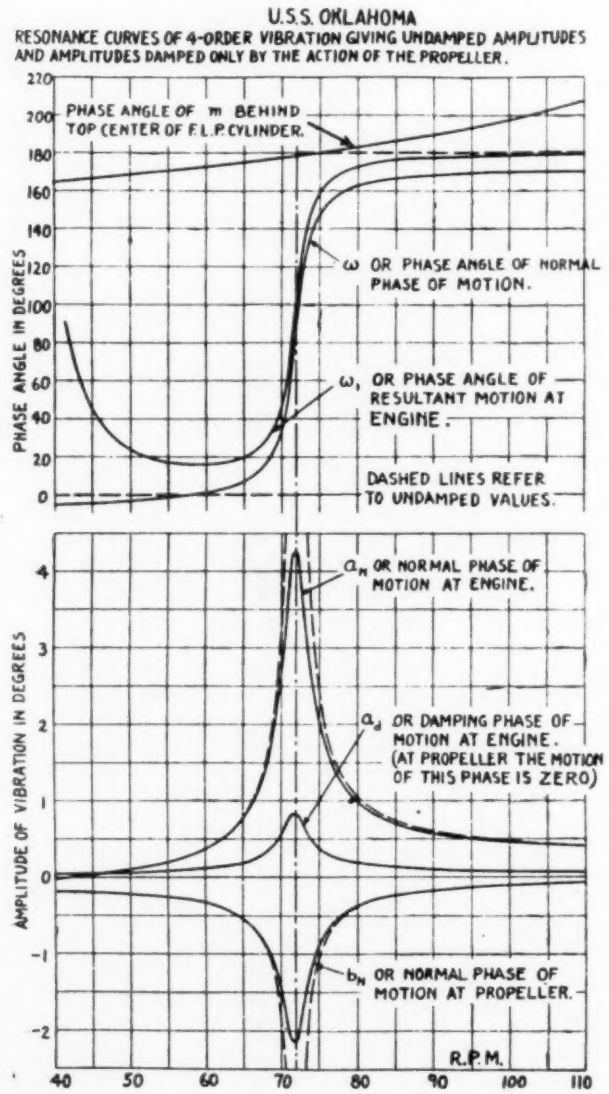

Fig. 13

and from the elastic hysteresis of the shafting, the damped resonance curves may be calculated from Equations [75] to [79]. Illustrating this, consider again the 4-order vibration of the installation on the *Oklahoma* at $n = 4.65$. The value of f_1 for the equivalent shaft whose length is 2020 in. and diameters are 17.75 in. outside and 8.75 in. inside may be computed from [70]. This gives $f_1 = 0.01230$. As before $m_0 = 0.4070$, $\alpha = -0.4178$, $\beta = -0.5677$, $\rho_1 = 0.3740$. Thus Equation [77] for the first approximation can be written

$$0.1657 - 0.00914\textcircled{H}^2 = [0.0566\textcircled{H} + 0.01744\textcircled{H}^{1.3}]^2$$

By substituting trial values in this equation, it will be found that $\textcircled{H} = 3.24$ deg. Thus the other values for the first approximation become $a_N = 2.067$, $b_N = -1.173$, $a_d = 0.4922$, etc.

For a second approximation, Equation [73] may be evaluated to give $f_2 = 0.01234$, and $\delta = 0.00259$. Thus Equation [75] can be written

$$0.1657 - 0.00989\textcircled{H}^2 = [0.05675\textcircled{H} + 0.01750\textcircled{H}^{1.3}]^2$$

From this equation it is found that $\textcircled{H} = 3.166$ deg., so that the other values of the second approximation become $a_N = 2.017$, $b_N = -1.149$, $a_d = 0.483$, etc.

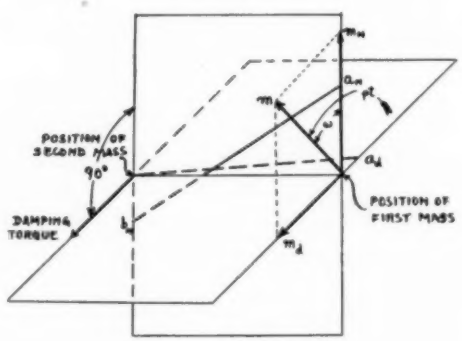

Fig. 14

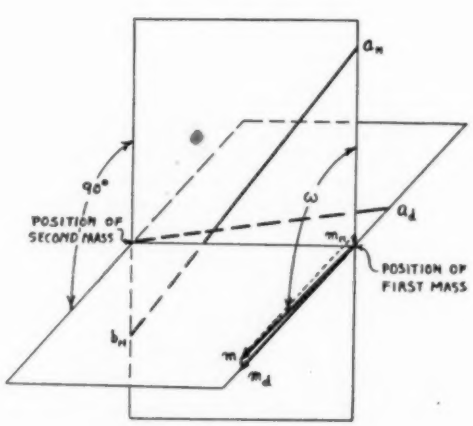

Fig. 15

A third approximation gives the same results as the second to the significant figures given. This shows that the results given by the second approximation are the ones sought. It is observed that the results of the first approximation are correct within about two per cent.

A graphical representation of the values at synchronism computed in a manner similar to that just given is illustrated in Fig. 15.

The resonance curve for the 4-order vibration damped both by the propeller and elastic hysteresis computed as just described is shown in Fig. 16, and the calculated results are given in Table 13. The phase angles of the vibration behind m, and m behind top center of the F.L.P. cylinder, are also shown in Fig. 16.

Several important characteristics of damped vibrations are

TABLE 12 CALCULATED AMPLITUDES OF 4-ORDER VIBRATION FOR INSTALLATION ON U. S. S. "OKLAHOMA"

* Synchronism.

illustrated by the results of the calculations shown in Figs. 13 to 16, and Tables 12 and 13. These may be summarized as follows:

1 The damping phase of the motion is small in comparison with the motion of the normal phase.

2 At frequencies a little removed from synchronism, the motion of the normal phase for damped vibrations is only slightly smaller than the undamped vibration.

3 The maximum value of the damped resonance curves usually occurs very near to synchronism, and its value is only slightly greater than the amplitude at synchronism.

These characteristics show that the range of severe vibration can be safely taken from the undamped resonance curve and the severity of the vibration can be judged by its amplitude and stress at synchronism.

The calculated amplitudes of the first six orders of vibration over the speed range of 40 to 125 r.p.m. are given in Fig. 17. It is evident from this figure that in addition to the large 4-order vibration at 72 r.p.m. there is also a large 3-order vibration at 96 r.p.m. Other vibrations in the speed range are relatively small.

In Fig. 18 is given the vibration stress in the smallest uniform section of the shafting (17.5 in. outside and 8.75 in. inside diameter) occurring in the thrust shaft. The stress due to the mean power torque is also shown in Fig. 18. By combining the vibration stresses at any speed in their proper phase relation, and adding the resultant to the stress due to the mean power torque, the maximum combined stress at any speed may be obtained. This value is represented in Fig. 18 by the dotted line.

Similar stress curves can be drawn for any section of the shafting. The stresses in the crankshaft are augmented by the bending stresses due to the reciprocating weights. In this paper, however, attention is confined to the stress in the small section of the shaft line-up remote from the crankshaft.

II—U. S. S. "Texas," Starboard Propelling Unit

Since the engines for the *Texas* are similar to those for the *Oklahoma*, the impulses due to the pressure forces may be obtained as described for the *Oklahoma* from Figs. 5, 6, and 7. Thus the combined impulses acting at the center of the engine may be computed.

The propeller damping coefficient for the *Texas* was found to be the same as that for the *Oklahoma* given by Equation [12].

Thus the principal vibrations for the *Texas* over the speed range from 40 to 125 r.p.m. may be calculated from the data given. The results of such calculations are given in Fig. 19, which gives the calculated vibration stresses in the smallest uniform section of the shafting (17.75 in. outside and 11.5 in. inside diameter) occurring in the thrust shaft. The stresses due to the mean power torque and the maximum combined stresses at any speed are also shown in this figure.

III—U. S. S. "Minnesota" and U. S. S. "Kansas," Port Propelling Installation

The engines for these ships are also similar to those for the *Oklahoma*. Hence the impulses due to the pressure forces may be obtained as described for the *Oklahoma* from Figs. 5, 6, and 7, and the combined impulses acting at the center of the engine may be computed.

The propeller damping coefficient for the original three-bladed propeller was found to be the same as that for the *Oklahoma* given by Equation [12].

Therefore the principal vibrations for the *Minnesota* and *Kansas* over the speed range from 40 to 125 r.p.m. may be calculated where the original three-bladed propeller is used.

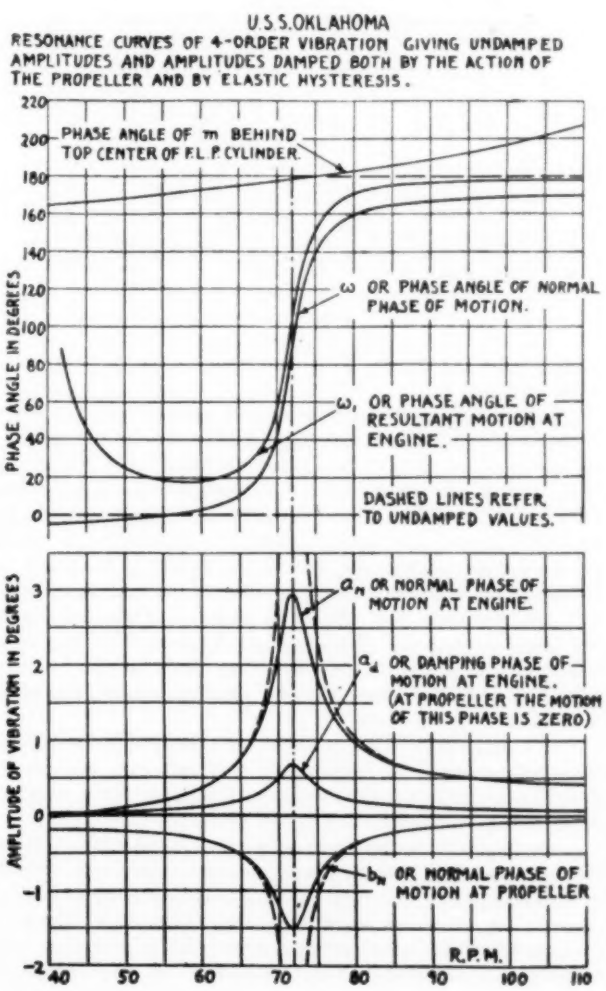

Fig. 16

The results of such calculations are given in Fig. 20, which gives the calculated vibration stresses in the smallest uniform section of the shafting (15.5 in. outside and 9.5 in. inside diameter) occurring in the thrust shaft. The stresses due to the mean

* Synchronism.

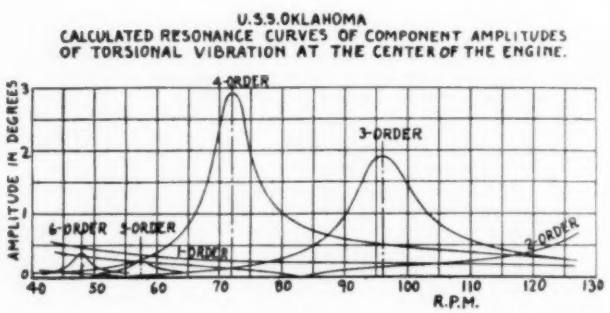

FIG. 17

power torque and the maximum combined stresses are also shown in this figure.

The agreement of the calculated and recorded magnitudes of vibration for the above installations will now be discussed.

Torsion-meter tests of the actual stresses in the shafting of the U. S. S. *Minnesota* and U. S. S. *Kansas* were made some time prior to 1917. The results of these tests were described by Ernest N. Janson and Lieut.-Comm. J. O. Richardson, U. S. N. ("Investigation of Shafting Failures and Engine Vibration on Vessels of the Louisiana Class," *Journal of the American Society of Naval Engineers*, Vol. 29, 1917, page 1). These tests were performed on both the *Minnesota* and *Kansas*. The *Minnesota* was tested with four-bladed propellers fitted in place of the former three-bladed ones, but the old three-bladed propellers were used on the *Kansas*.

The torsion meter used in these tests was made by Messrs. Denny-Edgecombe, of Dumbarton, Scotland, and was so designed as to obtain a continuous record on paper of the torsional stress during each revolution of the shaft.

A maximum stress was found to occur at 83 r.p.m. for the *Kansas* equal to 10,952 lb. per sq. in., and at 80 r.p.m. for the *Minnesota* equal to 11,380 lb. per sq. in. The calculated results, given in Fig. 20 above, show a maximum to occur at 85 r.p.m. equal to 12,400 lb. per sq. in. for the installations equipped with three-bladed propellers. The comparison of the calculated stresses and the observed values given by Janson and Richardson are shown graphically in Fig. 20. In regard to the observed difference in location of the maximum of the *Minnesota* and *Kansas*, it is believed that the WR^2 of the four-bladed propellers used on the *Minnesota* was greater than that of the three-bladed ones used on the *Kansas*, causing the synchronous frequency of the vibration on the *Minnesota* to be lower than that on the *Kansas*. The calculated and recorded stresses, however, are seen to be in fair agreement.

The instruments used in testing the installations on the *Texas* and *Oklahoma* were torsiographs. These instruments were designed by Dr. J. Geiger, and record on paper the amplitude of vibration at any section to which they are attached. Two torsiographs were used in testing each installation, one belted to the

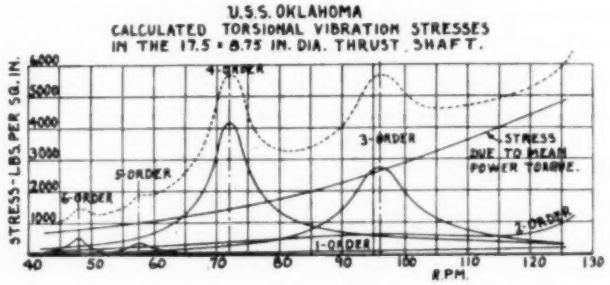

FIG. 18

shaft just aft of the engine and the other just forward of the after inboard coupling.

In the case of the *Texas*, records of the vibration in the shaft were obtained every five revolutions per minute apart from 40 r.p.m. to 105 r.p.m.

A large 4-order vibration was observed between the speeds of 70 r.p.m. and 85 r.p.m. Its maximum value of about 2.4 deg. at the forward instrument occurred at 77 r.p.m. A smaller 3-order vibration was observed at higher speeds having a maximum value at the forward instrument of about 1.3 deg. at 102 r.p.m. Several small vibrations of scarcely noticeable amplitude were observed at other speeds. The 5-order vibration was seen at 61 r.p.m. combined with a forced vibration of the 4-order of about the same amplitude. The 6-order vibration was seen at 51 r.p.m. and the 8-order at 39 r.p.m. The amplitudes obtained by the torsiographs and those obtained by calculations at the positions of the forward and after instruments are listed in Table 14. The calculated and recorded values are seen to be in fair agreement.

In the case of the *Oklahoma*, torsiographic records of the vibration in the shaft were obtained every five revolutions per minute apart from 40 r.p.m. to 80 r.p.m.

A large synchronous 4-order vibration was observed at 72 r.p.m. having a maximum value at the after instrument of about 1.25 deg. The calculated value of the 4-order synchronous vibration at this instrument was 1.36 deg. occurring at 72 r.p.m. These values are seen to be in fair agreement with the recorded values.

One of the main considerations in judging the severity of vibrations is the magnitude of the stress caused by the vibration. Furthermore, the seriousness of the vibration stresses is greatly magnified by stress concentrations at the various discontinuities in the shafting.

The results of fatigue tests gathered from various sources[4] show that the average endurance limit for steel in reversed torsion is about 25 per cent of the ultimate tensile strength, and that such discontinuities as square shoulders and V-notches reduce this endurance limit 50 to 60 per cent. The ordinary discontinuities in the shafting of a reciprocating engine installation probably have nearly the same effect in reducing the endurance limit of the shafting as square shoulders and V-notches. Thus the maximum allowable torsional vibration stress for an engine shafting is about 10 per cent of the ultimate tensile strength.

The ultimate tensile strength of the material used in the shafting of the installations described above was about 80,000 lb. per sq. in., which indicated a maximum allowable vibration stress of 8000 lb. per sq. in. Referring to Figs. 11, 12, and 13, it is seen that the 4-order vibration stress for the *Minnesota* and *Kansas* is above the allowable stress value, and failure of the

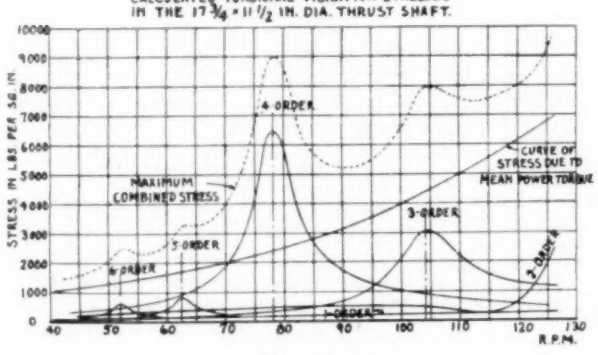

FIG. 19

shafting at some section of stress concentration could be expected eventually. This is what actually did occur several years ago on these ships.

The vibration stresses for the case of the *Oklahoma* and *Texas* are seen to be below the maximum allowable stress. In regard to these ships it may be stated that no failures have occurred in the ordinary discontinuities of the shafting, such as flanged couplings, changes in shaft diameter, oil holes, etc. Failures have occurred in these ships, however, in the outboard couplings. These couplings are the usual sleeve type of design, consisting of a sleeve into which taper portions of the line shaft and propeller shaft are inserted and drawn up by tapered wedges driven through large radial holes cut in the sleeve and shafts. The failures of the sleeves of these couplings show that they are a point of local weakness, which is probably due to high stress concentrations occurring around the large holes in the sleeves.

[4] See H. F. Moore and J. B. Kommers, "Fatigue of Metals," 1927.

In redesigning the above installations to avoid vibration troubles, the following remedies suggest themselves.

1 Redesign the outboard coupling to give it greater fatigue strength.

2 Install a damping device to absorb the energy of vibration before it reaches an excessive value.

3 Increase the mean diameter of the shafting to such a size that it can safely withstand the stress of the 4-order vibration.

4 Increase the mean diameter of the shafting to shift the 4-order vibration above the maximum operating speed.

5 Change the inertia of the engine and propeller to decrease the vibration stresses.

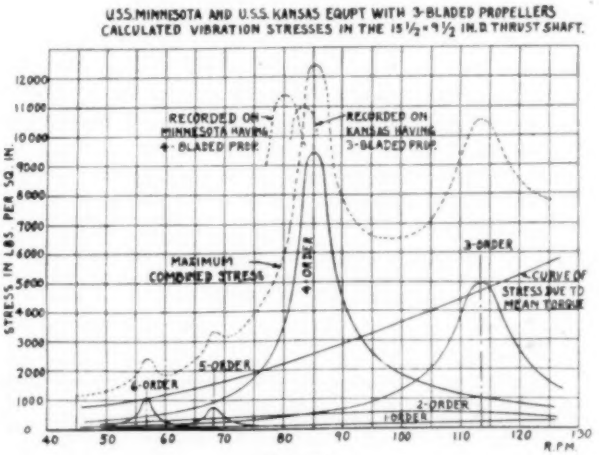

FIG. 20

The desirability of redesigning the outboard coupling to give it greater fatigue strength has been shown in the case of the *Oklahoma* and *Texas* by several failures that occurred to this part of the shaft line-up. This could easily be done by making, for example, the sleeves of the coupling out of some high fatigue strength material. It is probable that if this were done less trouble from torsional vibration would be experienced on these ships. Such a solution, however, would not correct the difficulty for the *Minnesota* and *Kansas*.

A well-known damping device is the Lanchester damper. This consists of a slipping flywheel whose only contact with the shaft is through friction surfaces. The equations whose solutions give the amplitude of vibration when the engine mass is acted on by a friction damper are given in Appendix No. 2.

To illustrate the effect of a friction damper, calculations have been made for the *Oklahoma* that are summarized in Fig. 21. Several different WR^2 values of the damper flywheel were considered for any friction torque that might act across the friction surfaces. The amplitude plotted in Fig. 21 gives the resulting amplitude of the normal phase at synchronism for the center of the engine. It is evident from this figure that the total friction torque for a friction damper is an important detail if the damper is to function in an efficient manner.

Fig. 21 shows that a flywheel having, for example, a WR^2 value of 6,000,000 lb-in.^{2} or 17.5 per cent of the engine WR^2 can be used to reduce the amplitude at the engine to less than one-half of its value without the damper if the friction surfaces between

TABLE 14 AGREEMENT OF CALCULATED AND RECORDED VIBRATION OBTAINED ON THE U. S. S. "TEXAS"

	Recorded values				Calculated values			
	4-Order		3-Order		4-Order		3-Order	
	R.p.m.	Amp.	R.p.m.	Amp.	R.p.m.	Amp.	R.p.m.	Amp.
For'd inst.	77	2.40°	102	1.46°	78.1	2.84°	104.2	1.35°
After inst.	77	1.10°	102	0.65°	78.1	1.30°	104.2	0.62°

the flywheel and engine are designed to hold about 180,000 in-lb. torque.

Calculations have also been made to show the effect of increasing the mean diameter of the shafting and changing the WR^2 values of the engine and propeller for the case of the *Minnesota* and *Kansas*. The results obtained will also apply qualitatively to the *Oklahoma* and *Texas*.

Fig. 22 shows the calculated results of the effect of changing the mean diameter of the shafting. It is noted that increasing the mean diameter of the shafting does not indicate necessarily a decrease in the vibration stress. The maximum vibration stress due to the 4-order occurs at 97.5 r.p.m. for 17.6 in. mean outside diameter. It is also observed that this stress is still undesirably large for a diameter of 20 in., which raises the synchronous speed for the 4-order to the maximum operating speed. This shows that the mean diameter of the shafting cannot be increased to such a value in the speed range of the installation that it can safely withstand the stress of the 4-order synchronous vibration.

It may be seen from Fig. 22 that if the mean outside diameter of the shafting were increased to 20.8 in., the 4-order synchronous vibration would be raised to 135 r.p.m. In this way the 4-order vibration could be removed from the operating range and the stress in the shafting could be kept to a moderate value.

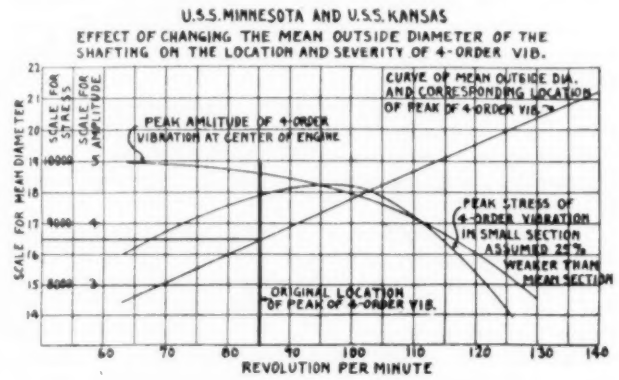

FIG. 22

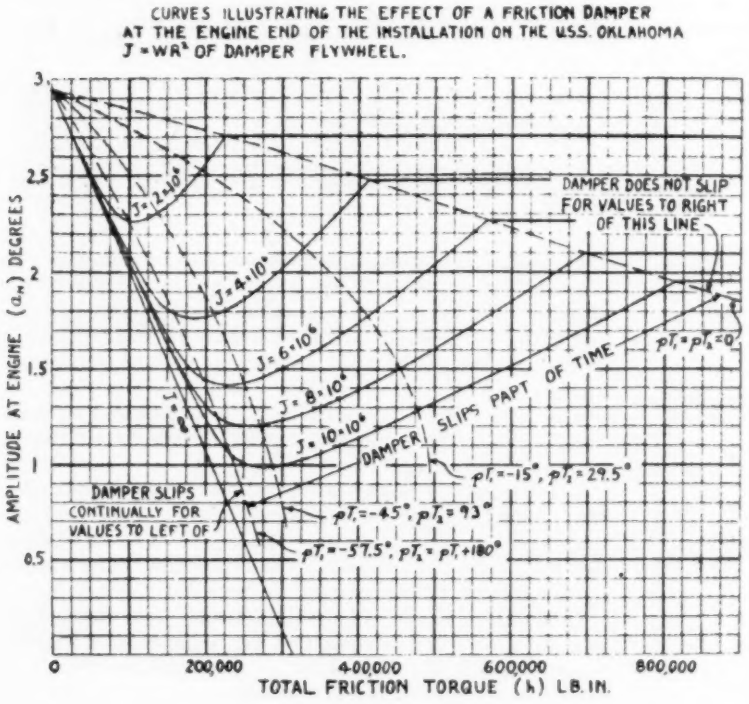

FIG. 21

Increasing the inertia of the engine and decreasing the inertia of the propeller has been found to have a large effect on decreasing the amplitude and stresses of vibration. This is due to the fact that such changes tend to decrease the amplitude at the engine and increase the amplitude at the propeller causing greater damping to occur at the propeller. The effect of changing these inertias in this manner is shown in Fig. 23. It is seen in this figure that if a flywheel is placed near the engine such as to increase the engine inertia 50 per cent, the vibration stress of the 4-order is decreased 39 per cent, while if the engine inertia is increased 100 per cent, the stress is decreased 58 per cent. Similarly if the propeller inertia is reduced 60 per cent, such as could be done by casting the propeller out of duralumin, the vibration stress is reduced 67 per cent. If the inertia of the engine is increased 100 per cent and at the same time the propeller inertia is decreased 60 per cent, the vibration stress of the 4-order is decreased 83 per cent corresponding to a stress of only 1600 lb. per sq. in. It is thus seen that such a solution offers rather wide possibilities.

Appendix No. 1

TORSIONAL VIBRATION OF TWO CONCENTRATED MASSES CONNECTED BY AN ELASTIC SHAFT HAVING NO MASS, WITH VARYING IMPRESSED TORQUES ACTING ON THE FIRST MASS AND A DAMPING TORQUE PROPORTIONAL TO THE VELOCITY ACTING ON THE SECOND

LET quantities with subscripts 1 and 2 not otherwise defined refer to the first and second masses, respectively. Consider that the first mass is acted upon by the impressed torques and the second by the damping torques.

If θ is the angular deflection in radians, the twisting moment acting on the shaft is $C(\theta_2 - \theta_1)$. If the weight polar moment of inertia of either mass is J, and its angular acceleration is $\frac{d^2\theta}{dt^2}$, the inertia torque of the mass is $\frac{J}{g}\frac{d^2\theta}{dt^2}$. Let the impressed torques acting on the first mass be given by M_t. Let the damping torque acting on the second mass be $\rho\ d\theta_2/dt$, where ρ is the constant of proportionality.

TABLE 15

Installation	Order of vibr.	R.p.m.	$-10^6\rho\beta/C$	$g\,10^6/J_2\rho$	$\rho 10^{-6}$	a_d/a_N	$-M_d/M_N$	$\sqrt{a_n^2+a_d^2}/a_N$	$\sqrt{M_n^2+M_d^2}/M_N$
Minnesota	3	113.6	0.242	0.1788	0.922	0.223	0.1650	1.025	1.014
	4	85.2	0.242	0.1788	0.664	0.1608	0.1188	1.013	1.007
	5	68.2	0.242	0.1788	0.487	0.1180	0.0872	1.007	1.004
	6	56.8	0.242	0.1788	0.409	0.0991	0.0728	1.005	1.003
Oklahoma	3	96.0	0.283	0.1885	0.916	0.259	0.1728	1.033	1.015
	4	72.0	0.283	0.1885	0.696	0.1970	0.1312	1.019	1.009
	5	57.5	0.283	0.1885	0.598	0.1695	0.1128	1.014	1.006
	6	48.0	0.283	0.1885	0.548	0.1550	0.1034	1.012	1.005
Texas	3	104.0	0.231	0.1575	1.318	0.305	0.208	1.046	1.022
	4	78.0	0.231	0.1575	0.968	0.224	0.1527	1.025	1.012
	5	62.5	0.231	0.1575	0.873	0.201	0.1378	1.020	1.009
	6	52.0	0.231	0.1575	0.817	0.1887	0.1288	1.018	1.008

Then the sum of the torques acting on one side of any section is equal to the torque in the shaft at that section. Thus it follows that just beyond the first mass

$$\frac{J_1}{g}\frac{d^2\theta_1}{dt^2} - M_i = C(\theta_2 - \theta_1) \quad \ldots\ldots [22]$$

and just beyond the second mass

$$\frac{J_2}{g}\frac{d^2\theta_2}{dt^2} + C(\theta_2 - \theta_1) + \rho\frac{d\theta_2}{dt} = 0 \quad \ldots\ldots [23]$$

Any form of torsional vibration of the two masses for the case considered will have torsional displacements that satisfy Equations [22] and [23]. The vibration may be periodic or changing depending on the impulses and the length of time of their application. If the impressed torques M_i are periodic and are applied to the first mass for a long time, the vibration will become periodic in nature. In the following solution only periodic or steady state vibrations will be considered.

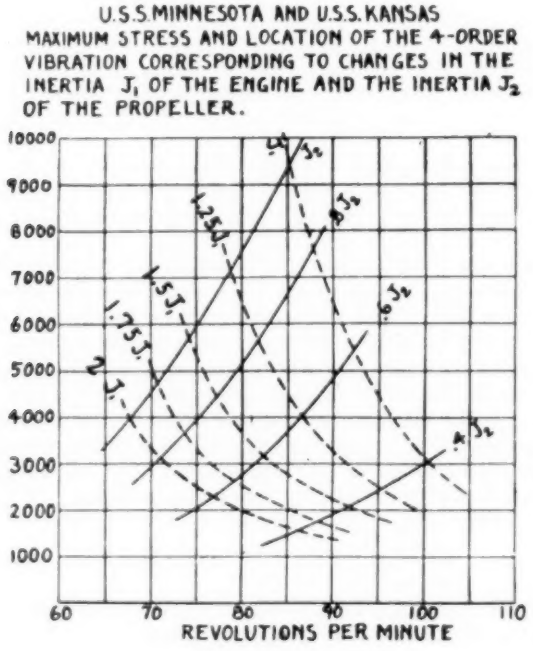

FIG. 23

Expand M_i by Fourier's theorem into a trigonometric series of the variable t. Consider that the vibration stimulated by each harmonic component of M_i is obtained as a solution of Equations [22] and [23] where M_i is replaced by the particular component of M_i considered. The algebraic sum of all such elements of vibration will satisfy Equations [22] and [23] and will be the resultant vibration stimulated by M_i.

Let the harmonic element of M_i to be considered be given by $m \cos pt$. Thus the reference point of time is taken as the instant that the component of M_i under consideration has its maximum value.

Replace the impressed torque with two components having a 90-deg. phase difference. Thus let

$$\left.\begin{aligned} m\cos pt &= m_N\cos(pt-\omega) - m_d\sin(pt-\omega) \\ \text{where } \omega &= \tan^{-1}\frac{m_d}{m_N},\ m^2 = m_N^2 + m_d^2 \end{aligned}\right\} .[24]$$

and $p = 2\pi n$, in which n is the frequency of the periodic force.

Any harmonic motion θ_N in the phase of the first component, i.e., in phase or 180 deg. out of phase with $m_N \cos(pt - \omega)$, is called motion of the normal phase. Similarly any harmonic motion θ_d in the phase of the second component or $-m_d \sin(pt - \omega)$ is called motion of the damping phase.

Since the damping torque at the second mass is given by $\rho\frac{d\theta_2}{dt}$, it is seen that any harmonic motion at the second mass causes a damping torque to occur 90 deg. out of phase with the motion. Thus any motion at the second mass in either the normal or damping phase causes a damping torque to occur in the other phase of the motion but in no other phase. It is evident, therefore, that for a steady-state vibration, the motion must be harmonic in nature and at each mass must be the sum of θ_N and θ_d.

As yet, however, the two components of $m \cos pt$ are only restricted by the condition that they have 90 deg. difference in phase. Let another condition to determine these components be that the amplitude of the damping phase of the motion at the second mass is zero. This makes the damping torque in the normal phase of the motion at the second mass equal to zero.

The forces of the normal phase, therefore, satisfy the following equations:

$$\frac{J_1}{g}\frac{d^2\theta_{N1}}{dt^2} - m_N\cos(pt-\omega) = C(\theta_{N2} - \theta_{N1}) \quad \ldots\ldots [25]$$

$$\frac{J_2}{g}\frac{d^2\theta_{N2}}{dt^2} + C(\theta_{N2} - \theta_{N1}) = 0 \quad \ldots\ldots [26]$$

And the forces of the damping phase satisfy the following equations:

$$\frac{J_1}{g}\frac{d^2\theta_{d1}}{dt^2} + m_d\sin(pt-\omega) = -C\theta_{d1} \quad \ldots\ldots [27]$$

$$-C\theta_{d1} + \rho\frac{d\theta_{N2}}{dt} = 0 \quad \ldots\ldots [28]$$

Adding the corresponding sides of Equations [25] and [27], [26], and [28], and putting $\theta_1 = \theta_{N1} + \theta_{d1}$, $\theta_2 = \theta_{N2}$, $M_i = m\cos pt$, it will be found that these equations reduce to Equations [22] and [23]. Hence a solution of Equations [25] to [28] will also be a solution of [22] and [23].

Writing

$$\left.\begin{aligned} \theta^\circ_{N1} &= a_N\cos(pt-\omega) \\ \theta^\circ_{N2} &= b_N\cos(pt-\omega) \\ \theta^\circ_{d1} &= a_d\sin(pt-\omega) \\ \theta^\circ_{d2} &= 0 \end{aligned}\right\} \quad \ldots\ldots [29]$$

where θ° is θ in degrees, the solution follows by evaluating a_N, b_N, a_d, m_N, m_d, and ω from Equations [24] to [28].

It is convenient in the solution to put

$$\left.\begin{aligned} &\alpha = 1 - \frac{J_1p^2}{gC},\ \beta = \left(1 - \frac{J_2p^2}{gC}\right)^{-1},\ \rho_1 = \frac{\rho p}{C} \\ &m_0 = \frac{180m}{\pi C},\ m_{N0} = \frac{180m_N}{\pi C},\ m_{d0} = \frac{180m_d}{\pi C} \end{aligned}\right\} \quad \ldots\ldots [30]$$

Hence putting [29] and [30] into Equations [25] to [28], they may be reduced to

$$\alpha a_N - b_N - m_{N0} = 0$$

$$\beta a_N - b_N = 0$$

$$\alpha\, a_d + m_{d0} = 0$$

$$a_d + \rho_1 b_N = 0$$

Therefore, solving these equations with [24] as simultaneous equations, the solution will be stated as follows:

$$\theta^\circ_1 = a_N \cos(pt - \omega) + a_d \sin(pt - \omega) \quad [31]$$

$$\theta^\circ_2 = b_N \cos(pt - \omega) \quad [32]$$

where

$$a_N = \frac{m_0}{\sqrt{[(\alpha - \beta)^2 + (\rho_1 \alpha\beta)^2]}} \quad [33]$$

$$b_N = \beta\, a_N \quad [34]$$

$$a_d = -\rho_1 b_N \quad [35]$$

$$\omega = \tan^{-1} \frac{\rho_1\, \alpha\beta}{\alpha - \beta} \quad [36]$$

The amplitude of the normal and damping phase of the motion at any point of the shaft and a statement of the resultant amplitude at any section of the shaft may be constructed from the above solution. Such equations are given in Appendix No. 2, Equations [65] to [68].

If there were no damping, i.e., if $\rho = 0$, the damping phase of the motion would be zero. In this case, omitting the subscript N,

$$\theta^\circ_1 = a \cos pt \quad [37]$$

$$\theta^\circ_2 = b \cos pt \quad [38]$$

where

$$a = \frac{m_0}{\alpha - \beta} \quad [39]$$

$$b = \beta a \quad [40]$$

It is seen from Equation [39] that if there is no damping the maximum values of θ_1 and θ_2 are infinite for values of n that make

$$\alpha - \beta \text{ or } 1 - \frac{J_1 p^2}{gC} - \left(1 - \frac{J_2 p^2}{gC}\right)^{-1} = 0 \quad [41]$$

unless m is zero. This means that vibrations of any amplitude, satisfying Equation [40], will exist indefinitely at this frequency with no impressed torque. The vibration at such a frequency is called "the normal mode of free vibration," and the frequency is called the "natural frequency," "synchronous frequency," or the "frequency of free vibration."

Solving Equation [41] for the value of p and putting $p = 2\pi n$, the synchronous frequency will be found to be

$$n = \frac{1}{2\pi} \sqrt{\frac{gC(J_1 + J_2)}{J_1 J_2}} \quad [42]$$

Substituting this value into Equation [40], it is seen that at synchronism

$$\frac{a}{b} = -\frac{J_2}{J_1} = \frac{1}{\alpha} = \frac{1}{\beta} \quad [43]$$

Hence the amplitude of undamped vibration at any point along the shaft at synchronism is given by

$$y = a \left\{1 - \frac{x}{l}\left(\frac{J_1 + J_2}{J_2}\right)\right\} \quad [44]$$

If x_{nd} is the distance of the node, or position of zero amplitude of vibration, from the first mass at synchronism for the case of no damping, Equation [44] gives

$$\frac{x_{nd}}{l} = \frac{J_2}{J_1 + J_2} \quad [45]$$

It is thus seen that the node for the undamped synchronous vibration of two concentrated masses connected by an elastic shaft having no mass is at the center of gravity of the inertia values considered as weights.

The characteristics shown by Equations [43], [44], and [45] to belong to the undamped synchronous vibration, are easily shown also to belong to the normal phase of the damped vibration at synchronism.

The sign of tan ω for the damped vibration depends on the sign of

$$\frac{\alpha - \beta}{\alpha\beta} \text{ or } 1 - \frac{J_2 p^2}{gC} - \left(1 - \frac{J_1 p^2}{gC}\right)^{-1} \quad [46]$$

Let $p^2 = p_s^2 - \delta$ where $p_s/2\pi$ is the synchronous frequency given by Equation [42] and δ is a small quantity. If δ is positive, $p/2\pi$ is less than the synchronous frequency, and if δ is negative, $p/2\pi$ is greater than the synchronous frequency. Thus

$$p^2 = \frac{gC(J_1 + J_2)}{J_1 J_2} - \delta$$

Substituting this value of p into [46], it can be written

$$\frac{\delta \dfrac{p^2 J_2}{gC}}{\dfrac{gC}{J_2} - \delta}$$

From this it follows that if δ is positive and approaches zero as a limit, tan ω is positive, and if δ is negative and approaches zero as a limit, tan ω is negative. Hence tan ω passes from $+\infty$ to $-\infty$ as n increases through the synchronous value. It will be assumed that near synchronism m_d is positive, therefore ω increases through 90 deg. at synchronism as n increases.

In a similar manner it can be shown that for the case of undamped vibration a is positive a little below synchronism and negative a little above synchronism.

Equations [34] and [35] can be combined to give

$$\frac{M_d}{M_N} = \frac{a_d}{b_N - a_N} = -\frac{g\rho}{J_2 p}$$

where M_d and M_N are the twisting moments in the shaft due to twisting the two masses through the angles a_d and $b_N - a_N$, respectively.

The significance of the last equation and [35] is best seen by numerical examples. In Table 15 these equations are evaluated at the synchronous frequency of several orders of vibration for the *Minnesota*, *Oklahoma*, and *Texas*, assuming that the only damping action comes from the propeller. As may be seen by a reference to Table 15, a_d and M_d are only a small fraction of a_N and M_N for the vibrations given, and the resultants $\sqrt{a_N^2 + a_d^2}$ and $\sqrt{M_N^2 + M_d^2}$ are only a small per cent greater than a_N and M_N. Hence for these vibrations, the damping phase of the motion can be neglected, and without much error the normal phase of the motion can be taken as the resulting vibration.

Appendix No. 2

GENERAL CASE OF DAMPED VIBRATIONS

THE solution for the steady-state vibrations stimulated by periodic torques acting at the first mass and damped by forces acting at either mass and at any point along the shaft will now be considered.

There are two types of damping forces that may act on a vibrating system. First, the damping forces may have their origin in some disturbance outside the system. In this case a damping force acting on the system coexists with an equal and opposite force acting on something outside of the system. Such a damping force, for example, acts on a marine propeller and will be called "outer damping." Second, the damping forces may exist between two members or particles of the system. For example, hysteresis damping forces may be considered as friction between the molecules of the shafting material. This type will be called "inner damping."

In general damping forces that act on a vibrating system have a certain characteristic in common. If the motion at the point of damping is harmonic such as

$$\theta^\circ = y_N \cos(pt - \omega) + y_d \sin(pt - \omega) \quad \ldots\ldots [47]$$

the function $F(pt - \omega)$ expressing the damping force at any instant obeys the relation $F(pt - \omega) = -F(pt - \omega + \pi)$, where $p = 2\pi n$ in which n is the frequency of the harmonic motion. Therefore the function F can be expanded into a Fourier series of odd multiples of $pt - \omega$. Thus

$$F(pt - \omega) = A \sin(pt - \omega) + A_3 \sin 3(pt - \omega) + \ldots$$
$$+ B \cos(pt - \omega) + B_3 \cos 3(pt - \omega) + \ldots$$

With very little error, the harmonics of F higher than the first can be neglected since their disturbing influence is small and their frequencies are much higher than that of the fundamental harmonic. Thus the expression for the damping force for the case of harmonic motion at the point of damping can be written as

$$\left.\begin{aligned} F(pt - \omega) &= A \sin(pt - \omega) + B \cos(pt - \omega) \\ A &= \frac{2}{\pi}\int_0^\pi F(\xi) \sin \xi \, d\xi \\ B &= \frac{2}{\pi}\int_0^\pi F(\xi) \cos \xi \, d\xi \end{aligned}\right\} \quad \ldots\ldots [48]$$

It is sometimes convenient to use Equation [48] in a slightly different form.

$$\text{Let } F(pt - \omega) = F_0(pT), \text{ where } pt - \omega - \omega_0 = pT \quad \ldots [49]$$

Then $F_0(pT) = A' \sin pT + B' \cos pT$

where

$$\left.\begin{aligned} A' &= \frac{2}{\pi}\int_0^\pi F_0(\xi) \sin \xi \, d\xi \\ B' &= \frac{2}{\pi}\int_0^\pi F_0(\xi) \cos \xi d \, \xi \end{aligned}\right\} \quad \ldots\ldots [50]$$

So that

$$F(pt - \omega) = A' \sin(pt - \omega - \omega_0) + B' \cos(pt - \omega - \omega_0)$$

Hence by expanding the trigonometric expressions, it is found that

$$\left.\begin{aligned} A &= B' \sin \omega_0 + A' \cos \omega_0 \\ B &= B' \cos \omega_0 - A' \sin \omega_0 \end{aligned}\right\} \quad \ldots\ldots [51]$$

Consider the action of a harmonic stimulating impulse given by $m \cos pt$. Resolve the impulse into two components having 90-deg. phase difference.

Thus let

$$\left.\begin{aligned} m \cos pt &= m_N \cos(pt - \omega) - m_d \sin(pt - \omega) \\ \text{where} \qquad \omega &= \tan^{-1}\frac{m_d}{m_N}, \text{ and } m^2 = m_N^2 + m_d^2 \end{aligned}\right\} \quad \ldots [52]$$

As in the solution of Appendix No. 1, any motion in the phase of the first or second component will be called motion of the normal or damping phase, respectively.

From Equations [47] and [48], it is evident that two harmonic motions having a 90-deg. phase difference, cause a damping force to occur in the phase of each of the vibrations. This characteristic is similar to that already observed for a damping force proportional to the velocity. Thus the motions produced by the components of the impulse in each of their phases will cause damping forces, and therefore motion in both of their phases, but (omitting the higher harmonics of the damping forces) in no other phase. For this reason the conditions for equilibrium of the forces acting in the vibrating system need only be written for the two phases of the components of the impulse.

The conditions for equilibrium of the forces may be stated as follows: The sum of all the outside forces on one side of any section in either phase of the motion is equal and opposite to the internal resisting forces in the shaft at that section. It should be noted that the inner damping forces are internal resistances in the material of the shaft.

As yet, however, the two components of $m \cos pt$ are only restricted by the condition that they have 90-deg. difference in phase. Let another condition to determine these components be that the amplitude of the damping phase of the motion at the second mass is zero.

Let θ_N and θ_d be the motion of the normal phase and damping phase, respectively. Consider that the function F is expressed as a torque. Let A_1 and B_1 be the amplitudes of the components of F for outer damping acting at the first mass. Similarly, let A_2 and B_2 be these amplitudes for outer damping at the second mass. Also, let A_i and B_i be the amplitudes of the components of F for inner damping along the shaft.

The forces of the normal phase of the motion, therefore, satisfy the following equations,

$$\left.\begin{aligned} \frac{J_1}{g}\frac{d^2\theta_{N1}}{dt^2} - m_N \cos(pt - \omega) + B_1 \cos(pt - \omega) &= Cl\frac{\partial \theta_N}{\partial x} \\ &\quad + B_i \cos(pt - \omega) \\ \frac{J_1}{g}\frac{d^2\theta_{N1}}{dt^2} - m_N \cos(pt - \omega) + B_1 \cos(pt - \omega) & \\ + B_2 \cos(pt - \omega) + \frac{J_2}{g}\frac{d^2\theta_{N2}}{dt^2} &= 0 \end{aligned}\right\} \quad [53]$$

The forces of the damping phase satisfy

$$\left.\begin{aligned} \frac{J_1}{g}\frac{d^2\theta_{d1}}{dt^2} + m_d \sin(pt - \omega) + A_1 \sin(pt - \omega) &= Cl\frac{\partial \theta_d}{\partial x} \\ &\quad + A_i \sin(pt - \omega) \\ \frac{J_1}{g}\frac{d^2\theta_{d1}}{dt^2} + m_d \sin(pt - \omega) + A_1 \sin(pt - \omega) & \\ + A_2 \sin(pt - \omega) &= 0 \end{aligned}\right\} \quad [54]$$

Writing

$$\left.\begin{aligned} \theta^\circ_{N1} &= a_N \cos(pt - \omega) \\ \theta^\circ_{N2} &= b_N \cos(pt - \omega) \\ \theta^\circ_{d1} &= a_d \sin(pt - \omega) \\ \theta^\circ_{d2} &= 0 \end{aligned}\right\} \quad \ldots\ldots [55]$$

the solution follows by evaluating a_N, b_N, a_d, m_N, m_d, and ω from Equations [52] to [54].

As in Appendix No. 1, it is convenient in the solution to use

the contants α, β, m_0, m_{N0}, m_{d0} as defined in [30]. It is also convenient to use $\textcircled{H} = a_N - b_N$.

Putting [55] into [53] and [54], they may be reduced to

$$\left.\begin{aligned} &\alpha a_N - b_N + \frac{180}{\pi C}(B_1 - B_i) - m_{N0} = 0 \\ &(\alpha - 1)a_N + \left(\frac{1}{\beta} - 1\right)b_N + \frac{180}{\pi C}(B_1 + B_2) - m_{N0} = 0 \\ &\alpha a_d + \frac{180}{\pi C}(A_1 - A_i) + m_{d0} = 0 \\ &(\alpha - 1)a_d + \frac{180}{\pi C}(A_1 + A_2) + m_{d0} = 0 \end{aligned}\right\} \quad \ldots\ldots [56]$$

Combining the first and second equations gives

$$b_N = \beta a_N - \frac{180}{\pi C}\beta(B_2 + Bi) \quad \ldots\ldots [57]$$

Combining the third and fourth equations gives

$$a_d = \frac{180}{\pi C}(A_2 + A_i) \quad \ldots\ldots [58]$$

Putting this into the third equation gives

$$m_d = -A_1 - \alpha A_2 + (1 - \alpha)A_i \quad \ldots\ldots [59]$$

Putting [57] into the first equation makes

$$m_N = \frac{\pi C}{180}(\alpha - \beta)a_N + B_1 + \beta B_2 - (1 - \beta)B_i \quad \ldots [60]$$

Now since $m^2 - m_N{}^2 = md^2$, Equations [59] and [60] give

$$m_0{}^2 - \left\{(\alpha - \beta)a_N + \frac{180}{\pi C}\left[B_1 + \beta B_2 - (1 - \beta)B_i\right]\right\}^2 = \left(\frac{180}{\pi C}\right)^2\left[-A_1 - \alpha A_2 + (1 - \alpha)A_i\right]^2 \quad \ldots\ldots [61]$$

Thus a_N can be obtained as a root of Equation [61]. At and near the frequency that makes $\beta = \infty$, however, Equation [61] becomes hard to evaluate. In this case it is more convenient to solve for $\textcircled{H} = a_N - b_N$. This may be done as follows: Subtracting βb_N from both sides of Equation [57], and dividing by $1 - \beta$ gives

$$b_N = \frac{\beta}{1 - \beta}\left[\textcircled{H} - \frac{180}{\pi C}\left(B_2 + B_i\right)\right]$$

Putting this into the first equation of [56] makes

$$m_N = \frac{\pi C}{180}\left(\frac{\alpha - \beta}{1 - \beta}\right)\textcircled{H} + B_1 - \frac{J_1}{J_2}B_2 - \left(1 + \frac{J_1}{J_2}\right)B_i \quad [62]$$

Thus since $m^2 - m_N{}^2 = m_d{}^2$, Equations [59] and [62] give

$$m_0{}^2 - \left\{\frac{\alpha - \beta}{1 - \beta}\textcircled{H} + \frac{180}{\pi C}\left[B_1 - \frac{J_1}{J_2}B_2 - \left(1 + \frac{J_1}{J_2}\right)B_i\right]\right\}^2 = \left(\frac{180}{\pi C}\right)^2\left[-A_1 - \alpha A_2 + (1 - \alpha)A_i\right]^2 \quad \ldots\ldots [63]$$

Therefore, summarizing, a_N may be obtained as a root of Equation [61], or $\textcircled{H}$ may be obtained as a root of Equation [63]. Then

$$\left.\begin{aligned} &a_N = \textcircled{H} + b_N = \frac{\textcircled{H}}{1 - \beta} - \frac{180\beta}{\pi C(1 - \beta)}(B_2 + B_i) \\ &b_N = \beta a_N - \frac{180}{\pi C}\beta(B_2 + B_i) = \frac{\beta}{1 - \beta}\left[\textcircled{H} - \frac{180}{\pi C}\left(B_2 + B_i\right)\right] \\ &a_d = \frac{180}{\pi C}(A_2 + A_i) \\ &\omega = \tan^{-1}\frac{m_d}{m_N} \end{aligned}\right\} \quad [64]$$

where m_d and m_N are given by Equations [59], [60], or [62], α and β are expressed in [30], and A and B with various subscripts are obtained from [48] or [51].

The vibrations at the first and second masses are therefore stated by Equations [55], the resultant vibration at either mass being $\theta_N + \theta_d$.

The amplitude of the normal phase at any point of the shaft will be

$$\left.\begin{aligned} &\theta^\circ{}_N = y_N \cos(pt - \omega) \\ &\text{where} \quad y_N = a_N - \frac{x}{l}\textcircled{H} \end{aligned}\right\} \quad \ldots\ldots [65]$$

The amplitude of the damping phase at any point of the shaft will be

$$\left.\begin{aligned} &\theta^\circ{}_d = y_d \sin(pt - \omega) \\ &\text{where} \quad y_d = a_d\left(1 - \frac{x}{l}\right) \end{aligned}\right\} \quad \ldots\ldots [66]$$

The statement of the amplitude of vibration at any section of the shaft may be stated in terms of a single harmonic by combining the normal and damping phase of the motion. Thus

$$\theta^\circ = \sqrt{y_N{}^2 + y_d{}^2}\cos\left(pt - \omega - \tan^{-1}\frac{y_d}{y_N}\right) \quad [67]$$

and at the first mass

$$\left.\begin{aligned} &\theta^\circ{}_1 = \sqrt{a_N{}^2 + a_d{}^2}\cos(pt - \omega_1) \\ &\text{where} \quad \omega_1 = \omega + \tan^{-1}\frac{a_d}{a_N} \end{aligned}\right\} \quad \ldots\ldots [68]$$

(a) Damping Proportional to the Velocity Together With Elastic Hysteresis Damping

Consider that an outer damping force acts at the second mass proportional to the velocity and that inner damping forces due to elastic hysteresis are acting along the shaft.

The energy absorbed per unit length by elastic hysteresis for one reversed cycle of torsional stress is given by Equation [4] as

$$K = \frac{69.7\,(d_2{}^{4.3} - d_1{}^{4.3})}{10^{10}(d_2{}^4 - d_1{}^4)^{2.3}}M^{2.3} \quad \ldots\ldots [69]$$

where M is the maximum positive twisting moment of the stress cycle.

Since the value of M in K is given by

$$M = \frac{\pi}{180}Cly'$$

where $y' = dy/dx$ is the maximum value of the angular deflection

in degrees per unit length, the hysteresis loss per unit length may be written as

$$K = \left(\frac{\pi}{180}\right)^{2.3} \frac{69.7\ (d_2^{4.3} - d_1^{4.3})}{10^{10}\ (d_2^4 - d_1^4)^{2.3}}\ (Cly')^{2.3}$$

The value of K is the same as the work done by the torque which opposes an increasing or decreasing stress given by

$$Q = \left(\frac{\pi}{180}\right)^{1.3} \frac{2.3 \times 69.7 (d_2^{4.3} - d_1^{4.3})^{2.3}}{4 \times 10^{10}\ (d_2^4 - d_1^4)^{2.3}}\ (Cl)^{2.3}(y')^{1.3}$$

for one reversed stress cycle where y' in this case is the absolute value of the deflection per unit length at any instant of the stress cycle. This may be seen by integrating Q over the stress

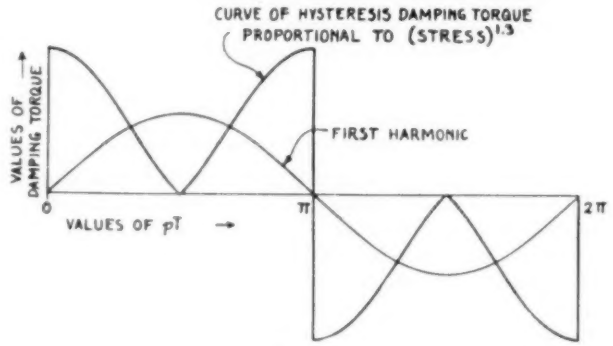

FIG. 24

cycle. Thus, since the work done by Q over the whole cycle is four times that done from $y' = 0$ to $y' =$ a maximum, the work done by Q is $\dfrac{\pi \times 4 \times y'}{180 \times 2.3}$ times Q, which evidently is equal to K.

For the purpose of simplifying Q, put

$$f_1 = \left(\frac{\pi}{180}\right)^{0.3} \frac{69.7 C^{1.3}\ (d_2^{4.3} - d_1^{4.3})}{\pi\ 10^{10}\ (d_2^4 - d_1^4)^{2.3}}$$

$$= \frac{6.58 l\ (d_2^{4.3} - d_1^{4.3})}{10^{10}\ C} \left(\frac{C}{d_2^4 - d_1^4}\right)^{2.3} \quad \ldots\ldots [70]$$

For $G = 11{,}800{,}000$ lb. per sq. in.

$$f_1 = \frac{0.0502\ d_2^{4.3} - d_1^{4.3}}{l^{0.3}(d_2^4 - d_1^4)}$$

and if $d_1 = 0$, $f_1 = 0.0502 \left(\dfrac{d}{l}\right)^{0.3}$

Hence Q may be written

$$Q = \frac{\pi \times 2.3\pi}{180 \times 4} f_1 C l^{1.3} (y')^{1.3} \quad \ldots\ldots [71]$$

Now, from [65] and [66]

$$\theta^\circ = \theta^\circ_N + \theta^\circ_d = y_N \cos(pt - \omega) + y_d \sin(pt - \omega)$$

Differentiating this and putting $\dfrac{dy_N}{dx} = -\dfrac{\text{Ⓗ}}{l}$ and $\dfrac{dy_d}{dx} = -\dfrac{a_d}{l}$, the value of y' given in [71] will be

$$y' = \frac{1}{l} \sqrt{\text{Ⓗ}^2 + a_d^2} \cos pT$$

where $pT = pt - \omega - \tan^{-1} \dfrac{a_d}{\text{Ⓗ}}$

Therefore substituting in [71],

$$F_0(pT) = Q = \frac{\pi \times 2.3\pi}{180 \times 4} f_1 C (\text{Ⓗ}^2 + a_d^2)^{1.3/2} \cos^{1.3} pT$$

where $F_0(pT)$ changes its sign when cos pT starts to decrease, and the value of cos pT is taken as always positive without regard to its actual sign. A graph of $F_0(pT)$ for one harmonic stress cycle is shown in Fig. 24.

The value of A_1' and B_1' may now be obtained from Equations [50]. Then from Equations [51] the values of A_i and B_i may be obtained. Thus

$$A_i = \frac{\pi C}{180} f_2 \text{Ⓗ}^{1.3} \text{ and } B_i = -\frac{\pi C}{180} \delta \text{Ⓗ} \quad \ldots\ldots [72]$$

where

$$f_2 = f_1 \left(1 + \frac{a_d^2}{\text{Ⓗ}^2}\right)^{0.15} \text{ and } \delta = f_2 \frac{a_d}{\text{Ⓗ}^{0.7}} \quad \ldots\ldots [73]$$

The outer damping torque at the second mass, due to the damping force proportional to the velocity is, $\rho \dfrac{d\theta_{N2}}{dt}$ which gives

$$A_2 = -\frac{\pi C}{180} \rho_1 b_N = -\frac{\pi C}{180} \frac{\rho_1 \beta}{1 - \beta} (1 + \delta)\ \text{Ⓗ}, \text{ and } B_2 = 0 \quad [74]$$

where $\rho_1 = \rho p / C$. The second relation for A_2 is obtained from the first by replacing b with its equal from [64], putting $B_2 = 0$, and $B_3 =$ its value in [72].

Since no outer damping forces are considered acting at the first mass $A_1 = B_1 = 0$.

Hence Equation [63] may be written

$$m_0^2 - \left[\frac{\alpha - \beta}{1 - \beta} + \left(1 + \frac{J_1}{J_2}\right)\delta\right]^2 \text{Ⓗ}^2 = \left[\frac{\rho_1 \alpha\beta}{1 - \beta}(1 + \delta)\ \text{Ⓗ} + (1 - \alpha) f_2 \text{Ⓗ}^{1.3}\right]^2 \quad \ldots\ldots [75]$$

where f_2 and δ are given by [73] and

$$\left.\begin{aligned} a_N &= \text{Ⓗ} + b_N = (1 + \beta\delta)\frac{\text{Ⓗ}}{1 - \beta} \\ b_N &= (1 + \delta)\frac{\beta\text{Ⓗ}}{1 - \beta} \\ a_d &= -\rho_1 b_N + f_2 \text{Ⓗ}^{1.3} = -\frac{\rho_1\beta}{1 - \beta}(1 + \delta)\text{Ⓗ} + f_2 \text{Ⓗ}^{1.3} \\ \tan\omega &= \frac{\frac{\rho_1\alpha\beta}{1 - \beta}(1 + \delta) + (1 - \alpha) f_2 \text{Ⓗ}^{0.3}}{\frac{\alpha - \beta}{1 - \beta} + \left(1 + \frac{J_1}{J_2}\right)\delta} \end{aligned}\right\} \quad [76]$$

As a first approximation δ may be taken equal to zero and $f_2 = f_1$. In this case the above equations become

$$m_0^2 - \left(\frac{\alpha - \beta}{1 - \beta}\right)^2 \text{Ⓗ}^2 = \left[\frac{\rho_1\alpha\beta}{1 - \beta}\text{Ⓗ} + (1 - \alpha) f_1 \text{Ⓗ}^{1.3}\right]^2 \quad [77]$$

or putting a_N for its equal $\text{Ⓗ}/(1 - \beta)$,

$$\left.\begin{aligned} m_0^2 - (\alpha - \beta)^2 a_N^2 &= [\rho_1\alpha\beta a_N + (1 - \alpha)(1 - \beta)^{1.3} f_1 a_N^{1.3}]^2 \\ b_N &= \beta a_N = \frac{\beta\text{Ⓗ}}{1 - \beta} \\ a_d &= -\rho_1\beta a_N + (1 - \beta)^{1.3} f_1 a_N^{1.3} = -\frac{\rho_1\beta}{1 - \beta}\text{Ⓗ} + f_1 \text{Ⓗ}^{1.3} \end{aligned}\right\} \quad [78]$$

At synchronism, this first approximation gives

$$\left.\begin{aligned} m_0 &= \rho_1\alpha^2 a_N + (1-\alpha)^{2.3} f_1 a_N^{1.3} \\ b_N &= \alpha a_N \\ a_d &= -\rho_1\alpha a_N + (1-\alpha)^{1.3} f_1 a_N^{1.3} \end{aligned}\right\} \quad \ldots\ldots [79]$$

where $\alpha = \beta = -J_1/J_2$.

Numerical evaluations of these equations have been given in the first part of this paper. An important characteristic that was illustrated by the numerical values was the accuracy of the first approximation. For this reason the assumption made for the first approximation, namely, that $f_2 = f_1$ and $\delta = 0$, will be used in the following pages.

(*b*) Friction Damper (Infinite Flywheel)

Consider the case of a friction damper at the first mass, damping proportional to the velocity at the second, and hysteresis damping along the shaft. Assume that the friction damper consists of a very heavy flywheel revolving at constant speed and having friction surfaces that press against the first mass. The value of the friction torque will be constant and independent of the velocity except that it reverses its sign whenever the velocity of the first mass reverses its sign. Let the absolute value of the total friction torque acting on the friction surfaces be h.

$$\theta_1^\circ = \theta_{N1}^\circ + \theta_{d1}^\circ = \sqrt{a_N^2 + a_d^2}\cos pT$$

where $pT = pt - \omega - \omega_0$, and $\omega_0 = \tan^{-1}\dfrac{a_d}{a_N}$

Therefore

$$F_0(pT) = -h \text{ from } pT = 0 \text{ to } pT = \pi$$
$$= h \text{ from } pT = \pi \text{ to } pT = 2\pi$$

Thus from [50] and [51]

$$A_1 = -\frac{4h}{\pi}\cos\omega_0$$

$$B_1 = \frac{4h}{\pi}\sin\omega_0$$

As obtained above (refer to [72] to [74] where $f_2 = f_1$ and $\delta = 0$),

$$A_2 = -\frac{\pi C}{180}\rho_1 b_N,\ B_2 = 0$$

$$A_i = \frac{\pi C}{180} f_1 ⓗ^{1.3},\ B_i = 0$$

Thus the equations for a_N, b_N, and a_d are as stated in [78], and Equation [63] becomes

$$m_0^2 - \left\{\frac{\alpha-\beta}{1-\beta}ⓗ + h_1\sin\omega_0\right\}^2 = \left\{h_1\cos\omega_0 + \frac{\rho_1\alpha\beta}{1-\beta}ⓗ + (1-\alpha)f_1ⓗ^{1.3}\right\}^2 \quad \ldots\ldots [80]$$

where

$$h_1 = \frac{720\,h}{\pi^2 C}$$

If there is no hysteresis damping acting, $f_1 = 0$ and $a_d = -\rho_1\beta a_N$ In this case if a_N is written for its equal $ⓗ/(1-\beta)$, Equation [80] becomes a quadratic in a_N. Its algebraic solution may be written thus:

$$a_N = \frac{(m_0^2 - h_1^2)\sqrt{1+\rho_1^2\beta^2}}{\rho_1\beta^2 h_1 + \sqrt{\{\rho_1^2\beta^4 h_1^2 + (m_0^2 - h_1^2)(1+\rho_1^2\beta^2)[(\alpha-\beta)^2 + \rho_1^2\alpha^2\beta^2]\}}} \quad \ldots\ldots [81]$$

At synchronism $\alpha = \beta$, and

$$a_N = \frac{(m_0^2 - h_1^2)\sqrt{1+\rho_1^2\alpha^2}}{\rho_1\alpha^2[h_1 + \sqrt{\{m_0^2(1+\rho_1^2\alpha^2) - \rho_1^2\alpha^2 h_1^2\}}]} \quad \ldots [82]$$

Approximately $1 + \rho_1^2\alpha^2 = 1$ and $\rho_1^2\alpha^2 h_1^2 = 0$ so that, as an approximation at synchronism,

$$a_N = \frac{m_0 - h_1}{\rho_1\alpha^2} = \frac{180\left(m - \dfrac{4h}{\pi}\right)}{\pi\rho p\alpha^2} \quad \ldots\ldots [83]$$

Hence, it is seen that for the case of a very heavy friction damper attached to the first mass, the stimulating impulse is effectively decreased by the amount of $4/\pi$ times the total friction force.

It is interesting to note that if the damping at the propeller were zero, i.e., if there were no damping forces other than that of the friction damper acting on the system, the amplitude at synchronism would be infinite in spite of the friction damper, if $m > 4h/\pi$.

(*c*) Friction Damper (Finite Flywheel)

Consider the case of a friction damper at the first mass, damping proportional to the velocity at the second mass, and hysteresis damping along the shaft. Consider the damper to be a slipping flywheel having an inertia J, whose only contact with the first mass is through friction surfaces. The total friction torque that can act on the friction surfaces will be constant and independent of the velocity except that it will reverse its sign whenever the relative velocity between the first mass and the damper flywheel reverses its sign. Let h be the absolute value of the total friction torque that can act on the friction surfaces.

The amplitude of vibration at the first mass is given by

$$\theta_1^\circ = \theta_{N1}^\circ + \theta_{d1}^\circ + \sqrt{a_N^2 + a_d^2}\cos(pt - \omega - \omega_0)$$

or

$$\theta_1 = a\cos pT$$

where

$$\omega_0 = \tan^{-1}\frac{a_d}{a_N},\quad a = \frac{\pi}{180}\sqrt{a_N^2 + a_d^2},\ \text{and } pT = pt - \omega - \omega_0$$

Thus

$$\frac{d\theta_1}{dt} = -ap\sin pT$$

$$\frac{d^2\theta_1}{dt^2} = -ap^2\cos pT$$

The torque that can act on the damper flywheel if it slips is

$$Q = \frac{J}{g}\frac{d^2\theta_0}{dt^2} = \pm h$$

where θ_2 is the amplitude of the vibration of the damper flywheel. Thus the possible acceleration of this flywheel is

$$\frac{d^2\theta_0}{dt^2} = \pm\frac{hg}{J}$$

There are three cases to be considered: First, when the damper flywheel does not slip; second, when the damper flywheel is slipping part of the time; and third, when the damper flywheel is slipping continually.

It will be convenient in the following development to use the following symbols:

$$h_1 = \frac{720h}{\pi^2 C}, \quad j = \frac{p^2 J}{gC}, \quad \omega_0 = \tan^{-1}\frac{a_d}{a_N} \ldots\ldots [84]$$

and α, β, ρ_1, m_0, m_{N0}, m_{d0} as stated in [30].

Case I.—When the Damper Flywheel Does Not Slip. If the possible acceleration of the damper flywheel is greater or equal to the greatest acceleration of the first mass, the flywheel will not slip.

This will occur if

$$ap^2 \leqq \frac{hg}{J} \text{ or if } 1 \leqq \frac{\pi h_1 \cos \omega_0}{4ja_N} \ldots\ldots [85]$$

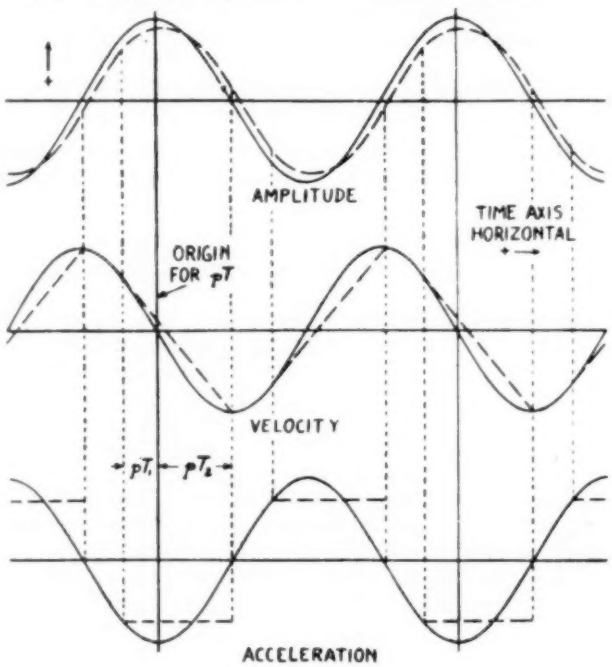

FIG. 25

In this case the solution is the same as the case of two concentrated masses, stimulated by $m \cos pt$, and damped by the propeller and hysteresis damping where the first mass is $J_1 + J$ and the second is J_2.

Case II.—When the Damper Flywheel Is Slipping Part of the Time. The damper flywheel will slip whenever the acceleration of the first mass becomes greater than the possible acceleration of the damper wheel. Thus slipping will occur if

$$1 > \frac{\pi h_1 \cos \omega_0}{4ja_N} \ldots\ldots [86]$$

The amplitude, velocity, and acceleration curves of the first mass and damper flywheel for the steady-state vibration of this case are illustrated in Fig. 25. Let T_1 be the negative value of T nearest zero where the velocity of the damper flywheel is equal to the velocity of the first mass. At this value the damper wheel will have reached its maximum negative acceleration. Its velocity will then continue decreasing at a uniform rate until the changing velocity of the first mass comes back to that attained by the damper wheel. Let T_2 be the value of T when this occurs. If the flywheel is to slip only part of the time $T_2 > 0$ and $< T_1 + \frac{\pi}{p}$. The velocity at $T = T_1$ is $-ap \sin pT_1$, and at $T = T_2$ is $-ap \sin pT_2$. Thus the slope of the velocity curve, or in other words the acceleration of the damper flywheel between T_1 and T_2, will be

$$\frac{ap}{T_2 - T_1}(-\sin pT_2 + \sin pT_1) = -\frac{hg}{J}$$

The acceleration of the first mass at T_1 is $-ap^2 \cos pT_1$. Thus the damper flywheel will begin to slip at this point provided

$$\cos pT_1 = \frac{1}{pT_1 - pT_2}(\sin pT_1 - \sin pT_2) = \frac{\pi h_1 \cos \omega_0}{ja_N} \quad [87]$$

It will slip only part of the time if

$$pT_1 < 0 < pT_2 < pT_1 + \pi \ldots\ldots [88]$$

The values of pT_2 corresponding to any value of pT_1 satisfying Equations [87] and [88] are plotted in Fig. [26].

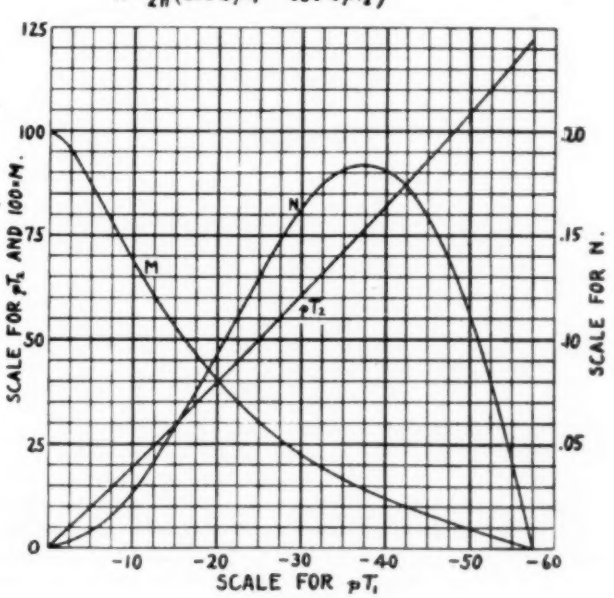

FIG. 26

The value of the friction torque $F_0(T)$ acting on the damper flywheel will therefore be $-h$ from $T = 0$ to T_2, $-\frac{J}{g}ap^2 \cos pT$ from $T = T_2$ to $\frac{\pi}{p} + T_1$, and h from $T = \frac{\pi}{p} + T_1$ to π. Hence from Equations [50] and [51],

$$A_1 = -\frac{2h}{\pi}\left[\cos(pT_1 + \omega_0) - \cos(pT_2 + \omega_0)\right] - \frac{\pi p^2 J}{180g}(a_d M - a_N N)$$

$$B_1 = \frac{2h}{\pi}\left[\sin(pT_1 + \omega_0) - \sin(pT_2 + \omega_0)\right] - \frac{\pi p^2 J}{180g}(a_N M + a_d N)$$

where

$$\left.\begin{aligned} 2\pi M &= 2\pi + 2pT_1 - 2pT_2 + \sin 2pT_1 - \sin 2pT_2 \\ 2\pi N &= \cos 2pT_1 - \cos 2pT_2 \end{aligned}\right\} \quad [89]$$

The values of M and N corresponding to any value of pT_1 and pT_2 which satisfy [87] and [88] as given by [89] are also plotted in Fig. [26].

As obtained above (refer to [72] to [74] where $f_2 = f_1$ and $\delta = 0$)

$$A_2 = -\frac{\pi C}{180}\rho_1 b_N, \quad B_2 = 0$$

$$A_4 = \frac{\pi C}{180} f_1 ⓗ^{1.3}, \quad B_4 = 0$$

Thus the equations for a_N, b_N, and a_d are as stated in [78], and Equation [61] or [63] may be written

$$m_0^2 - \{Ua_N - jNf_1(1-\beta)^{1.3}a_N^{1.3}\}^2 = \{Va_N + f_1(1-\alpha_1)(1-\beta)^{1.3}a_N^{1.3}\}^2 \quad [90]$$

CURVES ILLUSTRATING THE MOTION OF THE DAMPER FLYWHEEL WHEN IT IS SLIPPING CONTINUALLY. THE FULL LINES REFER TO THE FIRST MASS. THE DASHED LINES REFER TO THE DAMPER FLYWHEEL.

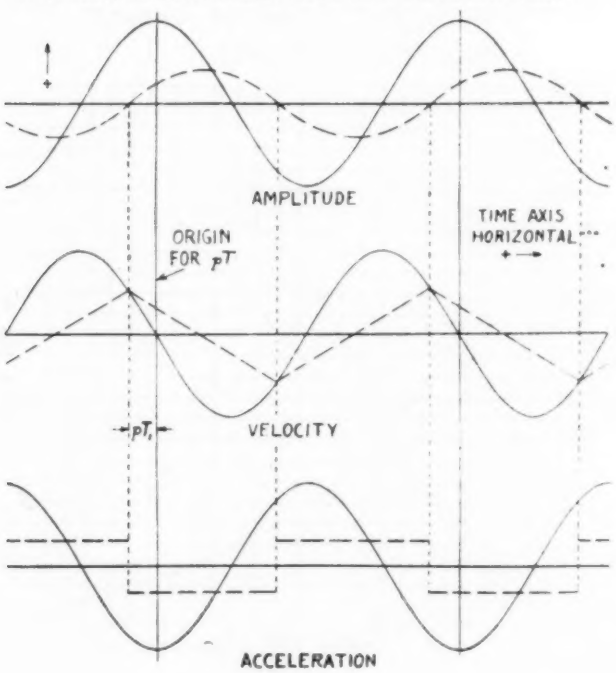

FIG. 27

where

$$\alpha_1 = \alpha - {}_jM = 1 - \frac{p^2}{gC}(J_1 - JM)$$

$$U = \alpha_1 - \beta + {}_jN\rho_1\beta + \frac{h_1}{2a_N}\left[\sin(pT_1 + \omega_0) - \sin(pT_2 + \omega_0)\right]$$

$$V = \rho_1\alpha_1\beta - {}_jN + \frac{h_1}{2a_N}\left[\cos(pT_1 + \omega_0) - \cos(pT_2 + \omega_0)\right]$$

$$\omega_0 = \tan^{-1}[-\rho_1\beta + f_1(1-\beta)^{1.3}a_N^{0.3}]$$

$$b_N = \beta a_N$$

$$a_d = -\rho_1 b_N + f_1(1-\beta)^{1.3}a_N^{1.3}$$

If there is no hysteresis damping the equations reduce to give

$$a_N = \frac{m_0}{\sqrt{U^2 + V^2}} \quad [91]$$

Case III.—When the Damper Flywheel Is Slipping Continually. The amplitude, velocity, and acceleration curves of the first mass and damper flywheel for the steady-state vibration of the case, where the damper flywheel is slipping continually are illustrated in Fig. 27. Let T_1 be the negative value of T nearest zero where the velocity of the damper flywheel equals the velocity of the first mass. The velocity at this point will be $-ap \sin pT_1$. The velocity at $T_1 + \pi/p$ will be $ap \sin pT_1$. Thus the slope of the velocity curve, or in other words the acceleration of the damper flywheel between T_1 and $T_1 + \pi/p$, will be $(2ap/\pi) \sin pT_1 = -hg/J$.

The acceleration of the first mass at T_1 is $-ap^2 \cos pT_1$. Thus the damper flywheel will slip continually provided

$$ap^2 \cos pT_1 \geqq -\frac{2ap^2}{\pi}\sin pT_1 = \frac{hg}{J}$$

or if $\tan pT_1 \geqq -\pi/2$. (This gives $pT_1 \geqq -57.5184$.) Therefore, for the flywheel to slip continually, the following relation must hold

$$\frac{hg}{J} \leqq \frac{2ap^2}{\sqrt{4+\pi^2}}$$

The value of T_1 for this case is given by

$$\sin pT_1 = -\frac{\pi^2 h_1 \cos\omega_0}{8ja_N}$$

where $$-\frac{\pi}{2} < \tan^{-1}-\frac{\pi}{2} \leqq pT_1 < 0$$

The solution follows from the several formulas given for Case II if $pT_2 = pT_1 + \pi$ subject to the conditions just given. Thus $M = N = 0$, and Equation [90] becomes

$$m_0^2 - U^2a_N^2 = \{Va_N + (1-\alpha)(1-\beta)^{1.3}f_1 a_N^{1.3}\}^2 \quad [92]$$

where

$$U = \alpha - \beta + \frac{h_1}{a_N}\sin(pT_1 + \omega_0)$$

$$V = \rho_1\alpha\beta + \frac{h_1}{a_N}\cos(pT_1 + \omega_0)$$

$$\sin pT_1 = -\frac{\pi^2 h_1 \cos\omega_0}{8ja_N} \geqq -\frac{\pi}{\sqrt{4+\pi^2}}$$

Appendix No. 3

LIST OF SYMBOLS

ALTHOUGH the symbols used in this paper were defined when they were first introduced, the following list of the more important ones is included for easy reference.

The dimensions of all values given are to be considered in the inch-pound-second system unless otherwise stated.

a Maximum value of undamped vibration at the first mass in degrees. Also in Appendix No. 2 (*c*) the value of $\frac{\pi}{180}\sqrt{a_N^2 + a_d^2}$

a_d, a_N Maximum values of θ°_{d1} and θ°_{N1}, respectively.

A Amplitude of the sine component of the fundamental harmonic of the function expressing the friction torque.

Subscripts 1 and 2 refer to outer damping at the first and second mass, and subscript i refers to inner damping along the shaft.

b Maximum value of undamped vibration at the second mass in degrees.

b_N Maximum value of θ°_{N2}.

B Same as A except that it applies to the cosine component.

C Proportional constant between the twisting moment M and the resulting angular deflection θ such that $M = C\theta$.

d Subscript denoting the damping phase of the motion.

f_1 Defined by Equation [70].

f_2 Defined by Equation [73].

f_m Defined by Equation [9]. Given in Table 4.

F Function representing the damping torque.

F_a, F_b, F_c Given in Tables 1, 2, 3.

g Gravitational constant.

G Shearing modulus of elasticity. For steel this is equal to 11,800,000.

h Absolute value of the total friction torque acting on the friction surfaces of the damper.

$h_1 = \dfrac{720\,h}{\pi^2 C}$

$j = \dfrac{p^2 J}{gC}$ [Appendix No. 2 (*c*)]

J Weight polar moment of inertia of shaft. Also in Appendix No. 2 (*c*) the polar moment of inertia of the damper flywheel.

J_1, J_2 Weight polar moment of inertia of the first and second mass, respectively.

k Crank-to-connecting-rod ratio.

K Energy absorbed by the damping forces.

l Length of shaft.

m Maximum value of the harmonically impressed torque. The following subscripts are attached: 0, $d0$, $N0$, 1 d, N. The subscript 0 is equivalent to multiplying by $180/\pi C$. The subscripts d and N refer to the components stimulating the damping and normal phase, and the subscript 1 refers to the value of m per unit mean piston area (i.e., mean of top and bottom area of piston) per unit crank radius.

M_i Impressed torque.

M Twisting moment. Also in Appendix No. 2, Case II of (*c*), M is defined by [89].

n Frequency.

N Subscript representing the normal phase of the motion. Also in Appendix No. 2 Case II of (*c*), N is defined by [89].

p Frequency constant $= 2\pi n$.

p_0 The value of p at synchronism.

Q Torque.

r Radius.

R Radius.

S Stress.

t Time variable.

T, T_1, T_2 Time variables referred to different initial values.

W Weight.

x Length variable from first mass.

y, y_d, y_N Maximum values of θ°, $\theta_d{}^\circ$, $\theta_N{}^\circ$, respectively.

$\alpha = 1 - \dfrac{J_1}{gC}\,p^2$

$\beta = \left(1 - \dfrac{J_2}{gC}\,p^2\right)^{-1}$

γ Constant of integration in degrees.

δ A small constant. Also in Appendix No. 2 (*a*), defined by Equation [73].

Δ Fraction of J for the shaft to be added to J_1 when the $J_2 = \infty$, to give the same frequency.

Δ_1 Fraction of the polar moment of inertia of the shaft from the first mass to the node to be added to the first mass.

Δ_2 Fraction of the polar moment of inertia of the shaft from the node to the second mass to be added to the second mass.

θ Amplitude of vibration in radians. This applies to θ with any subscript attached.

θ° Amplitude of vibration in degrees. This applies to θ with any subscript attached. The subscripts 1, 2, d, $d1$, $d2$, N, $N1$, $N2$ may be appended to θ or θ°. The subscripts 1 and 2 refer to the first and second mass, respectively. The subscripts d and N refer to the damping or normal phase of the motion, respectively.

$\textcircled{m} = a_N - b_N$

ρ Constant ratio for damping proportional to the velocity.

$\rho_1 = \dfrac{\rho p}{C}$

$\phi = \dfrac{360}{\sqrt{g}}\sqrt{\dfrac{J}{C}} = 18.33\sqrt{\dfrac{J}{C}}$ for $g = 385.9$ in. per sec. per sec.

ω Time-phase angle of normal phase of motion behind maximum value of impulse.

ω_0 Equations [49] to [51], any phase angle such that $pt - \omega - \omega_0 = pT$. Also elsewhere the special value of $\tan^{-1} \dfrac{a_d}{a_N}$.

ω_1 The time-phase angle at the first mass of the resultant of the normal and damping phase of the motion behind the maximum value of the impulse.

All positive time-phase angles represent the lag of the maximum positive value of the harmonic behind the origin of the time variable. They are given in degrees or radians and represent that part of one cycle of the harmonic where one cycle is considered to contain 360 deg. or 2π radians, respectively.

APM-51-23

Turbine Vibration and Balancing

By THOMAS C. RATHBONE,[1] LESTER, PA.

The limitations are discussed of the latest analytical methods employed in correcting the balance of turbine-generator rotors at speed and in operation. A strobo-vibroscope developed to study motion in a complex system is described, with the results of experiments made on a large rotor by means of this instrument. A method of balancing is then described, which takes into account the interaction of vibratory impulses communicated from one bearing to another, thus overcoming the chief difficulty with present methods. The proposed method also provides a means for evaluating the sensitivity of any installation, for comparative study of structures. There is also included a discussion of various factors other than simple unbalance which affect the vibration of large units, with references to some unusual cases encountered.

PART I FIELD BALANCING METHODS

Introductory

THE desirability of balancing large turbine-generator rotors in the shop at speed under conditions approaching those encountered in service, and also in actual operation in the field, has led to the development of various kinds of vibration instruments and analytical methods of balancing. Such methods are a great improvement over the old "hand balancing" process and yield fair results under favorable conditions. But being based on ideal assumptions which are never realized, particularly in the case of complex structures readily permitting interaction of vibration between bearings, these methods are sometimes found wanting.

It will be the purpose of this paper to discuss some of the more recent methods in use and their deficiencies, to describe apparatus for analyzing the vibratory motion at the bearings and the results of experiments carried out by their aid, and to propose a method of balancing on complex structures which compensates for the influences transmitted from one bearing to another. By this process the installation is evaluated in terms of the response from unit unbalance, and a means is thereby supplied for comparative study of the vibration characteristics of any unit particularly with regard to resonance, for purposes of design.

A brief discussion is also included of factors other than simple, fixed unbalance which affect the vibration of turbine-generator units.

Present Status of Field Balancing

As the sizes of turbine generators have increased and the operating conditions become more severe, it has been found that the balance obtained by means of the dynamic balancing machine, operating at relatively slow speed and room temperature, does not always insure quiet running in operation. The mass axis under operating conditions may not quite coincide with the initial axis. Because of this, it is now customary to check the balance of large rotors at speed and under temperature conditions simulating those in operation, in a special test set-up, in order to make any final adjustments of the running balance that prove necessary.

Changes in balance may occur in service due to seasoning, reblading, rubs, or other causes; therefore it becomes necessary at times to carry out balancing in the field under operating conditions. The problem of balancing at speed both in the shop and in service is therefore an important one and has received a great deal of attention in recent years.

Although some very creditable balancing has been accomplished by the familiar "hand balancing" methods, using the high-spot scribing on the shaft, this process is generally found tedious and unsatisfactory.

Various types of vibration instruments have been developed to aid in this work, and the quantitative information thus made available has been used as the basis for several new analytical methods of balancing. These methods are based on ideal assumptions, but have yielded fair results where the conditions have been favorable.

Fig. 1 Vibrometer

By means of the vibrometer,[2] a type of which is shown in

[1] Experimental Engineer, Large Turbine Division, Westinghouse Elec. & Mfg. Co., South Philadelphia Works.

Contributed by the Applied Mechanics Division and presented at the Akron Meeting, Akron, Ohio, October 21 to 23, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] This vibrometer, in common with most types, is based on the principle of the seismograph. For further description of vibrom-

Fig. 1, the amplitude of vibration in any direction at the bearings or any other part of the unit is determined. The balancing process consists generally in noting the changes in amplitudes resulting from applying known test weights at the end of the rotor nearest the bearing under observation. The amount and location of the unknown unbalance referred to the balancing holes are then deduced from the data obtained on three or more trials, by several methods.[3] It is assumed that the bearing

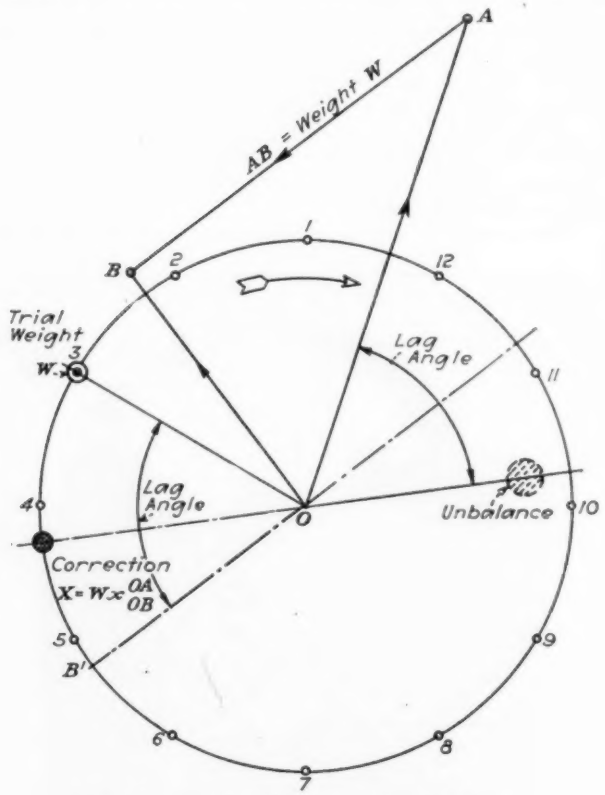

FIG. 2 SINGLE TRIAL BALANCING METHOD

under observation is not influenced by disturbances from other points and that amplitudes bear a linear ratio to unbalance.

Methods of balancing have also been devised, using the scribed high spot or employing the phase angle between a point in the vibratory motion and a reference datum on the rotor, by means of stroboscopic illumination of the vibrometer dial pointer. The change in the phase angle of the motion due to the initial unbalance on two successive trials with known weights in two positions affords sufficient data to determine the initial unbalance. The vector solution is simple.[4] It is assumed that the angle of lag remains constant for all amplitudes and under all conditions.

These ideal solutions have been reduced to the simplest possible terms by utilizing both the amplitude and phase relation of the vibratory motion. This solution has been termed the "single trial method" and has been used to advantage, especially on balancing machines. It is not believed to have appeared before in the literature,[5] and will be described here as use is made of this principle in developments to follow. By this method, the amplitude, with the phase angle between a point in the vibratory motion (for example, the vertical extremity) and the reference datum on the rotor, is observed for the initial unbalanced condition. In Fig. 2, representing the end of the rotor, the vector OA represents the phase and amplitude of this initial vibration. A known test weight is then inserted at any position, as at W. On this trial, a new amplitude and phase angle will result, representing the combination of the test weight and unknown initial unbalance. Let the new condition be shown by the vector OB. The closing vector AB now represents the known trial weight W in amount and phase. The initial vector OA, evaluated in terms of the weight scale of AB, determines the amount of the initial unbalance. The actual angle of lag is given by the difference in direction between OW and AB, which when laid off ahead of OA, fixes the location of the unbalance.

Under ideal conditions the high spot scribed on the shaft may be used instead of the phase relation of the vibration at the bearing.

The foregoing methods provide for balancing one end at a time. If the bearings can be considered as independent of each other, then the Marsland method[6] of compensating for the effect of the second end balance weight to prevent disturbing the first end already corrected, is applicable.

With the same assumptions as to independence of the bearings, and considering the system as a beam simply loaded, the two ends of the rotor can be balanced simultaneously by trial weights in both ends at once. In this case moments of forces about the bearings are used instead of direct weights at the balance planes.[7]

LIMITATIONS OF PRESENT METHODS

Some of these analytical methods have been used with fair success. They possess considerable advantage over "hand balancing." On many occasions, however, the disparity between the simple assumptions made and the actual conditions existing has been a source of trouble. Many additional trials then become necessary to obtain a satisfactory balance.

[4] This method, used by the author in 1923, is based on the principle that only one arrangement of the trial weight vectors is possible which satisfies the phase relations in the three trials.

[5] The method, based on combining amplitude and phase data, was suggested to the author by B. V. Anoschenko, Experimental Section, Large Turbine Div., Westinghouse So. Phila. Works.

[6] The correction for the first end balanced is allowed to remain. Then two weights are substituted for the second end corrector, one at each end of the rotor, by a simple simultaneous equation such that the moments about each bearing remain unaltered. This method avoids the labor of analyzing the static and dynamic components. See U. S. Patent No. 1,591,855, R. Marsland, 1923.

[7] The vector solution is similar to that described by M. W. Torbett in his discussion of the paper, "The Theory of the Dynamic Vibration Absorber," by Ormondroyd and Den Hartog, Trans. A.S.M.E., vol. 50, no. 17. A similar method was used by Akimoff. The determination of the center of gravity, however, is unnecessary.

The chief difficulty lies in the complex nature of the entire installation, regarded as a vibrating system. This is particularly true with relatively light structural steel foundations. The transmission of impulses from one end of the unit to the other through queer modes of vibration so confound the observed motions at a bearing that an analysis becomes difficult. The impulses from one bearing may augment or even neutralize the motion at another bearing. Observations on the shaft itself show the same influences. The author has often found the shaft "smooth" while the bearing pedestal indicated large vibration, and the reverse condition is frequently encountered.

It is perhaps a familiar experience to eliminate vibration at one bearing only to find it cropping up at another, or to suppress the vertical component at the expense of the lateral. It is difficult at times to determine which end of the rotor is responsible for the vibration. Often an intense vibration at the thrust end has later been found to originate at the coupling end. Again, much time may be consumed in attempting to balance the field when the spindle is the offender, and vice versa.

Because of the peculiarities of large units, wherein transient conditions are occasionally encountered, it is highly desirable to be able to make continuous observations from which the exact condition of the balance can be deduced over periods of time. This can only be partially accomplished by present methods.

Analysis of Motion

Regardless of the complexity of vibration characteristics encountered, it appeared probable that simple laws could be found which govern the make-up of the motion at any bearing or other point of the unit, thus making possible a prediction of the motion from a given set of conditions. In the following, simple harmonic motion is assumed throughout, which assumption is fairly well borne out in practice.

Fig. 3, upper drawing, represents a rotor on a non-rigid support, capable of communicating motion from one end to the other. Each bearing support may be considered as made up of two combined dynamic systems, one in the vertical and one in the lateral direction, each with its own inertia, elastic, and damping characteristics. The fundamental and higher natural frequencies in the vertical and lateral directions will therefore not be the same, unless by accident. The amplitude of motion in each direction occasioned by unbalance will depend on the ratio of the running speed to the natural frequency for the corresponding direction. Therefore, in going through the speed range, the vertical and lateral components will wax and wane independently of each other.

Assume a fixed speed and a given unbalance at A. The vertical component at the No. 1 bearing undergoes simple harmonic motion of an amplitude V_a, which may be represented as the diameter of the generating circle. This motion includes any effect coming from the No. 2 bearing due to A. Considering the balance-weight position as a reference point on the rotor, the angle of lag is the angle through which this point has turned beyond the vertical position at the instant the corresponding vertical component of motion has reached its upper extremity. In the diagram of Fig. 3, the point P_v in the path of motion V_a is shown at the instant when the unbalance is in the vertical position. Thus the corresponding points in the path of motion are laid off back from this reference.

Similarly the lateral motion L_a is shown as the diameter of the generating circle, with the phase of the motion referred to the reference A. The two simple harmonic motions compounded at right-angles generate the Lissajou ellipse P, and the point P on the ellipse is the instantaneous point in the path of motion when the rotor datum is passing through the upper vertical position. With this one point fixed, the elliptical path can be graduated in degrees or balance-hole positions to agree with the numbers on the rotor. It is important to note that if the unbalance is shifted through a given angle, the corresponding points on the ellipse will also move in agreement through the same angle, but the shape and inclination of axis will not change, nor the magnitude and direction of motion. It should also be noted that the phase difference between the vertical and lateral components may be such as to cause the bearing motion to rotate counter to the spindle. At first this appears to be a paradox. Any change in speed, inertia, or elastic scale will of course alter the figure.

Thus far, only the motion due to the unbalance A has been considered. This may be termed the "primary motion" for

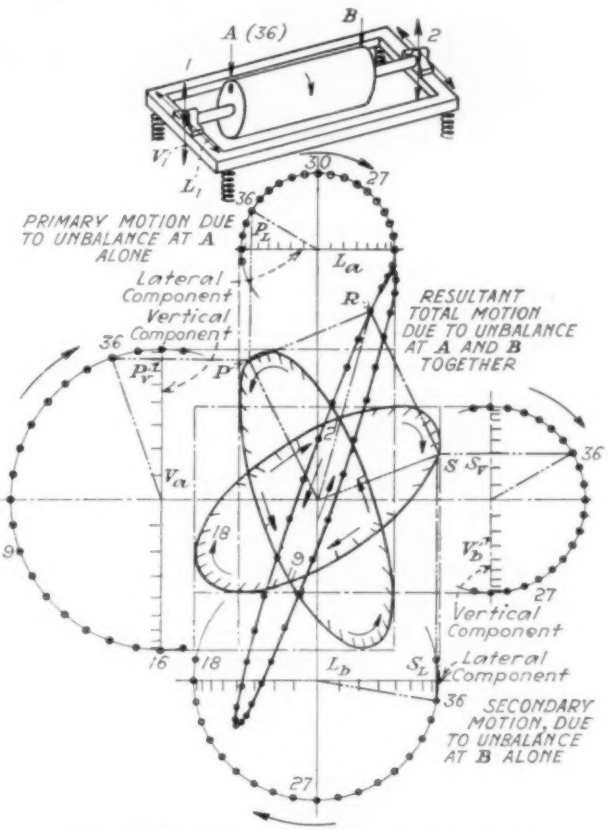

Fig. 3 Composition of Motion at a Bearing

the No. 1 bearing. Still considering this bearing, assume that the unbalance is removed from A and transferred to B. The centrifugal force developed influences the No. 1 bearing through the rotor, and also communicates a motion to it by way of the No. 2 pedestal and foundation. These two influences can be considered as a composite and need not be separated.

The generating circles for the vertical and lateral components of motion at the No. 1 bearing V_b and L_b due to the weight B are constructed with assumed phase relations, and compounding produces the ellipse of motion S. The point S in the path occurs when the reference on the spindle is at the top position and corresponds with the point P in ellipse P. This may be termed the "secondary motion" for the No. 1 bearing.

If the weight A is replaced, and the weight B left in, then the No. 1 bearing would be subjected to the two elliptic motions P and S. If the principle of superposition holds, then P and S can be compounded to give the resultant motion R, which

would obtain with both weights acting at the same time. The point R in this motion is the vectorial sum of OP and OS.

Similarly the same process holds for the No. 2 bearing, the data being obtained simultaneously. The primary motion for one bearing corresponds to the secondary motion of the other.

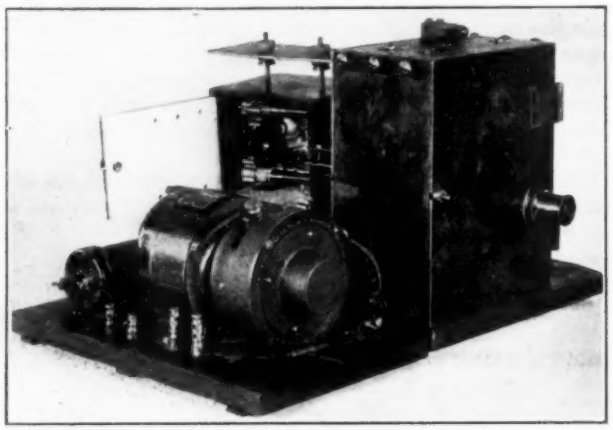

FIG. 4 VIBRATION PHASOMETER APPARATUS

These primary and secondary motions due to a unit unbalance may be termed "unit motions." They become a fixed characteristic or index for the system and completely determine the motion produced by all possible combinations of unbalance, with two provisos: every component magnitude of motion varies

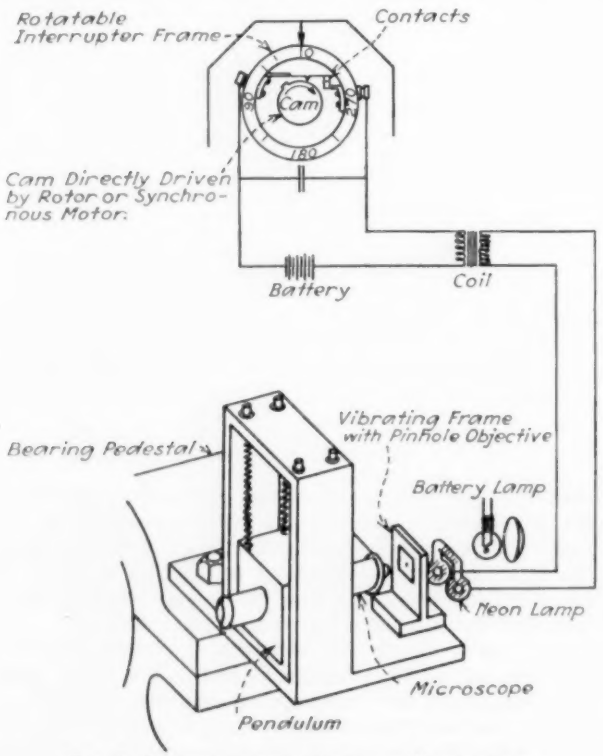

FIG. 5 SCHEMATIC ARRANGEMENT OF PHASOMETER

directly with the unbalance, and the several angles of lag remain constant.

THE STROBO-VIBROSCOPE

In order to demonstrate the principle outlined, experiments were carried out on a large rotor in its testing cylinder. Observations at the bearings were made with a special type of strobo-vibroscope, or vibration phasometer, shown in Fig. 4, developed at South Philadelphia for such studies.[8] The schematic arrangement is shown in Fig. 5. The microscope is mounted on a heavy pendulum suspended by light springs and is therefore practically stationary in space. The objective is an extremely small perforation in a sheet of foil, which is carried

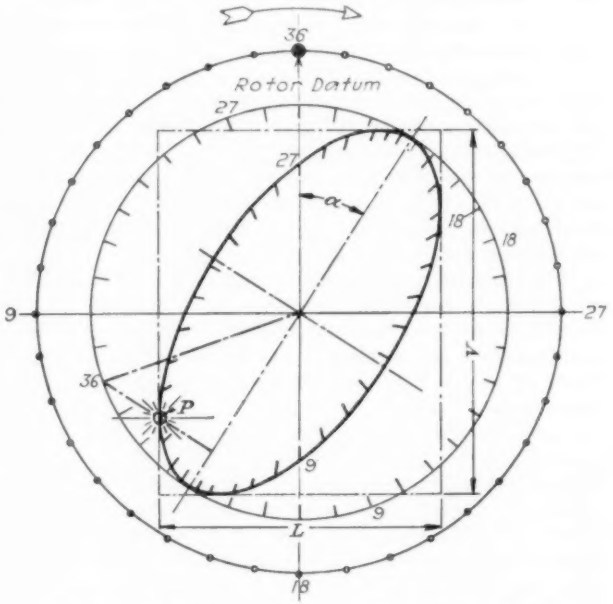

FIG. 6-*A* METHOD OF RECORDING ELLIPSE OF MOTION

FIG. 6-*B* DISTORTED MOTION

on a frame, the whole being rigidly mounted on the bearing and partaking of its motion.[9] Dual illumination is used; a steady light and a flashing neon lamp, both in the line of sight behind the pinhole.

When observing steady light through the pinhole the motion

[8] This is an improved design of the apparatus made by the author for investigations of obscure vibration phenomena in 1923. See "Unusual Vibration of a 25,000-Kw. Turbine Generator," by the author, *Elec. Journal*, vol. 25, no. 2, Feb., 1928.

[9] (*a*) See "Vibration Problem in Engineering," Timoshenko, p. 330, for description of method used by G. B. Karelitz, in observing motion figures through the microscope as reflected by points of steady light from emery cloth. The author has found the pinhole objective more satisfactory than reflected light or cross-hair intersection for stroboscopic work. (*b*) For an early attempt with stroboscopic methods see "L'Equilibramento delle masse rotanti a grande velocita," Dr. Ing. Carlo Luigi Ricci, Atti della Reale Accademia Delle Scienze di Torino, vol. 51, 1915–16, p. 188. A phase method using the Archimedes spiral is described. (*c*) See also a description of the Davey vibroscope, Electrocon Corp., loc. cit., for use with stroboscopic illumination. The Elverson oscilloscope and the stroborama are also examples of stroboscopic apparatus which may be adapted to study vibratory motion. See also "Optische Messungen an schnellaufenden Machinen," Dr. Ing. W. Kniehahn, in *Der Motorwagen*, Aug. 10, 1926, p. 2. (*d*) A phase-determining method is also described by Wheeler and Southwell in *Engineering*, vol. 99, p. 64, 1915.

appears as an illuminated figure. The size of the figure is determined by a graduated eyepiece, and the inclination of its axis is estimated by a graduated dial on the instrument.

A circuit interrupter, driven either by the main unit or a synchronous motor, is made to break a circuit including the primary of an induction coil once each revolution. The secondary coil operates the neon lamp, which flashes only when the circuit is broken. The flash is practically instantaneous. The interrupter frame can be rotated manually, its angular position being indicated by a graduated circle corresponding to the balance holes or graduations on the rotor.

The pink-colored neon flash observed through the pinhole appears as a pink spot somewhere in the illuminated path of motion. As indicated by *P* in Fig. 6-*A*, when the interrupter is rotated through 360 deg., the pink spot will make a complete circuit around the figure. A second neon lamp in the same circuit is provided to illuminate some exposed part of the shaft on which has been painted the balance hole or angular reference positions. These marks appear stationary in the stroboscopic illumination. By these means, the instantaneous position of the spindle corresponding to any point in the path of motion is directly determined. The interrupter dial may be adjusted to this setting and the spindle positions thereafter read directly from the dial position.

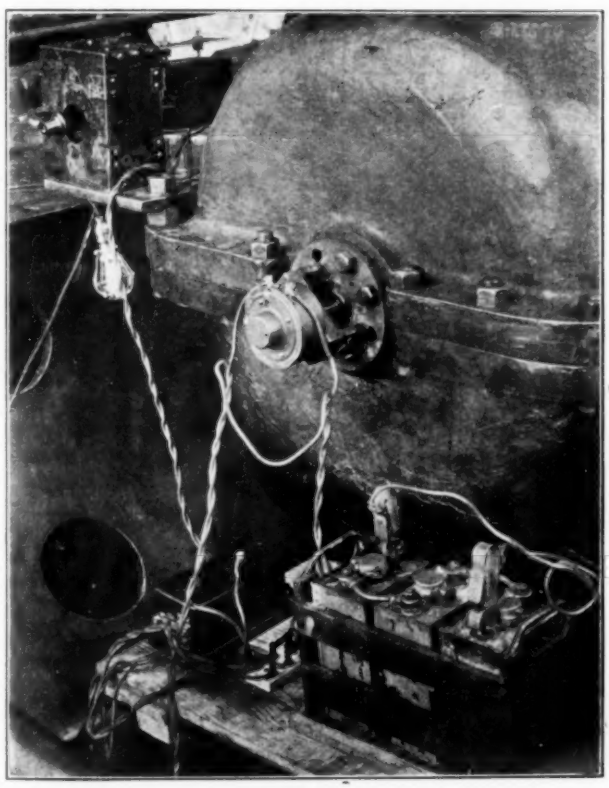

Fig. 7 Photograph of Apparatus on Testing Cylinder

Although the instrument can be arranged to record by photographic means, the one used was provided for visual observation only, in order to detect rapid changes. The method of recording an observation consisted in first sketching the shape of the ellipse and then determining the vertical and lateral dimensions of the enclosing rectangle, together with the inclination of the vertical axis. Then the phase angles for the important points in the path as shown were determined by the phasometer. Although only two points are needed (to locate all other points and show direction of motion), numerous points were observed for checking. The accuracy which can be obtained is quite remarkable. The phase angles repeatedly checked within three or four degrees with favorable conditions, and the amplitudes were estimated to a tenth of a mil. Two flashes per revolution 180 deg. apart were also used to obtain greater refinement.

Occasionally the figures observed are not true ellipses, and under unusual conditions they are greatly distorted, with a wide variation in the velocity of motion, as shown in Fig. 6-*B*. Such a condition is generally accompanied by a hard, sharp vibration, and is due to impact at some point. All sine motion at the same frequency lies in a plane. Axial components frequently occur, as this plane is not always perpendicular to the

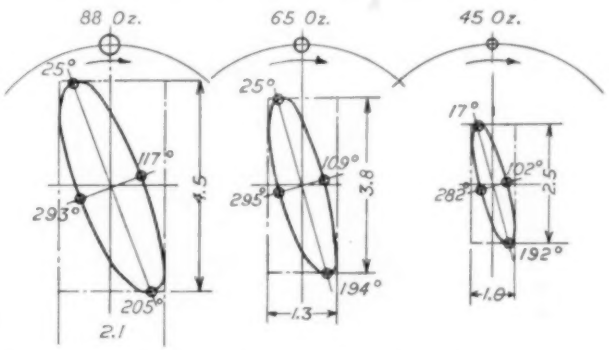

Fig. 8-*A* Preliminary Observations of Motion—Tests With Various Weights in Same Position (1400 R.P.M.)

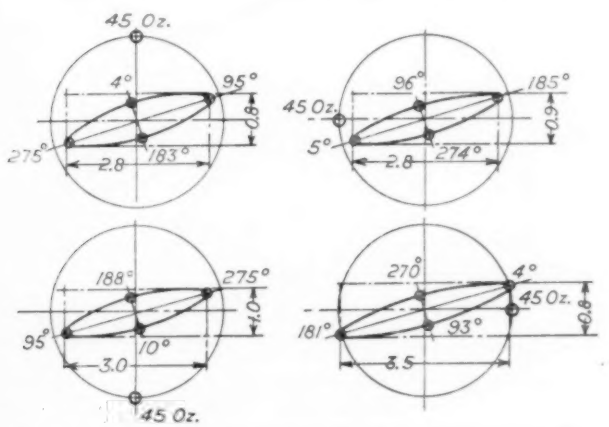

Fig. 8-*B* Preliminary Observations of Motion—Tests With Same Weight in Four Positions (1800 R.P.M.)

axis of the unit. Vibration figures simulating the figure 8 are produced by a curving of the plane of motion, and therefore one component must have a frequency of double the rotational speed. The true ellipse is the usual figure encountered.

Experimental Results

Fig. 7 is a view of the vibration phasometer mounted on a bearing housing of the overspeed and heat-testing cylinder for large spindles at the Westinghouse South Philadelphia Works. This set-up is very similar to an actual installation, as the bearings are both supported on the cylinder structure, and hence permit intercommunication of motion. A 50-ton spindle was used in the test, driven by an independently mounted turbine through a flexible coupling.

The spindle was first given a refined balancing at speed. No

vibration sufficient to interfere with the test was observed at any speed up to 2000 r.p.m.

First, a weight of 45 ounces was inserted at the 0 deg. reference at the thrust end of the rotor and observations made at the thrust-end bearing at various speeds up to 1900 r.p.m. Increasing the weight to 65 and 88 ounces resulted in a fairly proportionate increase in the size of the observed figure, as shown by

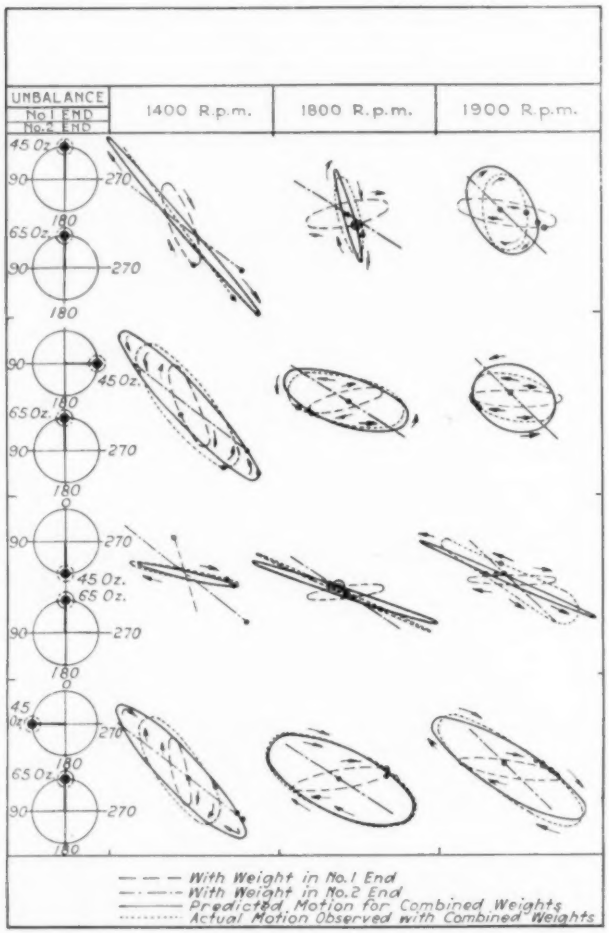

FIG. 9 ANALYSIS OF TEST RESULTS—VIBRATORY MOTION AT NO. 1 BEARING FOR VARIOUS SPEEDS

Fig. 8-*A*, but the shape and phase positions were not appreciably affected.

Observations were then made with the 45-ounce weight at 90, 180, and 270 deg. In each case the shape and size remained practically constant, but the phase positions shifted 90 deg. each time with remarkable fidelity, as shown by Fig. 8-*B*. The tests were repeated, removing the weight from the No. 1 end and trying 65 ounces in the No. 2 end at the 0-deg. and 180-deg. positions. The observed motions at the No. 1 bearing were the same for each case, and the phase positions reversed within about 20 deg. As this slight discrepancy held for all speeds, it was probably not due to error in maintaining a given speed, but to a small residual unbalance at the coupling end.

In the next series of tests, the No. 2 end weight of 65 ounces was kept at the 0-deg. position, and four trials were made with the No. 1 end weight of 45 ounces at the 0-, 90-, 180-, and 270-deg. positions on the rotor. The motions for each of these six cases separately having been observed, it remained to find if the weights in combination would produce motions agreeing with the motions predicted by superimposing the individual figures.

In Fig. 9 are shown the individual motions for each case, the predicted figure by superposition, and the actual motion observed by the weights in combination. The agreement is conclusive in all respects, in amplitude, shape or eccentricity of ellipse, inclination of axes, direction of motion (with or counter to rotor), and in the phase relation.

These results are particularly striking for the reason that the facilities for maintaining constant speed were not satisfactory. The phase relation of the motion to the rotor reference changes rapidly with speed. In a simple vibratory system, the angle of lag between the shaft deflection and the unbalance is expected to change swiftly from a few degrees to nearly 180 deg. going through the critical speed, the changes above and below being slight.

The experimental information obtained on these and other tests indicates, however, that the phase relation of the motion at a bearing of a large unit, which is really an index of the lag angle, changes continually with speed. In Fig. 10 is shown the relation between the phase angle and speed in tests on a large

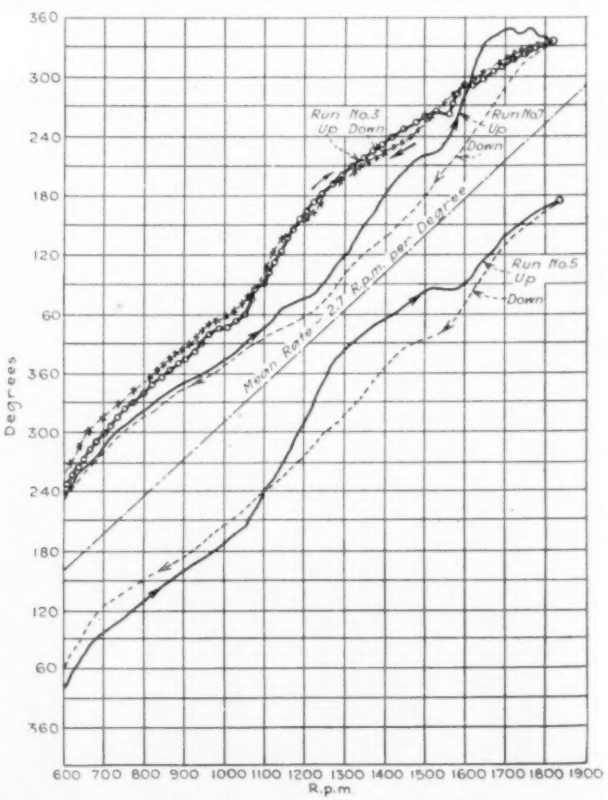

FIG. 10 CHANGE OF PHASE OF VIBRATION WITH SPEED—SPEED-PHASE CURVES OF LATERAL VIBRATION, NO. 1 BEARING, 50-TON SPINDLE, IN TEST CYLINDER

spindle in another testing cylinder made by Prof. Eric Therklesen[10] and the author in 1924. The remarkable fact developed that the angle of lag increased from 0 deg. to over 700 deg.—two complete revolutions—between the start and about 2000 r.p.m. The transit of vibration nodes across the point of observation and the influence of forces at other bearings must furnish the explanation. In the central station the slight variations in

[10] Dept. of Mech. Engrg., University of Montana, Bozeman.

frequency would not cause an appreciable change in the phase angle.

Other curious features observed in the present investigation deserve mention. The spindle shafts were carefully scribed for high spot on each test and at various speeds by A. R. Robertson.[11] There was little change in the mark between 1200 and 1900 r.p.m., and its position generally lagged about 90 deg. behind the weight. This ordinarily would have indicated resonance, but obviously resonance could not have existed throughout this entire range. Also noteworthy is the fact that when

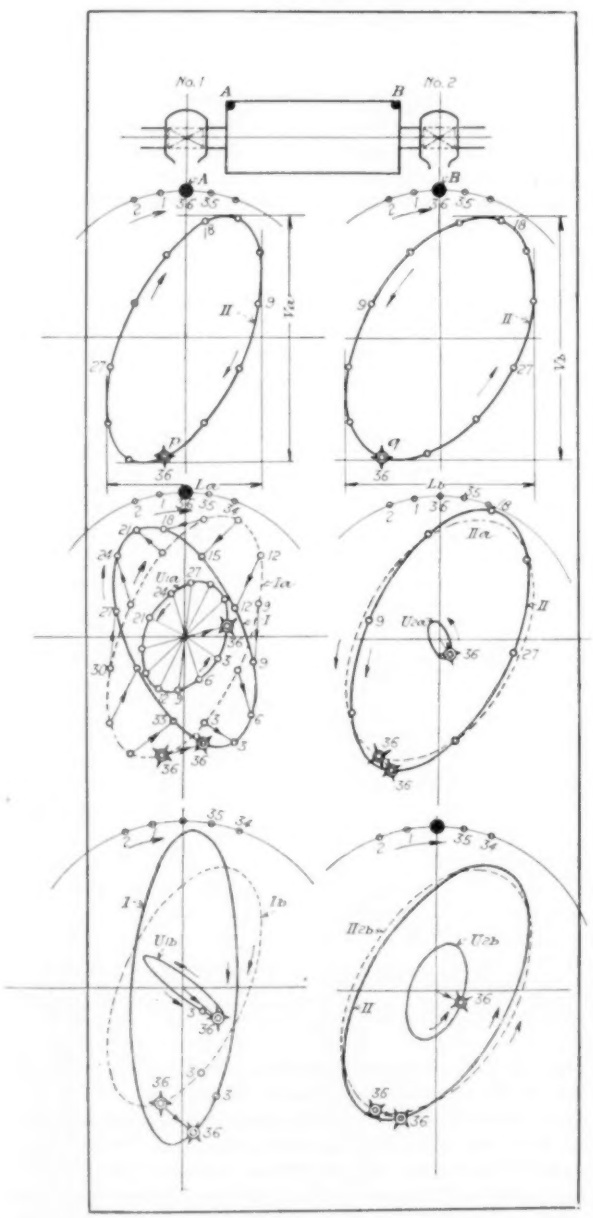

FIG. 11 METHOD OF DERIVING UNIT ELLIPSES OF MOTION FOR DETERMINING UNBALANCE

the 45-ounce unbalance at the No. 1 end led the 65-ounce weight in the No. 2 end by 90 deg., no high-spot location could be found. The shaft felt quite smooth, yet the vibration at the bearing was considerable. This may be explained by opposing impulses, and the occurrence emphasizes the unreliability of the scribed mark.

Another odd situation was developed by the experiment, but which might have been predicted by analysis. In the two

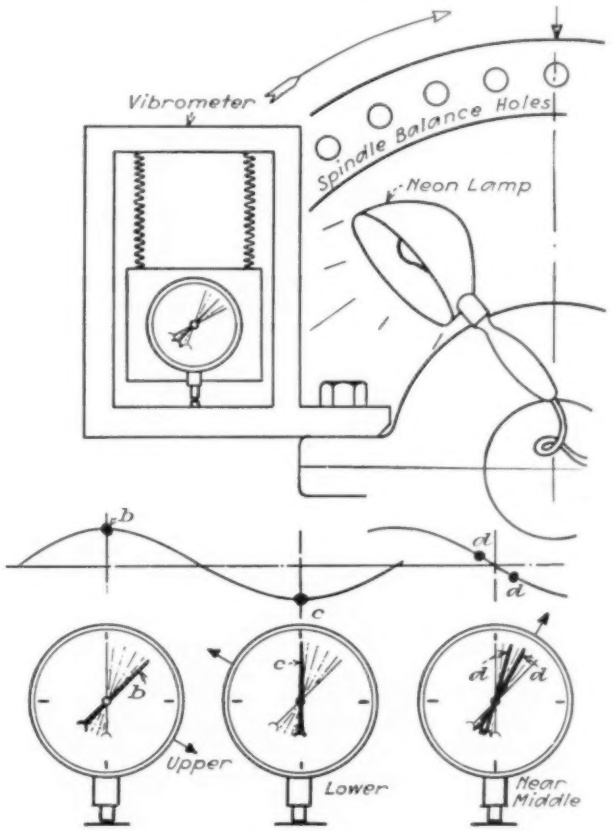

FIG. 12 VIBROMETER WITH STROBOSCOPIC ILLUMINATION FOR DETERMINING PHASE OF MOTION TO ROTOR

trials in which the unbalance of the No. 1 end first led the No. 2 weight by 90 deg. and then lagged 90 deg., it might have been expected from the usual academic treatment that the resultant vibration would be the same for both cases as the forces are identical. Actually, the results are totally different in every way. This indicates that a given combination of unbalance in a rotor mounted in intercommunicating supports will produce two sets of vibratory responses, one for each direction of rotation. On very large units the velocity of propagation of impulses through the structure from one bearing to another also enters the problem, as the rotor may turn through 10 or 15 deg. during this interval.

BALANCING SOLUTIONS BY UNIT MOTIONS

By utilizing the principles developed it is possible to determine any unknown unbalance in such a system. In addition to the two assumptions already made as to proportionality of amplitude for unbalance and constancy of lag angle, it must be assumed in the following that no change in the rotor or in the response takes place during observations. In Fig. 11 the rotor, operating at speed, is assumed to be unbalanced, requiring corrections at both balancing planes *A* and *B*. The first operation consists in determining the motion at each bearing as found and its phase relation to any reference datum on the

[11] Service Engineer, Westinghouse Elec. & Mfg. Co., So. Phila. Works.

rotor. Let these motions be represented by *I* and *II*, the points *p* and *q* representing the instantaneous positions in the paths of motion agreeing with the instant the reference on the rotor is passing through the upper position. Thus is the reference held throughout.

A known test weight, considered as a unit weight, is then inserted in balance plane *A*, for convenience at the reference point. The rotor is run to speed and a second set of observations made at each end represented by *Ia* and *IIa*, which will differ from the initial set. The weight is next transferred to the other end in the same angular position in plane *B*, and a third set of observations made, represented in the figure by *Ib* and *IIb*.

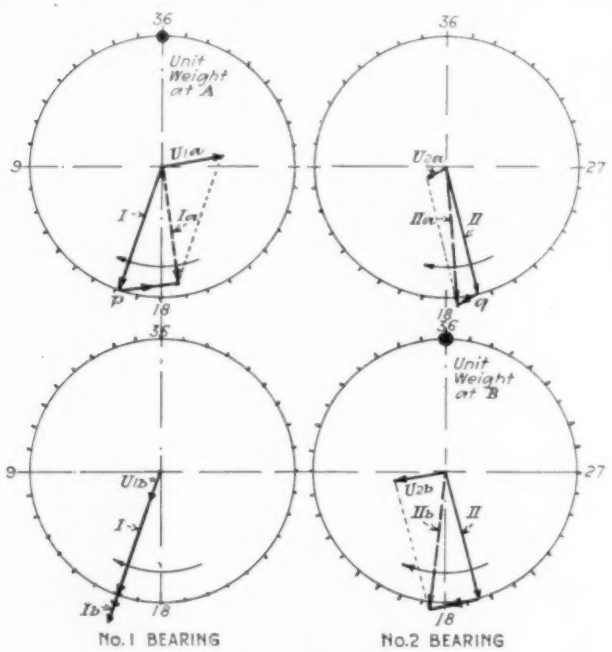

FIG. 13 DERIVATION OF UNIT MOTION VECTORS

(*I* and *II* represent motion at No. 1 and No. 2 bearing due to the initial unbalance. *Ia* and *IIa* result from adding unit weight at *A*. *Ib* and *IIb* result from adding unit weight at *B*. The closing vectors *U1a* and *U2a* are due to unit weight *A* alone, and *U1b* and *U2b* are due to *B*.)

No further information is necessary. The next step is the reverse of the procedure described in the experiment; that is, to find the ellipses of motion for the two trials which when added to the initial motions *I* and *II* would reproduce the composite motions *Ia*, *IIa*, *Ib*, and *IIb*. The process is indicated in detail for the figure *Ia* for the effect of the weight *A* on bearing No. 1. The ellipse *I* is the initial motion as before, and *Ia* is the motion with the weight added at *A*. The vectorial subtraction of *I* from *Ia* determines the motion *U1a*, which may be called the unit motion at the No. 1 bearing due to a unit weight at *A*. It is the motion at the No. 1 bearing which would have obtained had the rotor been in perfect balance before adding the weight *A*.

The process is repeated for deriving the unit motions for the other three observations, thus obtaining *U2a*, *U1b*, and *U2b*. With this information the resultant motions at both bearings for any combination of weights can be determined. Thus, by varying the weights at *A* and *B*, and shifting their location, the proper combination can be found by graphical or other means whose resultant motions will coincide with the initial motions observed, and the problem is completely solved.

The determination of the proper combination of weights can be made graphically, or by a mechanical device for combining two pairs of SHM's at right angles, or analytically. J. P. Den Hartog[12] has developed the complete mathematical analysis for the solution of the two-bearing unit by this method.

An analysis of the problem discloses that a superfluity of information is obtained from the ellipses; that two independent solutions exist which should check each other. This arises from the fact that the system considered is a dual one, having independent dynamic characteristics in both the vertical and lateral directions. Therefore, it should be possible to solve the unbalance by observing only the component of motion in either the vertical or lateral direction, without determining the shape of the ellipses. The method proposed takes advantage of this fact.

The necessary apparatus, therefore, can be greatly simplified, using the original arrangement with the vibrometer, observing the pointer with stroboscopic illumination as illustrated in Fig. 12.[13] If the vertical motion is chosen, then the phase reference is determined by the angle through which any datum on the rotor has turned from the vertical position, at the instant the motion reaches its vertical extremity. In the arrangement shown, the dial of the interrupter is turned until the needle stands out in the extreme clockwise position.

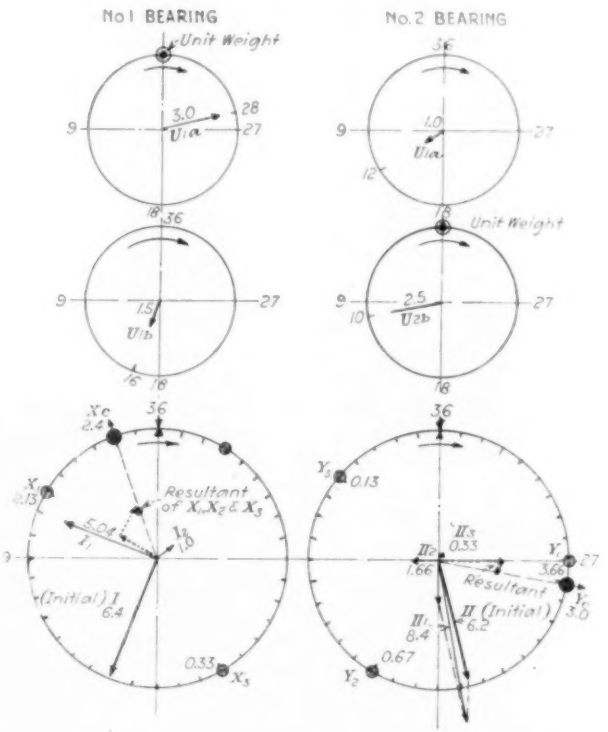

FIG. 14 GRAPHICAL METHOD OF DETERMINING INITIAL UNBALANCE BY MEANS OF UNIT MOTION VECTORS, FOR COMPONENT IN ONE DIRECTION

The conditions assumed in Fig. 11 are reproduced in Fig. 13 using only the vertical component of motion. The diagrams are again oriented by fixing the rotor datum in the upper position. *I* and *II* represent the initial vertical motion due to unknown unbalance, the points *p* and *q* being the instantaneous positions in the motion when the spindle datum is vertical. The motions can now be expressed as vectors representing amplitude and direction.

[12] Engineer, Mechanics Section, Research Dept., W. E. & M. Co., East Pittsburgh.

[13] This method was used to determine the phase data shown in Fig. 10.

With the known weight in A, the vectors are changed to Ia and IIa, and with the weight in B, vectors Ib and IIb result. The weights are assumed at the datum for convenience. The vectors representing the influence of the unit motions alone are derived, as shown, from the effect of the trial weights on the initial motion. In each case they are given as the closing vectors from the initial motion due to unbalance to the motion as affected by the weight. These unit vectors represent the motion which would have resulted had the rotor been in perfect balance before the trial weights were added.

As before, the solution consists in varying the amounts and locations of the two weights until the proper combination is found, producing vectors which duplicate the original vectors. This weight combination is then equivalent to the unknown unbalance. The mathematical solution, based on the linear component alone, is still quite involved.[14]

A simple graphical method for determining this combination will be described. In Fig. 14 are tabulated the unit vectors which are to be used as the basis for determining the unknown unbalance whose motion vectors are shown below. The graphical process consists in first assuming a weight at one end which cancels the initial vector at that end. Thus, in the example, the unit weight A would be multiplied by $I/U1a = X_1$ units and shifted to position X_1 to produce an equal and opposite vector nullifying vibration at this end. But in doing this, an additional vector is added to the motion at II, equal to $X_1 \times U2a$, in the corresponding direction. The resultant of this addition to the initial vector II is II_1.

For the next step, an assumed weight Y_1 at the B end is found whose vector cancels II_1. The only unbalance now remaining is that produced at the A end by the addition of Y_1 at the B end, and is equal to $Y_1 \times U1b/Ua$ and is canceled by X_2 at the corresponding location. As the continued process involves a rapidly converging series for the usual condition, one or two more adjustments should reduce the residual to an insignificant amount.

The several assumed weights, X, X_1, X_2 and Y, Y_1, Y_2, etc., are then added vectorially to give the resultant corrections Xc and Yc to apply to the rotor. If each weight produces a lesser motion at its own end than at the opposite end, then a motion at one end is corrected by inserting a weight at the opposite end, and in this way a converging series is obtained as before.

Four-Bearing System

The method outlined is applicable to the four-bearing system, as represented by the turbine-generator unit, but the solution is of course more involved. In addition to the initial observation of motion at all four bearings, four trial runs will be required to permit observations with the unit weight in each end of each rotor.

In Fig. 15 the four-bearing unit is represented with assumed initial motions at each bearing due to unbalances in each rotor. Below are tabulated assumed unit vectors, there being four sets of four simultaneous observations. The problem, as before, lies in adjusting the amounts and locations of the weight in A, B, C, and D until the combination is found which cancels all of the initial motions. Although the solution is much more tedious for the four-bearing unit than for the single rotor, an inspection of the unit vector table and comparison with the initial motions should yield clues as to about where the corrections belong, and thus indicate the sequence of trials, for the most rapid reduction of the initial motions.

Once having obtained the unit vectors, these methods then really represent balancing trials on a model of the unit, and are made on the drafting board, rather than on the actual unit itself, with obvious advantages. The solution by vectors based on the lateral component should check the vertical.

Evaluation or Vibratory Response of the Installation

The tabulation of unit weight vectors for each bearing in Fig. 15 supplies a criterion for evaluating the sensitivity of response in any installation at the operating speed due to unit unbalance. It has been a common experience to find that a given amount of unbalance produces a different vibratory response in two identically similar units on different types of foundations, or even on similar foundations. Types of units will also differ in their characteristics on similar foundations.

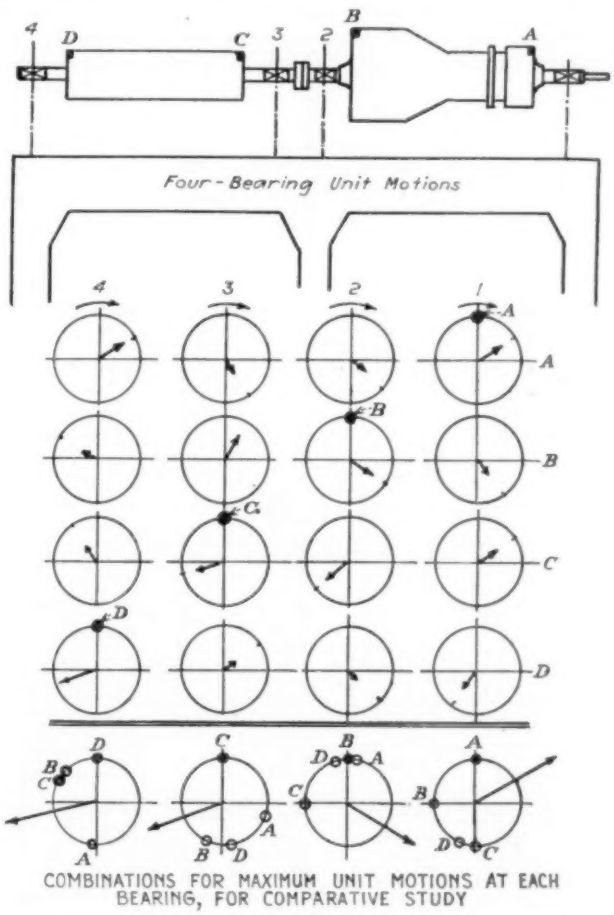

Fig. 15 Unit Motion for Four-Bearing Installation

The evaluation of sensitivity should therefore be valuable for comparative study of the characteristics of structures least conducive to vibration and in indicating desirable features of design. Such a criterion or index may be had by assuming a unit unbalance in both ends of both rotors at the same time, their angular relations being adjusted to produce a maximum vibration at each bearing in turn, as indicated in Fig. 15. The value of the largest response, and the average of the four, would furnish definite information as to sensitivity.

PART II FACTORS AFFECTING VIBRATION OTHER THAN SIMPLE, FIXED UNBALANCE

Vibration Due to Rotating Element

An analysis and solution of the vibration problem such as

[14] The solution, similar to Mr. Den Hartog's for the ellipses of motion, was worked out for the author by Nils O. Myklestad, undergraduate at the University of Copenhagen, Denmark.

outlined would not be complete without a discussion of its limitations and of complications encountered in practice which may on occasion make balancing difficult or even impossible. A recognition of these possible conditions must be had before any balancing process can be carried out intelligently and with assurance of results. The difficulties may have nothing to do with balancing.

One of the stipulations it is necessary to make in the method described is that the initial unbalance remains the same for each observation. It is obvious that any appreciable change in balance except that produced by the known trial weight will result in the derivation of a false unit motion. This is a most important point, as the usefulness of the method depends upon obtaining reliable and consistent data, and any small changes

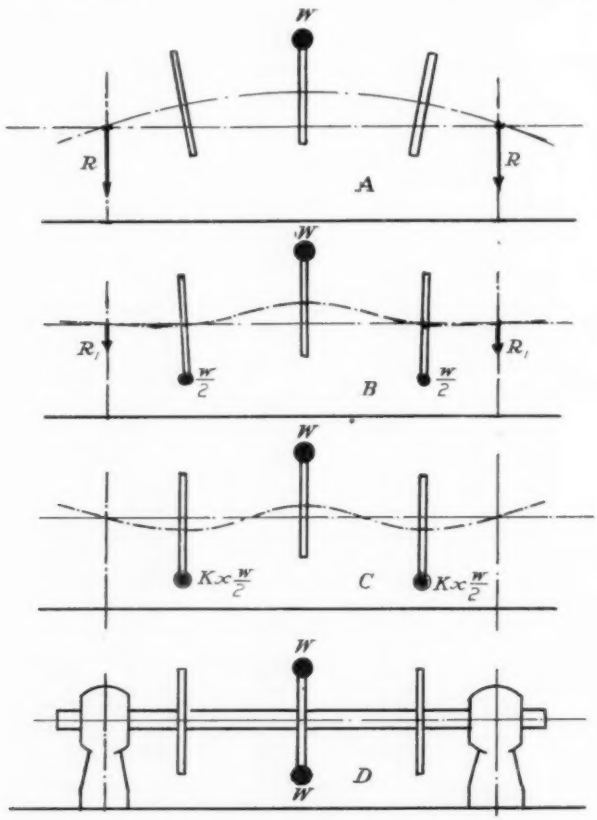

FIG. 16 EFFECT OF SHAFT DEFLECTION PRODUCED BY INTERNAL COUPLES AT SPEED

(*A*, deflection at speed due to unbalance at center. *B*, dynamic corrections $W/2$ at ends produce unbalance at speed because of greater displacement at center. *C*, additional corrector weights at ends to secure balance at a given running speed. *D*, ideal correction.)

which may occur throughout the range of operating conditions must be accounted for.

A number of purely mechanical faults may produce vibration, such as journal flats, rubbing contact at glands, dummy, spindle body, end bells, or loose windings. Vibrations set up by shaft whipping due to conditions in the oil film or to cramping fits have been described.[15] Other causes, such as pinched bearings and coupling misalignment, have been encountered. A slight wabble at the shaft has been suspected of setting up an oil-film condition conducive to local heating and hence increase of distortion. A bent shaft may set up axial vibration, particularly if the bearings are not properly self-aligning.

Rotors having considerable flexibility may undergo serious deflection at speed before the centrifugal and elastic forces balance. If the unbalance is chiefly near the middle, then the corrector weights at the ends produce double flexure at speed, and therefore must also compensate for an additional amount due to the preponderance of eccentric mass at the middle section. This

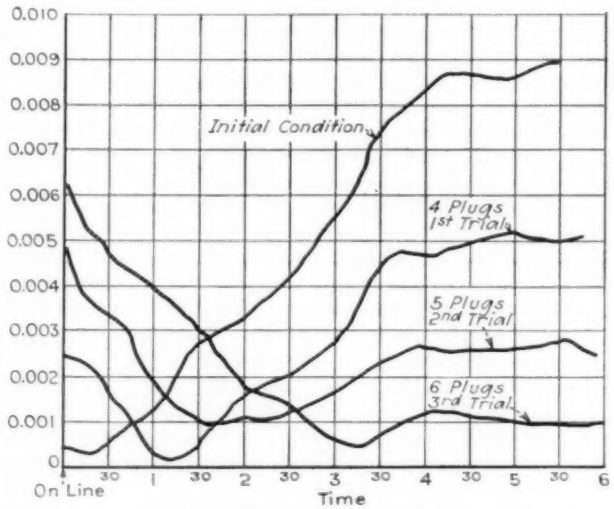

FIG. 17 VIBRATION-TIME RECORD, SHOWING EFFECT OF BALANCING OPPOSITE A DISTORTION REQUIRING ABOUT FOUR HOURS TO DEVELOP

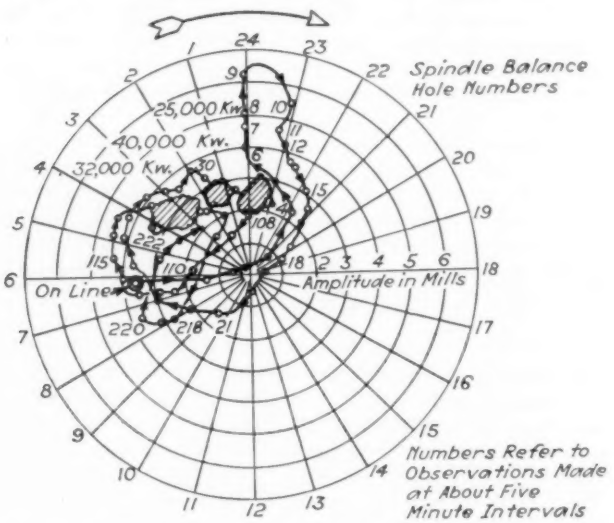

FIG. 18 CONTINUOUS RECORD OF VERTICAL VIBRATION VECTORS AT NO. 1 BEARING OF A 40,000-KW. UNIT, SHOWING CHANGES IN UNBALANCE WITH LOAD

(Numbers refer to observations made at about 5-min. intervals.)

is illustrated in Fig. 16. These excess corrector weights can be made to produce balance at a given speed, but only at that speed. In extreme cases axial vibration may be produced by the resulting wabble at the journals. In practice, the stiffness of most rotors permits satisfactory correction at the ends, but where flexibility must be taken into account, any large "static" unbalance correction is applied near the middle. So far as known, there is no device or method for determining the axial locations of unbalanced mass concentration, except by noting the effect on flexure developed at speed.

[15] (*a*) "Shaft Whipping." Dr. B. L. Newkirk, *Gen. Elec. Review*, vol. 27, no. 3, March, 1924. (*b*) "Shaft Whipping Due to Oil Action in Journal Bearings," Dr. B. L. Newkirk and H. D. Taylor, *Gen. Elec. Review*, vol. 28, no. 8, August, 1925.

Because of the practical impossibility of realizing ideal annealing, slight changes in the mass axis may occur under operating temperatures. These changes can often be detected with suitable instruments, and are sometimes sufficiently appreciable to warrant balance correction. On large units, from two to four hours of operation are required to develop fully the normal running condition. If the running condition is materially different from the cold condition, the direct procedure lies in lo-

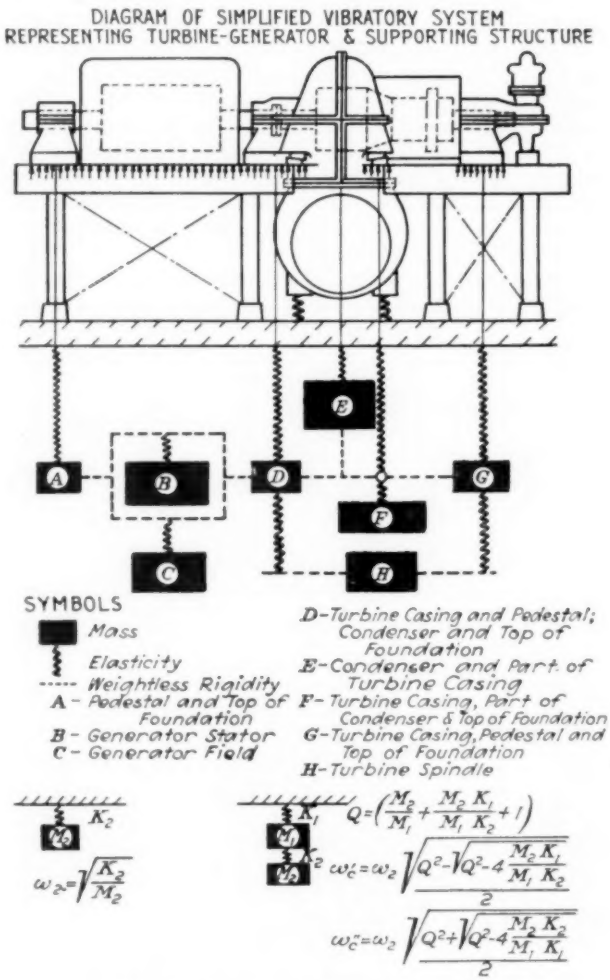

FIG. 19 SCHEMATIC FOUNDATION SYSTEM

cating the direction of the shaft distortion immediately after shutting down, and balancing opposite. Such a rotor will come to speed with some vibration, smoothing out after three or four hours. In Fig. 17 are shown vibration-time curves in an abnormal case, illustrating results of balancing opposite the bend. It is of course necessary to wait until conditions have stabilized before attempting observations for balancing by analysis of motion.[16]

Occasionally the balance is affected by changes in operating conditions, as by changes in load, temperature, etc., and in a few instances there was found a definite and consistent relation between distortion and certain loads. In such a case, the best average balance is desired. If the amplitudes at a bearing are plotted in their proper phase relation on a polar chart, and continued observations made throughout the range of operation at frequent intervals, a picture is had indicating the migration of the unbalance. Thus in Fig. 18, which is an actual record, the tendency for the points to group themselves for certain loads is apparent. The wide swings shown on this chart were due to other causes which will be described. As the best average balance is wanted, the center of the clusters is adopted for use in the balancing process.

Spindles are sometimes distorted in operation by outside agencies. Gland water at the high-pressure end getting to the hot spindle has often been the cause of trouble, especially of an intermittent nature, changing with the pressure behind the gland and simulating distortions supposedly due to load and temperature changes.

A spindle which has been standing while hot will "hump up,"

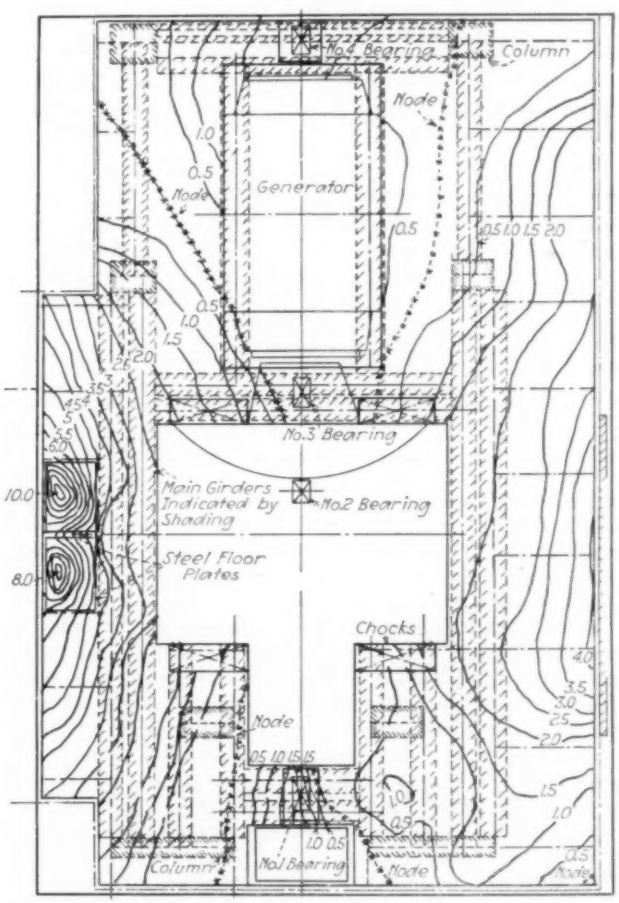

FIG. 20 FOUNDATION VIBRATION AT TURBINE FLOOR, IN MILS
(Load, 39,000 kw. Time, 10.15 to 10.45 P.M., June 24, 1927.)

due to the stratification of gases. This distortion reaches a maximum in from 8 to 12 hours on large solid rotors, and then slowly decreases. In starting up, most of this distortion must be "rolled out" before the unit is brought to speed. The spindle is usually rolled until the bend has straightened to within some prescribed amount, usually about 0.0015 in. (determined by experience from its effect on vibration), and then brought to speed. The location of this residual bend at speed is purely accidental, as the spindle may have stood in any position. The vibration which it produces usually disappears in from 30 to 45 minutes. It may either be such as to augment or reduce

[16] See also "Recent Applications of the Electric Micrometer," A. V. Mershon, *Gen. Elec. Review*, Oct., 1928, vol. 31, no. 10, p. 526, for examples of fluctuations after placing a unit in service, the records being made on the shaft itself by means of the electric micrometer.

other unbalances in the spindle, so that the vibration on going in service may vary greatly each time. These transitory conditions must be taken into account before attempting to balance.

Vibration may be caused by a fault in the rotor itself, as by a defective joint or bolting. Fortunately, such cases have been extremely rare. The wide swings shown in Fig. 18 were due to inadequate press fit in conjunction with a peculiar gland-water condition, which appeared to cause a working of the joint in one direction. On one other occasion of erratic vibration which could not be balanced out, an 8-lb. pipe plug was later found loose in the spindle cavity.

Vibration Augmented by Stationary Parts

It is now generally understood that the nominal critical speed

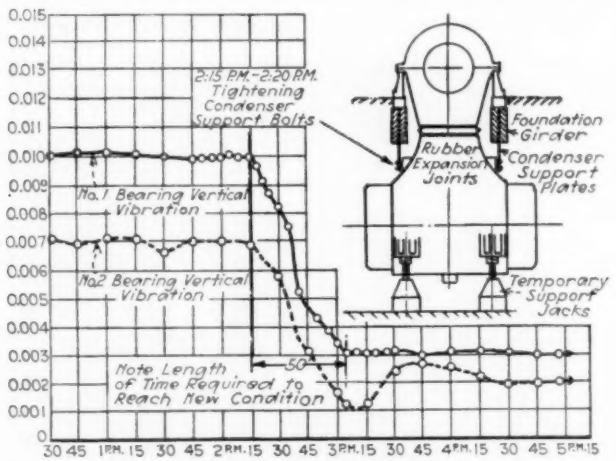

Fig. 21 Reduction in Vibration Brought About by Bracing Top of Foundation Through the Condenser

of the rotor (calculated with the assumption of rigidly supported bearings) loses its identity when the rotor is mounted on an elastic structure, and that the combination of rotor and foundation characteristics produces a number of different resonant speeds in various modes of vibration.

Eason[17] has expressed graphically the relations between the individual natural frequencies of rotor and support and the resulting critical speeds assembled, for the elementary compound system. Soderberg[18] suggests a diagrammatic method for solving the problem, with two or more degrees of freedom. These methods represent the nearest approach to the problem, but are for simple conditions only. Other treatments both here and abroad are based on such simple ideal assumptions, as mass concentration and elastic continuity, that their practical value is very limited.[19]

In Fig. 19 the author has attempted to reduce the dynamic characteristics of a large installation to the simplest representative system. Calculations of the many possible modes and critical speeds is practically out of the question. Yet the lateral vibration and the many diagonal and complex modes are also to be considered. To those who have made a study of the problem, it must appear remarkable that the operating speed of so many installations has not coincided with the natural frequency of any of these numerous modes.

Vertical vibration amplitudes on the top of the foundation of a large unit have been plotted and points of equal amplitudes connected in the diagram shown in Fig. 20. A symmetry of pattern is evident. This is more of a Chladni figure than a contour map, as the vibrations are opposite in phase on either side of the nodal lines. Vibration of this character is not at all unusual, and the figure indicates the complexity of motion usually encountered. These nodal lines of zero vibration could hardly have been predicted, and if the nodes are not determinable neither is the natural frequency.

The amplitude of vibration at any point in any direction depends not only on the amount of unbalanced forces, but also

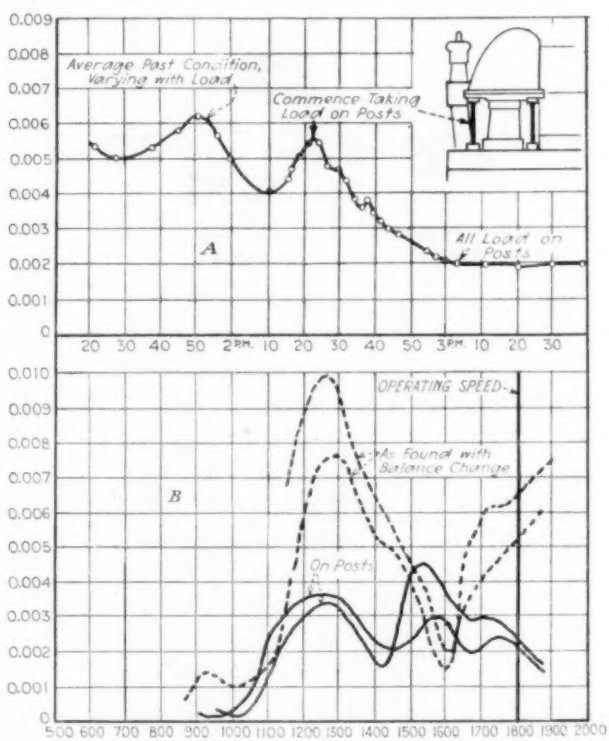

Fig. 22 Reduction in Vibration Effected on a 30,000-Kw. Unit by Changing Elastic Scale of the Support

(*A*, Vibration-time curve during alteration to scale of supports. *B*, Resonance curves before and after altering supports.)

on the proximity of the running speed to one of these numerous major or minor resonances. Herein lies at least a partial explanation of the dissimilar vibratory response of like units. Until more data are available governing the characteristics of an installation, the attempt to stipulate a certain fixed amplitude which the vibration must never exceed should be made with reservations.

Transient vibratory conditions can be set up through changes in the unit or foundation by temperature or other distortions Resonance characteristics depend among other factors on the distribution of loading. Distortions due to unequal heating

of the columns or warping of the structure can very materially shift the points of loading. Thus a natural frequency may be sufficiently changed to cause it to pass through the operating speed, producing a temporary increase in vibration. Such conditions are more apt to take place during the starting up period.

Several cases have been encountered where changes in the method of supporting have profoundly affected the vibration in operation. Fig. 21 is an actual record of the effect of altering the sling supports of the condenser of a 20,000-kw. unit and blocking up the bottom feet. In Fig. 22-*A* is shown the reduction in vibration secured by reducing the elastic scale of the cylinder supports at one end of a 30,000-kw. unit which had resisted all attempts at balancing until resonance was recognized as the cause. The condition encountered is readily explained by the Berger curves shown in Fig. 22-*B*. A resonance peak just below 1800 r.p.m. was converted into a valley by the substitution of the lighter supports. In this case it was easier

It has been a familiar experience to encounter localized vibration at various isolated points throughout the structure even when the units were known to have been in fair balance. On one occasion a rather severe vibration of the light flooring contiguous to the unit was practically eliminated by placing a weight on the antinode. Large vibrations frequently exist in one or more structural members which are nearly tuned to the running speed. On other occasions severe vibrations occur at lower speeds as they are passed through. Sometimes these conditions can be relieved; often, however, they are regarded as necessary evils which cannot be avoided except by drastic changes to the installation.[21]

In Fig. 24 is illustrated the manner in which structural members may vibrate. The motion of one column was parallel to the axis of the unit, while the other was transverse. Under certain conditions a violent and rhythmic energy exchange took place between the columns, one reaching maximum when the

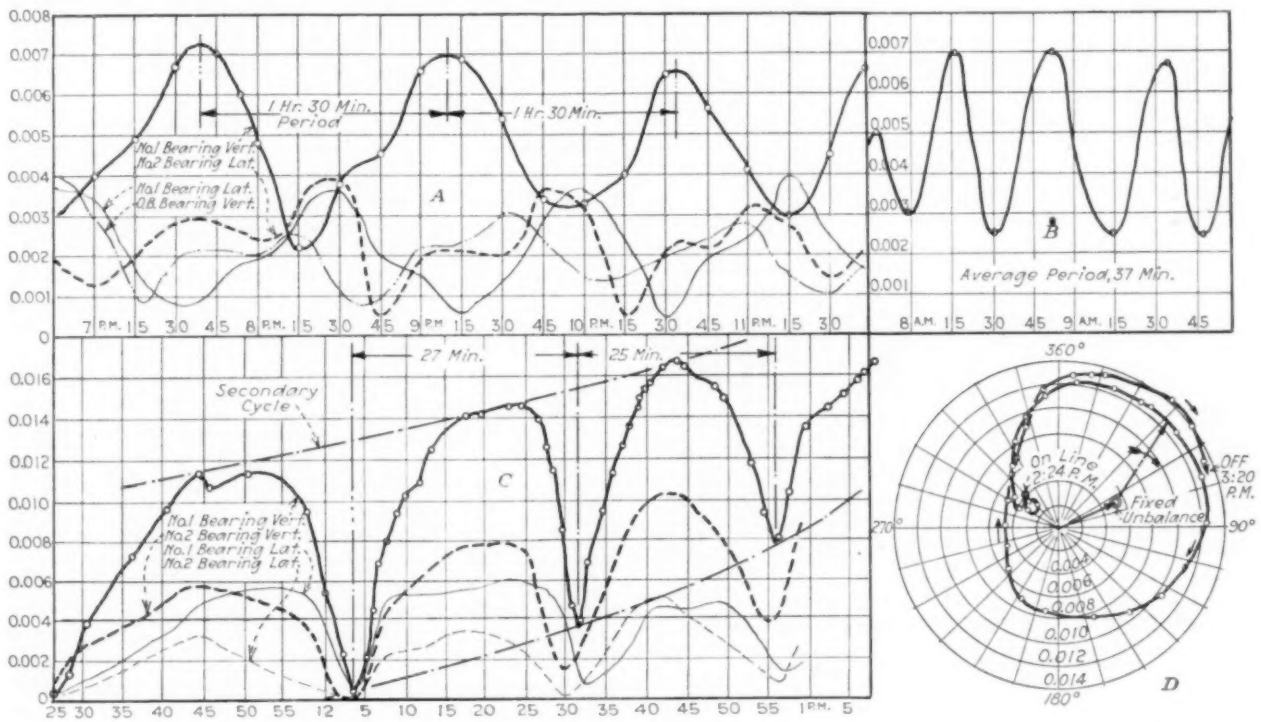

FIG. 23 CYCLIC VIBRATION

to alter the turbine supports than the foundation. Neither was at fault; the combination simply was unfortunate.

A most remarkable phenomenon has been encountered in at least two installations, characterized by a rhythmic waxing and waning of the vibration, in regular periods ranging from fifteen minutes in one case to an hour and a half in another. The analysis of motion seemed to indicate a combination of a fixed unbalance and a steadily creeping unbalance, the maximum and minimum vibration occurring when the two were in conjunction and opposition, respectively. Fig. 23 is typical of several actual records made with the vibration phasometer, indicating the observed vibration was made up of a fixed and a rotating vector. The vibration disappeared when a peculiar resonance in the supports and a vibrational energy exchange between the cylinder and steam chest were eliminated.[20]

[20] See footnote 8.

other was at the minimum. It should be stated that this large vibration was due to excessive unbalance in the spindle, and that in this case additional bracing to reduce the column vibration actually increased the amplitude on the unit itself. In other words, the columns served to a slight extent as vibration absorbers at that running speed.[22] When the unbalance in the spindle was eliminated, the column vibration was reduced to a small amount.

While a comprehensive discussion of turbine-generator foun-

dations does not come within the scope of this paper, attention should be drawn to some of the important features which have a direct bearing on vibration characteristics.

The question of steel versus mass concrete is receiving more attention today.[23] The almost general tendency in Europe on the larger sizes has been toward the heavy concrete structure. In this country are to be found examples of both extremes, from the massive concrete foundation to the tall, light, steel structure.

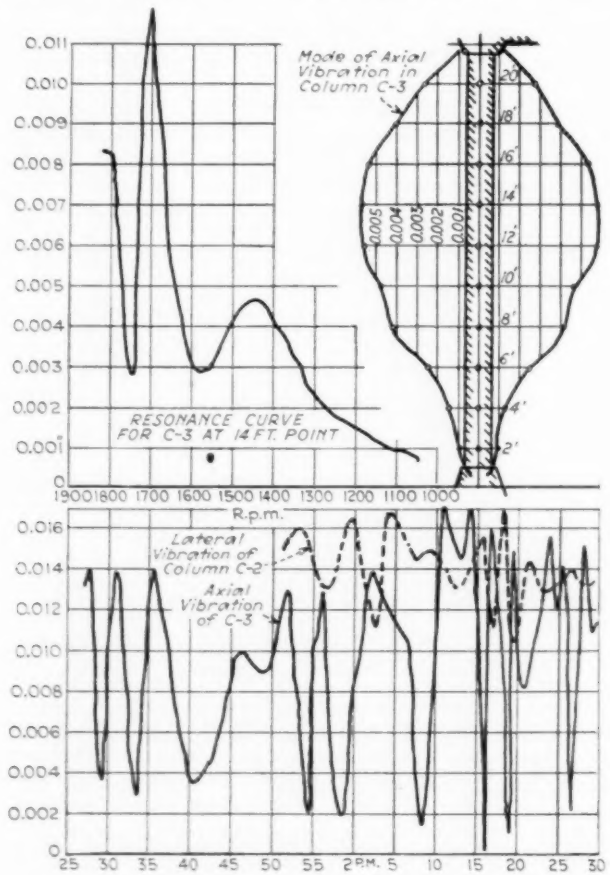

FIG. 24 FOUNDATION-COLUMN VIBRATION

Each has its advantages and disadvantages. The steel foundation is practically imperative where space is the paramount consideration. The problem of erection and the location of auxiliaries calls for this type of structure. Many large units are operating quite satisfactorily on relatively light steel foundations. But if insurance against vibration and allied operating difficulties is permitted to become the prime consideration, the indications are that the advantage lies with the massive concrete structure.

Upsetting the proper distribution of loading has been cited as affecting vibration. There have been cases found where steel columns expand 0.040 in. or more due to local heating, thus materially altering both the loading and the alignment. Local heating of longitudinal members, commonly encountered because of the location of the steam chest or piping, causes a lateral twisting and hence misalignment. Any attempt to relieve strains by postponing the final riveting at the joints until all the load is imposed can only be partially effective unless the structure has assumed the temperatures existing in operation. Some of these objections peculiar to steel because of its heat-absorbing propensity can be overcome by proper insulation. The welded structure, which is probably not so far off, will require especial attention with regard to prevention of internal stresses.

The unit stresses on even the lightest of structures from the static loading are commonly quite low, giving the impression that an ample factor has been allowed for the dynamic loading. Structural engineers, however, are prone to think of all dynamic loading in terms of the impact or "live" loading to which bridges and such structures are subjected. It is not always appreciated that dynamic stresses are a function of amplitude and that small harmonic forces may set up a much more severe condition than larger intermittent impacts. To take advantage of a time-honored illustration, a bridge designer would hardly attempt to compute the stresses caused by a body of soldiers marching in step unless he knew to a certainty the natural frequencies of his bridge.

Although the dynamic conditions at the operating speed are unquestionably of most importance, the operation at all speeds up to 10 per cent overspeed must also be considered. It would be very desirable to reduce the vibration which many units now go through at some lower "critical" speed. Stress calculations based on amplitudes under resonant conditions become so involved as to be impractical. But rather than assume an arbitrary minimum live-load factor, it would appear to be possible to adopt a procedure which would cover at least the fundamental modes of motion in the lateral and vertical directions. Such a method could be based on the centrifugal force due to an assumed eccentricity (say, 0.005 in.) and an amplification factor (say, 10) to take care of the ratio of the operating speed to any resonant speed, with the proviso that the stiffness should be such as to limit the resulting deflection to a given amount (say, 0.005 in.). The values given are tentative, by way of illustration, and neglect the mass of the stationary parts, but would insure only moderate vibration during abnormal conditions.

Because of the meager control now possible over the more complex resonance characteristics and the uncertainties which confront each new installation a recognition of the fundamental principles governing forced vibration in an elastic system, other than these resonance considerations, is desirable. The periodic forces of unbalance are absorbed in three ways: (1) In accelerating the masses involved. (2) In deflecting the elastic members. (3) In overcoming friction.

Other things being equal, the acceleration, and hence the resulting amplitude of vibration, is reduced by increasing the weight of the structure, increasing its stiffness, and employing material with the greatest internal damping. Simplicity of structure is also desirable, in that better control over the modes of vibration is secured.[24]

As the sizes of units become greater, with advances in design, and as other conditions such as are due to increases in temperature become more exacting, further attention may well be directed to the role which the foundation plays in influencing the vibratory characteristics of the unit as a whole.

In conclusion, the author wishes to express his appreciation of the valuable advice and assistance derived from his association with Prof. E. Therkelson, A. R. Robertson, J. Den Hartog, G. B. Karelitz, and B. V. Anoschenko, and to J. Burdette for aid in preparing this paper.

Discussion

S. TIMOSHENKO.[25] The author is to be congratulated on a very interesting paper. Guided by the theory of vibration, he has developed a new method of balancing based on an application of the stroboscope together with the vibrometer. In this way he can obtain the amplitude and the phase of pedestal vibration with reference to a definite point on the rotor. Having these data for the initial condition of the rotor and for the case when a known unbalance is added, the position and the magnitude of the initial unbalance may be calculated on the basis of certain assumptions. The experiments with trial weights showed that in many cases the method is accurate enough and may be recommended for the practical solution of balancing problems. The author also described the limitations of the method. Calculations are based on the assumption that the phase relation between the vibration of a pedestal and a definite point on the rotor remains constant. There are cases, however, when this phase is continuously changing. The author mentions several possible causes for such changes in the phase relation, but it seems that this phenomenon is not yet completely explained and that further investigation is desirable.

The paper contains a description of the motion of pedestals. It will be very interesting to get records of the motion of the shaft itself. The usual theory of vibration is based on the assumption that there are no clearances between the shaft and the bearings. In practice such clearances always are present and, due to changes in the thickness of the oil film, a certain amount of lateral motion of the shaft with respect to the bearing becomes possible. Hence, vibration of the pedestal may not represent the actual lateral motion of the shaft. The measurement of lateral motion of the rotor may be interesting in investigating the above-mentioned phenomena of changing phase.

Another important point discussed in the paper is the investigation of the vibration of foundations and the establishment of certain methods for determining the sensitiveness of foundations to vibration. The author uses trial balance weights for this purpose. More satisfactory results may be obtained in a much simpler way by using a special d.c. motor with definite eccentric weights. By running such a motor at various speeds, the critical speeds for the foundation and the corresponding types of vibration can be investigated. Such a method has been used in several cases by Westinghouse engineers at the suggestion of the writer. Just recently an analogous method was used for studying foundation vibration in Germany.[26]

It would be well if the author should give additional explanations of the terminology used in certain cases. A reader interested in dynamics of machines but not working specially in practical balancing will find some difficulty in understanding such expressions as "balancing at speed," "balancing in testing cylinder," "Marsland method of compensating for the effect of the second end balance weight," etc. Additional footnotes would be very helpful in such cases.

A. NADAI.[27] A very interesting result of the author's elaborate tests seems to be the astonishing fact of certain fluctuations of the amplitudes he measured during longer periods of time on steam turbines. The amplitudes of certain vibrations seem to increase and to decrease periodically. The periods of these fluctuations of amplitudes are astonishingly long, as certain fluctuations of the amplitudes have periods of the magnitude of one-half hour or more. The writer is much interested in this and should like to ask the author if there can be found a certain mechanical or other explanation for such unusually long fluctuations in the elastic vibrations of machine parts.

B. A. ROSE.[28] The paper gives a very interesting discussion of the experimental work done by the author in connection with the vibration and balancing of turbine-generator units. There are a few points brought out, however, for which there are no satisfactory explanations. That concerning the very gradual increase in the lag angle of the vibratory motion of the pedestal as the speed of rotation increases is very remarkable. It would be very interesting in this connection to have a record of the change in the lag angle of the turbine spindle itself, or of a true spot on the shaft as close to it as possible, to compare with the above. If the turbine spindle and the pedestal bearing are considered to be separate, distinct masses of a vibratory system and the unbalanced force is on the spindle, then the motion of the spindle itself should be of considerable interest in the study of the vibration.

The point the author makes concerning the flexibility of extra long rotors having an influence on the axial location of the balance weights is well taken, but this effect is of no importance except on the very long rotors. This condition will not be encountered on the turbine in any case, and will be confined always to an exceptionally long generator rotor.

It is the general practice of the Westinghouse Electric & Manufacturing Company to remove the greatest possible amount of the unbalance from their turbo-rotors by drilling in the heavy side. This drilling is done in the body of the rotor itself and particular care is taken with the longer rotors to get the static unbalance weight removed uniformly along the rotor body. This eliminates any possibility of this "double flexure" effect causing trouble.

M. STONE.[29] The paper presents an excellent picture of the complexity of the vibration problem in the operation of large machinery. In the second part, the author has pointed the way toward matters which still remain unsolved, and that will necessarily guide the efforts of future workers. Experience of this kind can only be obtained by close work on such important problems.

In his first section, the author has reviewed the various methods that are commonly appealed to in making balance adjustments in the field—a procedure that is continually becoming more and more necessary as machines are getting larger, and particularly more flexible.

In addition to the various methods that the author has listed for obtaining quickly the amount and position of static unbalance, the writer would like to add the following, which presents a simple way of getting phase angle from a slowing-down curve.

If we let the motion of a rotating shaft in one plane be represented by the conventional differential equation

$$M\ddot{x} + c\dot{x} + Kx = Mw^2e \sin wt \qquad [1]$$

where w = rotational frequency, the steady-state solution for the motion is

$$x = \frac{Mew^2 \sin (wt - \epsilon)}{\sqrt{(K - Mw^2)^2 + c^2w^2}} \qquad [2]$$

where

$$\tan \epsilon = \frac{cw}{K - Mw^2} \qquad [3]$$

[25] Professor of Mechanical Engineering, University of Michigan, Ann Arbor, Mich. Mem. A. S. M. E.

[26] See paper by Prof. H. Kayser in *Z.V.D.I.*, vol. 73 (1929), p. 1305.

[27] Research Department, Mechanics Section, Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa.

[28] Power Engineering Department, Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa.

[29] Research Mechanical Engineer, Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa.

ϵ is the lag angle between motion and force, and since w is rotational frequency of the shaft, ϵ is the physical angle as scribed on the shaft itself. Now from [3] it follows directly that

$$\sin \epsilon = \frac{cw}{\sqrt{(K - Mw^2)^2 + c^2w^2}} \quad [4]$$

Now, obtaining from [2] the maximum amplitudes X as a function of w, we have

$$X = \frac{Mew^2}{\sqrt{(K - Mw^2)^2 + c^2w^2}} \quad [5]$$

Combining [4] and [5],

$$\sin \epsilon = \frac{X}{w}\frac{c}{Me} \quad [6]$$

and at the critical frequency w_c, [6] becomes

$$\sin \epsilon_c = \frac{X_c}{w_c}\frac{c}{Me} \quad [7]$$

Now at $w = w_c$, $\sin \epsilon_c = 1$ from [4]. Then combining [6] and [7], we obtain

$$\sin \epsilon = \frac{X}{X_c}\frac{W_c}{c} \quad [8]$$

Thus from a slowing-down run, X_c and w_c are obtained, and at any w, X is measured on the vibrogram—this gives the phase angle ϵ of the unbalance ahead of the motion. Now if a mass m'

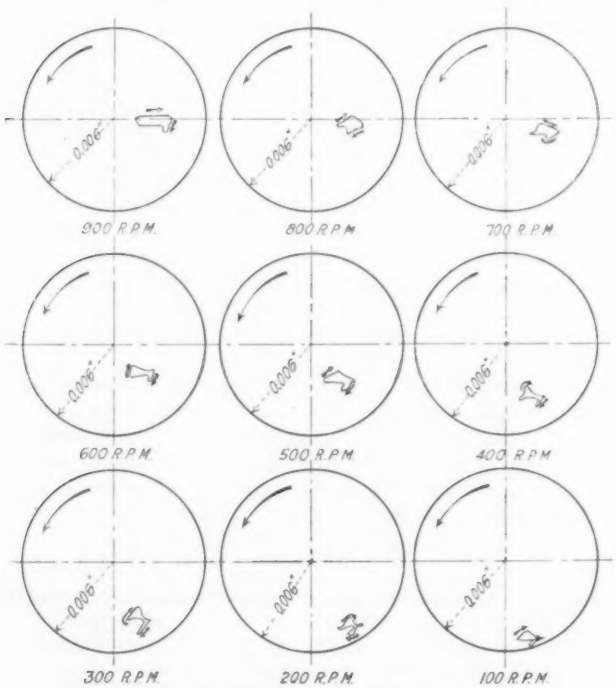

FIG. 25 EXPERIMENTAL STUDY OF SHAFT BEHAVIOR

is placed at a radius r, at the specified place, and a second run taken, we measure the amplitude at the speed w, X', we have from [5]

$$X = \frac{Mew^2}{\sqrt{(K - Mw^2)^2 + c^2w^2}} \quad [9]$$

and

$$X' = \frac{(Me - m'r)w^2}{\sqrt{(K - Mw^2)^2 + c^2w^2}} \quad [10]$$

Dividing [9] by [10] and solving for the necessary balance, as determined from the trial balance, (where $mr = Me$)

$$m = m'\left[\frac{1}{1 - \frac{X'}{X}}\right] \quad [11]$$

If m' is too large, then the correct value of weight at radius r is

$$m = m'\left[\frac{1}{1 + \frac{X}{X'}}\right] \quad [12]$$

The author's next important discussion has to do with the observation on bearing motion as affected by the vibratory condition of the rotor. In this connection, the writer made a series of very accurate experiments in 1927, studying the motion of the shaft of a two-bearing 7500-kva. 900-r.p.m. synchronous condenser. The motion was obtained to less than 0.00001 in. by very sensitive oscillographic recording of magnetic air-gap changes, and a series of pictures is shown in Fig. 25 giving the motion as a function of speed. The point the writer wishes to make in this discussion is the lack of simplicity of the motion—bearing little relation to the theoretical ellipse; the inability to determine phase relation; and further that vibrograph tests on the bearing pedestal showed quite different characteristics. This the author has also observed, but the important consequence is that balancing methods that depend on *accurately determined* values of lag angle and amplitude become difficult and often impossible.

The author's last discussion of the balancing of multiple-bearing sets presents the logical method of attack of the problem. However, the practicability of obtaining the correct combination of balances is difficult. In such combined sets, the simpler way to balance is to uncouple the parts, balance each unit separately, and then when vibration is observed in the coupled set, the cause is definitely attributable to incorrect alignment, which must then be corrected. In general, the author has emphasized the complexity of the balancing problem, when a rigorous solution is attempted.

AUTHOR'S CLOSURE

Dr. Timoshenko's suggestion that further investigation of the nature of the shaft motion itself would be desirable in the attempt to explain the continuous and progressive shifting of the phase of vibratory motion at the bearing with speed, as exhibited in Fig. 10, is quite in order. It is first necessary to differentiate between the absolute motion of the shaft in space and its net motion with respect to the bearings, as the apparent motion of the shaft is in part due to its own whirling from flexure, in part due to play in the oil film, and also very largely due to the bodily movement of the bearings. A. R. Robertson and the author have attempted to determine the amplitude and phase of the shaft motion coincident with a study of the bearing motion, and were able to derive the whirl motion of the shaft at a given point with respect to the bearing. If pendulum-type vibrometers are used, a vectorial subtraction of the shaft motion in space from the bearing motion yields the net shaft whirl as indicated in Fig. 26. Considering only the vertical (or lateral) component of motion, if s represents the amplitude and phase with respect to some datum on the rotor of the apparent shaft motion as determined by the pendulum vibrometer, and if b represents the motion at the center of

the bearing, then w, the vectorial difference, represents the net shaft motion or whirl neglecting the play in the oil film. The latter uncertainty can be eliminated by bringing the vibrometer

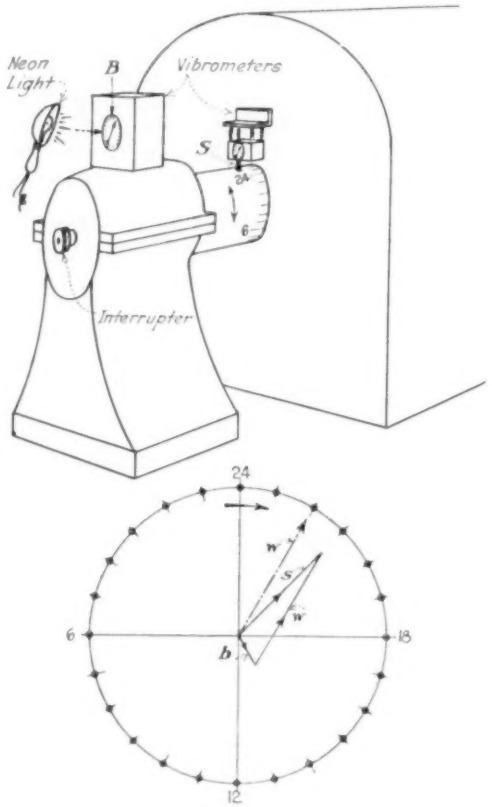

FIG. 26

b = amplitude and phase of vertical component at bearing B.
s = amplitude and phase of vertical component at shaft S.
w = vertical component of shaft whirl from flexure alone (neglecting position of other journal and play in oil film.)
NOTE: The complete paths of motion can be derived from the combination of simultaneous lateral and vertical observations at bearing and shaft.

indicator in contact with the journal itself. By a special arrangement the actual elliptical path of motion of the shaft at S can be determined, and from this the shape of the whirl due to shaft flexure alone. The data obtained by the author to date are not sufficiently complete to show just how the shaft motion follows the bearing motion throughout the speed range.

In one case the shifting of a node in the shaft itself along the axis was demonstrated for various conditions at the operating speed of 1800 r.p.m. It is proposed to extend the investigation to cover these and other points.

Some time ago, Dr. Timoshenko recommended that resonance characteristics of structures might be studied by means of an independent vibrating source, avoiding the necessity for operating the unit itself. This method appears to offer considerable advantage, as the vibrator may consist of an unbalanced motor which can be attached at various points on the structure or on the rotor itself. Although no important data have been obtained as yet, a motor-generator set driving a d.c. motor with an elaborate speed control has been secured to carry out such investigations.

With regard to the desirability of securing extreme flexibility in the turbine-generator supports, it is the author's belief that while such a system is feasible for smaller units which can be mounted on an integral and relatively stiff slab or base, with a flexible support, such an arrangement is impracticable for the larger sizes because of the difficulty in producing a continuous baseplate of sufficient rigidity. This baseplate itself in connection with the machinery masses might become resonant at the operating speed. If the various chock supports and pedestal bases are separately mounted on springs or the like, there would probably result so many simple, easy modes of vibration, each with its own critical speed, that it would be difficult to control these motions in bringing the unit to the operating speed without danger of rubs or coupling difficulties. In operation, there would exist little resistance to distortions or other disturbances, and the torque reactions would also present a problem in maintaining alignment.

To Dr. Nadai's question as to the cause of the cyclic vibration exhibited in Fig. 23, the author can state that every conceivable operating factor was investigated in the attempt to find something which could be correlated with the cycles. The only clue obtained was in the alternating nature of the vibration of the unit proper and the appended masses, consisting of the steam chest, throttle valve, and main steam line. These two systems reached their maximum and minimum vibration times about 180 deg. apart, suggesting an energy-exchange phenomenon. Such a system can be duplicated by means of a weight suspended by a spring, with means for altering the rotational moment of inertia of the weight, so that the torsional frequency can be made to agree very closely with the up-and-down frequency. If closely tuned, the bobbing motion will gradually be transformed into the purely torsional motion and so on indefinitely with a long period, as long as energy is supplied. The cyclic vibration described is very rare, and little opportunity has been available for a thorough investigation.

In reply to Mr. Donnell, the author believes that the progression of nodes and antinodes across a point of observation while running through the range of speed, accounts for the steady rotation of the phase of motion at the bearing with speed. During these tests the vibration waxed and waned in going continuously through the speed range apparently in some relation to the phase changes. These changes occur no matter where the vibrometers are located on the bearing, although the phase and rate may differ.

The question Mr. Rose asked concerning the motion of the shaft is answered in the reply to Dr. Timoshenko. Regarding the possibility of compound flexure in rotors, it was found necessary to balance out any appreciable static unbalance in the older long, double-flow spindles by applying the correction near the center, because of the deflections set up when concentrating weights at the ends of the spindle body. In fact, many of these spindles were provided with an extra balancing ring near the middle position. The later, solid types of spindles are sufficiently rigid to permit complete correction at the ends. Most of the static deflection occurs between the ends of the body and the journals. As the rotating elements become longer, however, the possibility of appreciable compound flexure must be kept in mind.

Mr. Stone's method of obtaining the value of phase angle from data obtained while the rotor is slowing down, is an interesting addition to the subject-matter, as it attacks the problem from a different angle and employs the fundamental concept of forced vibration of an ideal system. In 1923 the author carried out rather unsatisfactory experiments along these lines, in the attempt to determine the lag angle through observations at various speeds.

The equation of motion as stated specifies damping directly proportional to velocity. Although this assumption is known to be incorrect for mechanical vibratory systems, the discrepancy is probably small, and the solution for the equation is simple, leading to the following expression for the phase angle (using Mr. Stone's notations):

$$\tan \epsilon = \frac{C\omega}{K - M\omega^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [13]$$

If it is assumed that the damping factor C, the elastic restoring factor K, and the inertia factor M remain constant, then the phase angle ϵ can be defined in terms of the speed ω. In the actual experiments, two things were determined: the speed and the corresponding "high spot" scribed on the shaft (or point in path of motion of bearing with relation to a datum on rotor).

In Fig. 27 the angular locations of the high spots found at three different speeds ω_0, ω_1 and ω_2 are indicated. The angles α and β are directly observed. The actual lag angle ϵ_0 between the initial high spot at speed ω_0 and the force P is unknown and is to be determined. As we are not interested in the absolute values of the damping, elastic, and inertia factors, the expressions for the phase angles at the three speeds may be set down:

$$\left\{\begin{aligned} \tan \epsilon_0 &= \frac{\omega_0}{\frac{K}{C} - \frac{M}{C}\omega_0^2} \\ \tan (\epsilon_0 + \alpha) &= \frac{\omega_1}{\frac{K}{C} - \frac{M}{C}\omega_1^2} \\ \tan (\epsilon_0 + \beta) &= \frac{\omega_2}{\frac{K}{C} - \frac{M}{C}\omega_2^2} \end{aligned}\right.$$

from which the ratios $\frac{K}{C}$ and $\frac{M}{C}$ may be eliminated and ϵ_0 determined.

Such methods, however, generally break down on any but elementary ideal systems. It was for this reason that the author was led to develop the unit vector method proposed in this paper which is applicable to the more complex systems encountered in practice.

Mr. Stone's experiments on the 7500-kva. condenser are most instructive in showing the gradual shift of the journal position and change in the oil film as the speed is varied. The shaft whirl indicated is between $1^1/_2$ and 2 mils, which may be considered insignificant for speed of 900 r.p.m. and below. Further improvement in balance would hardly appear necessary.

The superimposed erratic motions of a quarter of a mil or less are to be expected under the conditions described, and especially where the total motion is so small. When the practical difficulty of maintaining shaft roundness to within a quarter of a mil is appreciated, it becomes a question whether the ripples disclosed by apparatus recording to the hundredth of a mil are due to the surface irregularities or to actual shaft motion. It is also necessary to insure that such records do not indicate changes in the magnetic characteristics of the shaft periphery rather than changes in the air gap or displacement. The data observed in this isolated case may not be used as a basis for generalizing on conditions to be found in practice on all types of units.

The motion of the bearing pedestal is generally much more consistent and reliable than that of the shaft, and after all, the sum total of the disturbances to the installation must be transmitted via the bearings. In all but two cases, the author has encountered fairly uniform elliptical motion, sufficiently undistorted to permit repeated checks on phase points to within a few degrees. This is a statement of actual experience on eight large units, which may be considered representative. The distorted motions observed in the excepted cases were found to have been due to impactive disturbances between bearing and pedestal, or bearing housing and its seat, and actually furnished the clue to this condition. In such cases the mechanical difficulty should be corrected before any balancing process is attempted. This brings up the point that the proposed balancing process has an indirect value in disclosing conditions which are not due to simple unbalance, thereby indicating that investigation should be directed elsewhere.

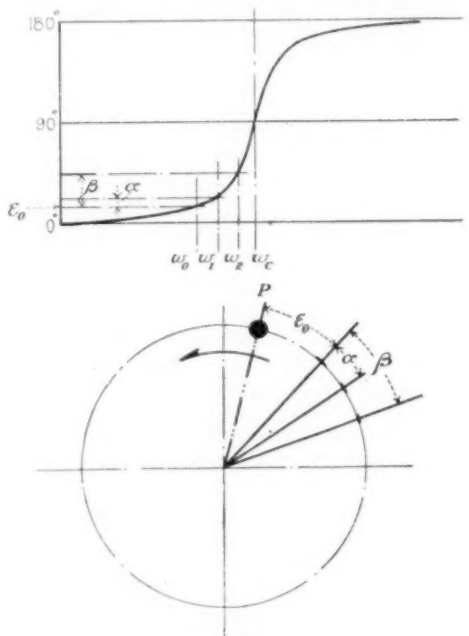

FIG. 27

The solution of the unbalance in the three- or four-bearing units by the proposed method is not so formidable as it may appear, as an inspection of the unit vector table should suggest at once the most advantageous sequence of graphic trials. On small, simple machines it is naturally in order to balance the two rotors individually. Unfortunately, this procedure is generally out of the question for large turbine-generator units in the central station, first, because it is rarely practical to take a second large unit out of service to bring up the generator field synchronously, and secondly, because of the desirability of balancing under normal load conditions at stabilized temperatures.

It has not been the author's intention to convey a too pessimistic impression of the complexities encountered, but rather to indicate that with improved methods of observation and better knowledge of the agencies at work, turbine operating difficulties are being more readily overcome.

Stress Distribution and Hysteresis Losses in Springs

Progress Report No. 4 of the A.S.M.E. Special Research Committe on Mechanical Springs (Technological)

By M. F. SAYRE[1] and ANTHONY HOADLEY,[2] SCHENECTADY, N. Y.

The present report covers the first year of investigations carried on by the Committee at Union College, Schenectady, New York. The purpose of these investigations is to examine more closely than heretofore the fundamental characteristics of spring action in order that more reliable constants for a code of design on mechanical springs (see Bibliography, No. 18) might ultimately be established. The experiments were conducted by Anthony Hoadley under the direct supervision of M. F. Sayre. Certain of the results were covered in Progress Report No. 3, which report was not published. It should be considered as a progress report, in that, while a number of valuable results have been obtained, the field opened up is so wide that much of the work must be considered as preliminary only.

Particular points of interest are: (1) A study of distribution of stresses in bending in spring steel, at the very high unit stresses often used in practice. This has practical importance in furnishing a partial explanation of the large discrepancy between theory and practice as to allowable unit stresses, in furnishing a theoretical guide as to the amount of recoil to be expected when winding a spring about a mandrel of a given size, and in determining the effect of the initial stresses induced in a spring during the winding operation, upon the future behavior of the spring. (2) A comparison of proportional limit and of modulus of elasticity for the same material in bending and in tension at high and at low stresses, both in virgin condition and after a cyclical state has been reached. This has a possible importance in determining what weight should be attached to tensile tests in measuring the suitability of a proposed spring material. It also was done in order to investigate certain theoretical and practical discrepancies between properties in bending and tension. (3) A study of the comparative internal friction in spring material in bending and in tension, for varying stress ranges, up to very high loads. This has a bearing in its effect on the possible accuracy of spring-controlled measuring instruments, and a smaller bearing on the energy losses in power springs. It is also highly desirable to know accurately how this internal friction or hysteresis varies with the load range and the position of the load range in order to determine what relation may exist between it and both the proportional limit and the fatigue limit of the material, as governing allowable safe loads. An unexpected result of the investigation is that the hysteresis in tension was found to be far less in proportion to that in bending than was expected. This result should be considered as tentative only. Every effort is being made to discover any instrumental defects which may have contributed to this result, and lacking this, to find satisfactory theoretical reasons.

COMMON assumptions in engineering work are that all stresses dealt with are below the proportional limit of the material used, and that the distortions of the structure are of negligible magnitude. Both these assumptions are of doubtful validity in spring design. As a result, independently of the problems involved in the manufacture, selection, or protection of the spring material, many problems arise, which of course are of varying importance in different cases. Some of these problems are:

1 What is the effect upon true stress distribution in the metal of using working stresses which exceed the proportional limit of the material, and may approach the yield point?

2 During the manufacture of springs, internal stresses are introduced (*a*) during cold rolling or drawing, and (*b*) during cold shaping or coiling. How great are these initial stresses, and how much effect do they have upon the behavior of the spring after loading? Do these initial stresses make matters worse, or can they be so placed as to partly counterbalance the effect of the working stresses? How much effect, quantitatively, do they have?

3 Internal friction in the material operates to lower the accuracy of a spring as a measuring device, and to decrease its efficiency as a tool for storing up power for later use. What laws govern this hysteresis? Does the law of hysteresis variation in any way correlate with the fatigue limit of the material? Is this wasted energy in any way being used to gradually break the strength of the material?[3]

4 Springs distort sufficiently under loading so that the changes in shape are often not of inappreciable magnitude. What effect do these changes produce (*a*) directly, as through changes in load lever arms, and (*b*) indirectly, by causing secondary stresses? Can customary formulas be modified to care for these effects?

5 Natural frequency, particularly as it may cause resonance, often is an important factor. What is the natural frequency of springs of various types? What factors may affect natural frequency? What secondary vibrations exist?

Theoretical and practical studies have been made during the past year in an endeavor to open up an approach to the first three problems outlined. Attention has been concentrated on bending behavior rather than on torsional behavior, as a simpler problem and one present in practically all springs, even in helical springs under tension or compression, where the initial internal stresses due to the process of coiling are of importance. Some preliminary work on torsional theory has been done to lay a foundation for a future program. Tensile behavior has been studied as a necessary part of the program.

The experimental problems have not been entirely simple. The elastic changes in shape of a metal, particularly in tension or compression, are themselves small. Much of the work done has required the measurement of slight discrepancies in this elastic behavior of the order of magnitude of 0.00001 in., and so calling for the highest available degree of precision, with repetition of work to allow for elimination of erratic results and for use of average values. As a logical method of attack, one typical material was selected and its behavior studied in detail, with a view to later inclusion of other materials.

The material selected for the initial tensile and bend tests

Presented at the Annual Meeting, New York, N. Y., December 3 to 7, 1928, of The American Society of Mechanical Engineers.

[3] As a side issue also arises the question of external friction, both air friction and rubbing friction, in power springs and such springs as hair springs, which are constantly in motion. How great is this friction and how may it be reduced?

was a $^1/_2$-in. by $^1/_8$-in. oil-tempered wire. By using a fairly large size, the difficulties in determining the cross-section are made smaller. The flat shape was chosen so that as large a proportion of the material as possible should reach the proportional limit in bending at the same time.

The manufacturer states that the wire had gone through the following processes:

A tempered annealed rod $^1/_2$ in. × 0.162 in. is rolled and straightened and then lead-annealed at 0.160 in., rolled to 0.147 in., then to 0.140 in., lead-annealed at this stage, and then rolled successively to 0.135, 0.130, and 0.125 in.

In hardening and tempering this wire, the furnace for heating is at 1550 deg. fahr. and the temperature of the tempering furnace is 900 deg. fahr.

The analysis of this material is as follows:

Carbon	0.68 per cent
Manganese	0.67 per cent
Sulphur	0.046 per cent
Phosphorus	0.036 per cent
Silicon	0.201 per cent

The hardness numbers obtained were:

Shore	51.7
Brinell	374
Rockwell	C 39-C 40 (manufacturer's figures.)

The body of the report is divided into three sections: a statement of tension methods and results, followed by results of bend tests, and that in turn followed by a summary.

Physical Properties in Tension

This section of the work included the usual tensile tests,

carried to rupture. These were followed by an extended study of elastic behavior and of hysteresis for various maximum stresses, taking stress-strain curves with ascending and descending loads for a number of successive loads until cyclical conditions had been approached. The stress ranges studied and the results obtained are indicated in Tables 1 and 2.

Apparatus. The bars were tested in a machine of the hydraulic type which had been calibrated a short time before the tensile tests were made. The machine showed an error of not over one-sixth of one per cent over nearly its full range.

The extensometer used for most of the work was one of the mirror type developed by one of the authors.[4] The extensometer automatically averaged the elongations on both sides of the test bar. One division on the extensometer scale indicated a unit elongation of 0.00001 in. per in. An Olsen extensometer equipped with a "last word" dial on which one division corresponded to a unit strain of 0.00005 in. per in. was used in conjunction with a Riehlé electrical contact extensometer on the ultimate load tests and in conjunction with the mirror extensometer on some of the hysteresis loops.

The mirror extensometer was calibrated by taking a run on a previously calibrated bar. The mirror and Olsen extensometers were then both attached to a comparison bar with a 10-in. gage length. Simultaneous readings were taken on both extensometers during a load cycle so that their calibrations could be compared.

In the straight tension tests both the Olsen and Riehlé extensometers were attached to the bar at the same time. An initial load of 250 lb. (or 4200 lb. per sq. in.) was used, and readings were taken on both instruments or on only the Olsen up to the yield point. As its full range had been used in going to this point, the Olsen extensometer was then removed. Below the yield point the load was held constant while each reading was taken, but above this point the load was continually increased to the maximum, extensometer readings being taken "on the run."

The mirror extensometer was used in taking a majority of the hysteresis loops. The cycles were run between a stress of 4200 lb. per sq. in. and the maximum. The load increments were taken so that there would be 11 or 12 readings on each side of the loop. Readings were usually taken on the first, second, third, eighth, and eighteenth load cycles. Where the permanent set was likely to be large in the first few cycles, the Olsen extensometer would be used as it had a larger range than the mirror extensometer. When shifting from one instrument to the other, consecutive cycles, such as the third and fourth, or eighth and ninth, would be taken, using first the Olsen and then the mirror extensometer. The extensometers were left on the bar during the load cycles in which no readings were taken. It took about 9 min. to take readings on a complete cycle, and when readings were not taken, the load was applied at such a rate that a load cycle would be completed in 1.5 min.

Results. The tension tests showed characteristically, on first loading the specimen, an initial proportional limit of 80,000 to 126,000 lb. per sq. in., with a mean value of 103,000 lb. per sq. in. The modulus of elasticity up to this proportional limit ranged from 28.7 to 30.2 × 10^6 lb. per sq. in., with an average of 29.6 × 10^6 lb. per sq. in.

Above this initial proportional limit there was but a slight change in slope of the stress-strain curve, with usually a second straight portion of the curve with a slope indicating an apparent modulus of elasticity (for that portion of the curve only) averaging 26.8 × 10^6 and ranging from 25.2 to 29 × 10^6 lb. per sq. in. An "upper proportional limit" at the upper end of this second straight line came at 133,000 to 165,000 lb. per sq. in., averaging 144,000 lb.

This secondary straight portion of the stress-strain curve occurred so consistently in these tension tests that it seemed advisable to give throughout values for both the lower or true proportional limit, and of the upper pseudo-proportional limit.

[4] For a description of this extensometer see Proc. A.S.T.M., vol. 26, part 2, p. 660.

Extensometer readings were taken to a precision of 0.00001 in. per in. or better, so that the proportional limit as commercially determined would lie between the two apparent proportional limits as just given.

The yield point came at 175,000 lb. per sq. in., and varied but little in different bars. The ultimate strength ranged from 197,000 to 199,000 lb. per sq. in.

TABLE 3 TENSION-TEST SUMMARY

(Bars as received)

	Range	Average
Lower proportional limit (l.p.l.)	80–126,000	103,500
Upper proportional limit (u.p.l.)	133–165,000	144,000
Yield point		175,000
Modulus of elasticity below l.p.l.	28.7–30.2	29.6
Modulus of elasticity between l.p.l. and u.p.l.	25.2–29.0	26.8
Ultimate strength	197–199,000	198,700
Percentage of elongation in 2 in.:		
Including break	9.5–11	10.3
Adjacent to break	4–5	4.9

Table 3 summarizes the results of the tension tests. Yield-point, elongation, and ultimate-strength values are based on the tests of six bars. The other figures are based on tests of ten bars.

One erratic bar showed a lower virgin proportional limit of 67,000, with a second break in the curve at 117,000 lb. per sq. in.

Extensometer readings were taken at 175,000 and 180,000 lb. per sq. in. If a reading had been taken between these values it might have justified the reporting of a slightly higher yield point. The stress-strain diagrams were plotted to such a scale that below the proportional limit they make an angle of 55 deg. with the horizontal. The line between 175,000 and 180,000 lb. per sq. in. makes an angle of 5 deg. with the horizontal, so that there is a definite break in the line at 175,000 lb. per sq. in.

The fractures were about evenly divided between the cup and shearing types. When looking at the edge of the bar, the shearing fracture made an angle of about 45 deg. with the longitudinal axis of the bar. Both types of fracture showed comparatively smooth surfaces with a fine grain.

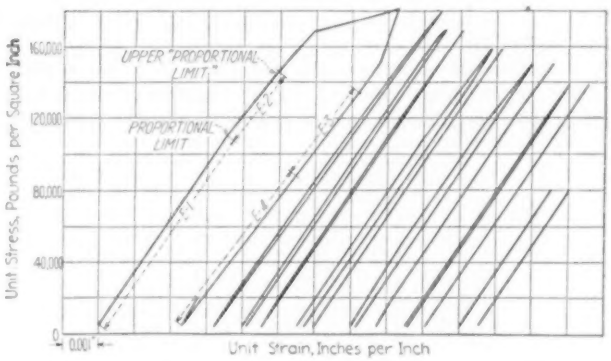

FIG. 3 INITIAL AND CYCLICAL LOOPS FOR BARS TESTED AT DIFFERENT MAXIMUM STRESSES

(The first loop of each pair is the initial one; the second cyclical.)

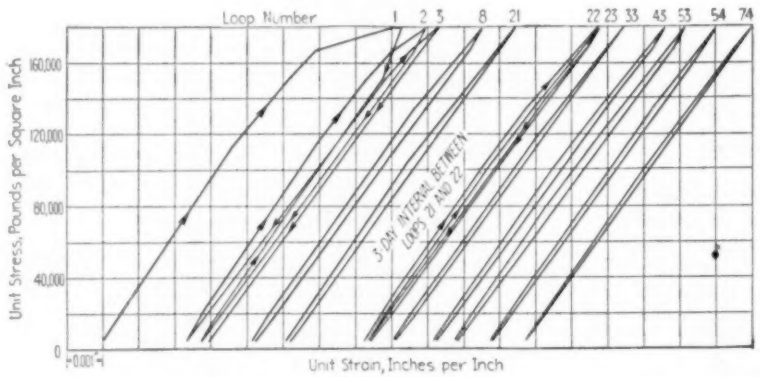

FIG. 1 SUCCESSIVE TENSILE HYSTERESIS LOOPS ON ONE BAR

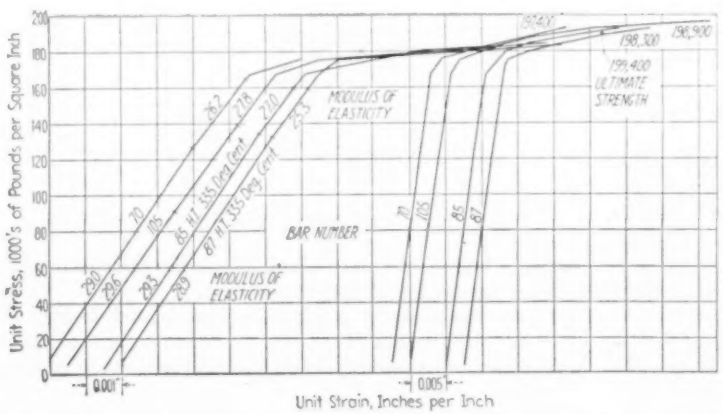

FIG. 2 TENSILE STRESS-STRAIN DIAGRAMS FOR SPRING STEEL. BARS NOS. 70 AND 105 AS RECEIVED; BARS NOS. 85 AND 87 AFTER SLOW ANNEAL FROM 335 DEG. CENT.

For the spring designer a knowledge of the condition of the material after it has reached a cyclical state, under varying loading, is probably at least as important as a knowledge of its behavior when first loaded. A particularly important problem in view of the high stresses which it is desirable to use in spring design is the effect upon elastic properties of repeated operation at stresses well above the proportional limit, approaching or exceeding the yield point. For this reason a large number of tests were made in tension, using varying maximum loads repeatedly applied, and taking accurate stress-strain curves for the initial loading and unloading cycle, and for successive cycles at intervals until a cyclical state had apparently been approached. Typical curves for successive runs on a single bar are shown in Fig. 1, and initial and final curves on different bars for various maximum stresses in Fig. 3. As indicated by these curves, the main part of the hysteresis loop consists of several straight lines, ordinarily two on the ascending and two on the descending segment, with shorter straight or curved lines connecting them at top and bottom. The two ascending segments in cyclical state are much more nearly parallel than for the initial loading, as would be expected, and it is somewhat uncertain whether the upper or lower break in the curve should be given as the true proportional limit. Both values are given in Tables 1 and 2.

It will be noticed that the lower proportional limit in the cyclical state is somewhat higher than for the initial loop, but that the upper proportional limit is usually the same. *E*-1, *E*-2, *E*-3, and *E*-4 are values of the modulus of elasticity corresponding to various parts of the loop, as indicated in Fig. 3.

The above values of the modulus of elasticity show the gradual changes that take place, but for purposes of computation or comparison a median value will ordinarily be more useful. For

this purpose a straight line has been drawn connecting the upper and lower ends of the loop, and its slope chosen as a median value of E. This median line is ordinarily closer to the descending than to the ascending side of the loop. The average value of the modulus of elasticity as given by this method is 29,700,000 lb. per sq. in.

Values of the hysteresis loss per cycle, in inch-pounds per cubic inch, have been plotted against maximum stress in Fig. 4. Below maximum unit stresses of 160,000 lb. per sq. in. the energy

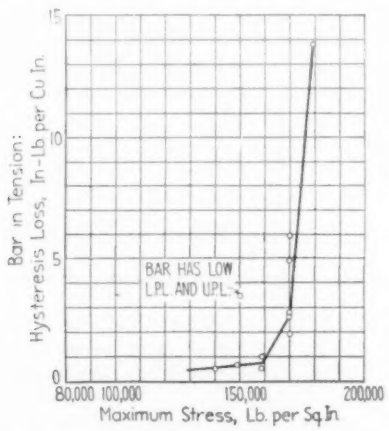

FIG. 4 LOSS OF ENERGY IN TENSILE HYSTERESIS

loss is extremely small, and corresponds to a mean width of loop of 0.000005 in. per in. or less. A sharp increase begins at 160,000 lb. per sq. in. This value lies between the upper proportional limit and the yield point of the material. These values are also plotted to logarithmic scale in Fig. 15. At 160,000 lb. per sq. in. the energy loss represents one-quarter of one per cent of the total elastic energy of the bar.

One particular bar gave erratic results. It showed a lower proportional limit of 67,000 on the initial loop and 56,000 after 21 runs at 150,000 lb. per sq. in. maximum load, both very much lower than for any other bar. Accompanying this low proportional limit was a relatively high hysteresis loss, reaching 3.5 in-lb. per cu. in., about six times the amount which would be expected based on the other bars tested.

The energy loss per cycle, for successive cycles on the same bar, is plotted in Fig. 6.

Most of the permanent set takes place in the first three cycles, so that after the third cycle the rate of energy loss greatly decreases. The first number after each curve is the serial number of the bar, and the second gives the maximum stress in thousands of pounds per square inch. After having partially attained a cyclical state, bar 94 had a three-day rest, and in that period it lost part of the effect of the cycles that had been run on it as shown by the large increase in loss of energy after the rest period. A loss of energy of 1 in-lb. per cu. in. represents a loop width of only 0.000006 in. when the maximum stress is 160,000 lb. per sq. in., so that the lower values on the curves cannot be expected to be very exact.

The tension-test bars were not run through as many cycles as the bend-test bars due to time limitations, and were probably not as near to the cyclical state. At the higher loads, where the maximum loop width would be 0.00005 in. or more, the set per inch in the last cycle might be 0.000005 in. to 0.00001 in. In the bend tests cycles were run until the last ten cycles showed a set in deflection of 0.0002 in., which corresponded to a set in the extreme fiber of 0.000001 in. per in., or from a fifth to a tenth of that obtained in the tension test.

One great difficulty in obtaining satisfactory hysteresis curves lies in the pseudo-hysteresis due to backlash in the extensometer used. This probably accounts for the sharp drop in energy loss in three of the bars after cycle 8, at which point a change in extensometers was made. All the other curves were made using the mirror extensometer. Calibration runs indicated that backlash with this extensometer was extremely small.[5]

BEHAVIOR IN BENDING

There are a number of factors entirely aside from the relatively simple features of the usual elastic theory of bending, which render the behavior of a material in bending much more complex than that of the same material in tension.

1 The elastic theory ceases to be valid as soon as stresses at any point pass the elastic limit. Furthermore, such initial overstressing, as in cold coiling a spring, introduces internal stresses in the metal and affects stress distribution for any future loading.

2 The side of the bar which is in compression tends to expand laterally, and the side in tension to contract, thus intro-

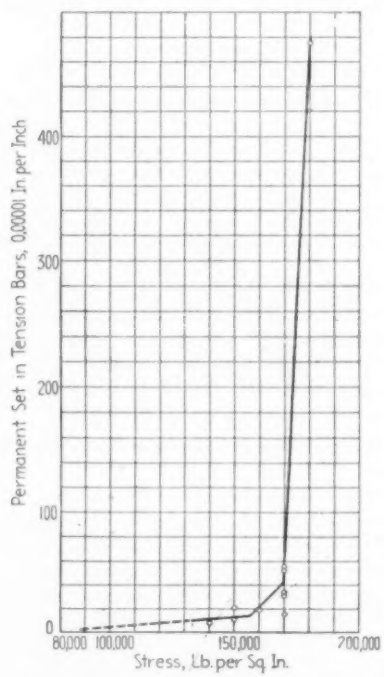

FIG. 5 PERMANENT SET AT CYCLICAL STATE IN TENSION

ducing a lateral curvature which affects the stresses in the bar and its apparent modulus of elasticity.

3 Bending moment is generally not uniform in magnitude over the entire length of the bar. As a result, stresses are also not uniform over the length and the yield point may be reached

[5] The amount of this backlash was estimated from several pairs of loops as follows:

Bar	Max. stress	Hysteresis areas, in-lb. per cu. in. Extensometer No. (1)	(2)	Difference between (1) and (2)	Equivalent backlash on 2-in. gage length
96	170,000	17	5.4	11.6	0.000136
95	170,000	14.6	3.8	10.8	0.000128
94	180,000	31.5	25.0	6.5	0.000076
121	170,000	16.7	3.9	12.8	0.000150

The two calibration runs which were subsequently made, with both instruments simultaneously on the same bar, indicated a backlash of 0.00018 and 0.00022 in. for extensometer (1) and zero for extensometer (2). The above table shows that the backlash can entirely hide the actual hysteresis value.

at certain places while others are still lightly stressed. Simultaneously, horizontal and vertical shearing stresses come into play, which modify the apparent stiffness of the bar.

These factors have of course been investigated in the past.[6] The results of much of the work done in England and Germany are not readily available, and consequently are not well known in this country; and apparently very little work has been done toward the direct application of these results in spring design. For these reasons both theoretical investigation and experimental work seemed necessary, and a start has accordingly been made.

The experimental work done to date has included studies of values of the proportional limit and of the modulus of elasticity on first loading, for comparison with corresponding tensile values; studies of the amount of recoil after overstressing, as an aid in determining the magnitude of internal stresses; of the rate at which the bars approach cyclical conditions when repeatedly loaded; and of values of hysteresis in cyclical conditions for ranges of stress from zero to a maximum value P, from zero to $^1/_2\,P$, from $^1/_4\,P$ to $^3/_4\,P$, and from $^1/_2\,P$ to P, for various values of P.

So far as could be discovered, the procedure employed in previous investigations of bending behavior had been to treat the test specimen either as a cantilever or else as a simply supported beam centrally loaded. In each case the bending moment varies over the length of the beam from zero to a maximum. Neither one even approximates the condition of uniform stressing present in most springs, whether laminated springs, power springs, or helical springs in bending. There are three other major objections: In the first place, when the test bar is loaded as a cantilever the bending moment varies along the length of the bar, and the material near the fixed end will be stressed to failure before the material near the load is even moderately stressed. In the second place, the presence of a shearing force leads to complications in computing the residual stresses in the bar after the outer fibers have been overstrained in bending. And the third reason is that the high local stresses at the jaw of the clamping device will have a considerable effect on the ultimate strength shown by the test specimen. Much better results can be obtained by so loading the bar that it is subjected to uniform bending over its entire length. This eliminates horizontal shearing stresses, and equalizes the tensile and compressive stresses so that the outside fibers over the entire length of the bar reach the proportional limit simultaneously. This condition of uniform bending moment can be obtained over the central section of a specimen by supporting it as a simple beam and loading it with two symmetrically placed equal loads. Except for unduly thick bars, however, the deflections will be very large before the proportional limit of the material is reached, and to allow them to take place the end supports will have to be on rollers. However, even if the details of this arrangement could be worked out satisfactorily, there would be a longitudinal tension in the beam due to its slope at the end supports.

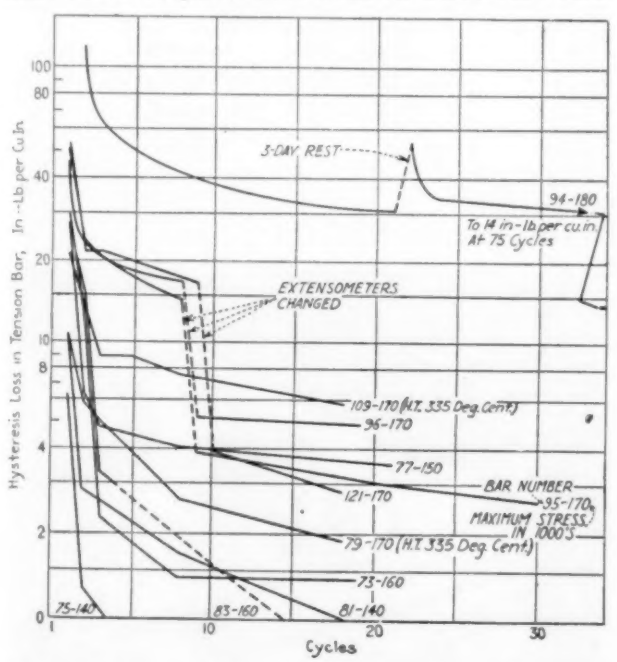

FIG. 6 INFLUENCE OF STRESS REPETITION ON TENSILE HYSTERESIS

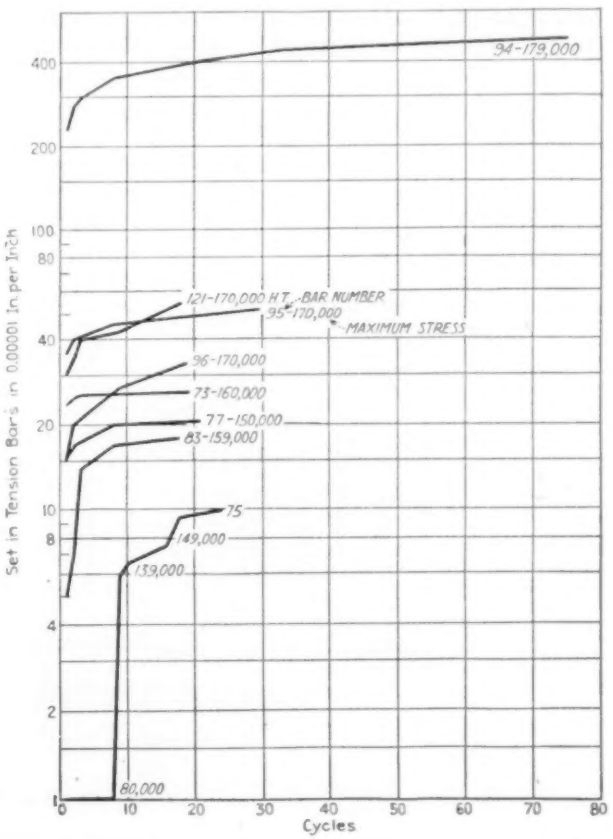

FIG. 7 INFLUENCE OF STRESS REPETITION ON TENSILE SET

It is believed that the difficulties already mentioned have been essentially avoided in the device actually used. In this the bar is clamped between hardened steel blocks at one end. At the other end, instead of applying a single load and compelling the bar to act as a cantilever, a torque or bending moment is applied. This is composed of two equal parallel forces, acting in opposite directions at points 180 deg. apart on the edge of a disk 6 in. in diameter. Fig. 8 gives details of the apparatus as originally built, while Figs. 9 and 10 show the apparatus with later modifications.

The method used is believed to be new, and naturally a number of details had to be carefully worked out. Parallelism of the cords which applied the loads was secured by carrying them over pulleys on a radius arm which could be adjusted by hand as desired. To reduce friction to a minimum, the pulleys used

[6] See Bibliography at end of report.

were supported on carefully made ball bearings. Difficulty was experienced at first in finding a cord which was at the same time sufficiently strong and sufficiently flexible. This was finally overcome by using two strands of 50-lb.-test braided silk line. Vertical load on the test bar was avoided by supporting the torque disk from the ceiling, using a carefully balanced counterweight.

The depth gages and micrometer heads by which the deflections were measured were attached to a section of $^5/_8$-in.-square

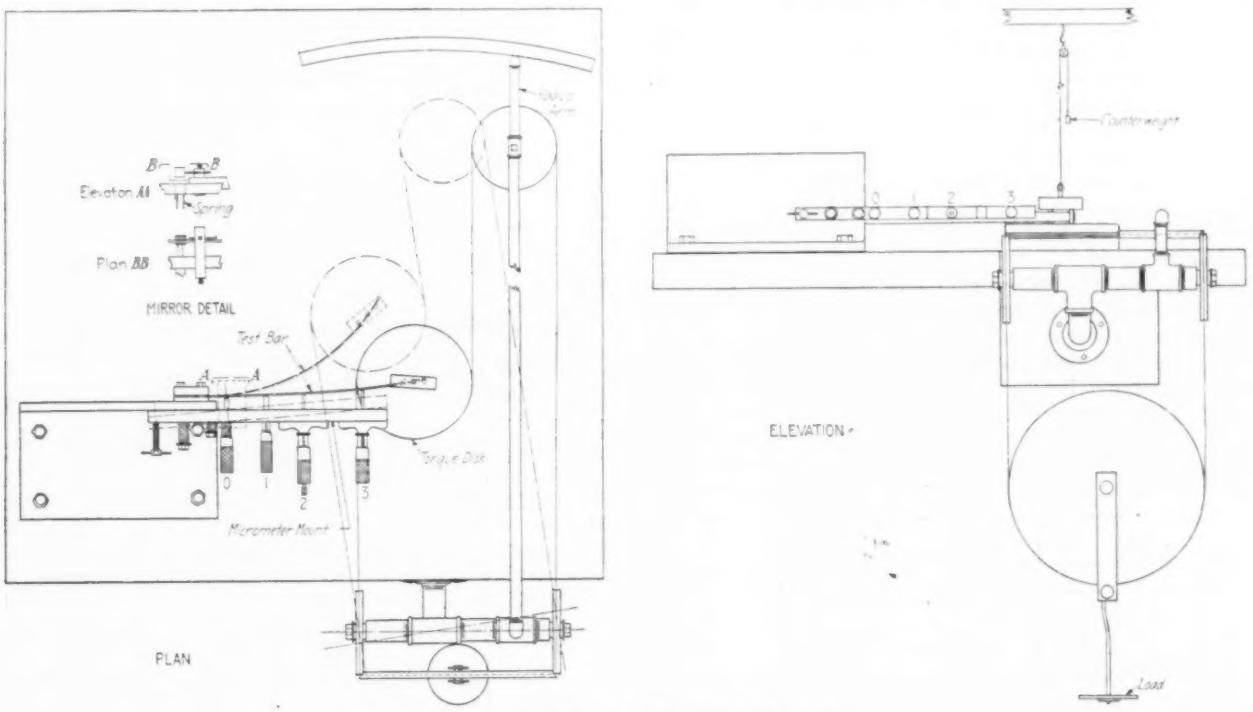

FIG. 8 DIAGRAM OF BEND-TEST APPARATUS

steel bar. These measuring instruments read directly to 0.001 in. and by estimation to 0.0001 in. The center line of the micrometer mount was in the same horizontal plane as the center line of the test bar. It can be seen in the photograph of the bend-test apparatus that the left end of the micrometer mount rests on top of the fixed block and is separated from the part of the mount carrying the gages by a spacer. The spacer also acts as an insulator between the two parts of the micrometer mount. The micrometer mount was pivoted about a $^1/_4$-in. vertical pin which was placed in the fixed block as near as possible to the point at which the test bar enters the clamping block. The micrometer mount can be rotated about this pin by means of a tangent screw located at the left end—the end farthest from the torque disk—of the mount, so that it is parallel to the test bar in its initial position.

Under ideal conditions the test bar, originally perfectly straight and free from irregularities in cross-section and from internal stresses, would be held in a perfectly fixed condition at point C of Fig. 11. The bar will be bent into a circular arc CA. The radius of curvature R can be determined from the deflection if the base distance B is known:

$$R = \frac{B^2}{2D} + \frac{D}{2}$$

Actually difficulty is caused by a slight yield at the clamping block (point B of Fig. 12). This shift does not affect the radius of curvature to which the bar is bent for a given load. It does, however, shift the location of the point at which the circular arc (prolonged if necessary) becomes tangent to a line parallel to the original position of the test bar. By measuring the deflections to three points on the test bar, the location of this point of tangency could be obtained, as explained more fully in Appendix No 2. Sixteen computations for the location of the point of tangency showed h (Fig. 12) to have a mean value of 0.146 in., varying within a maximum range of from 0.091 in. to 0.220

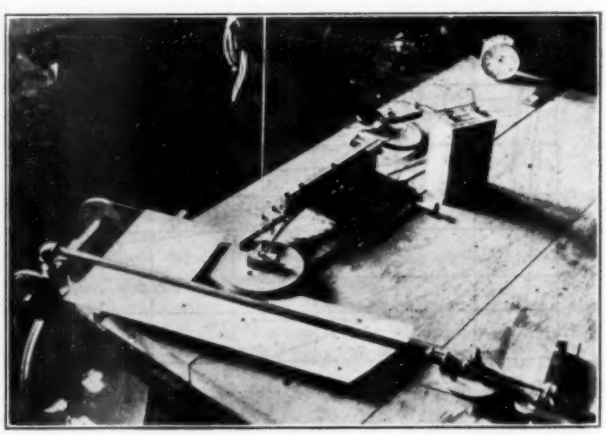

FIG. 9 PHOTOGRAPH OF BEND-TEST APPARATUS

in., and $R-k$ to have a mean value of 0.0014 in., within the range 0 to 0.003 in. In other words, the effective position of the point of tangency was not at the face of the hardened steel clamps, but was in from the face a distance averaging slightly greater than the thickness of the test specimen.

A study was made of various methods of overcoming errors due to this factor. One method used was to support a mirror

on the test specimen next to the clamp, and a second mirror on the micrometer mount. By using a telescope, and sighting on these mirrors, the micrometer mount was adjusted initially parallel to the test specimen. After each load increment on the specimen, the micrometer mount was so adjusted as to keep the mirrors parallel. It was found that settings could be duplicated so that micrometer readings checked within 0.0005 in. This method was used particularly during the preliminary runs, before the clamping blocks had been improved in form. A second method was to adjust the micrometer mount parallel to the test specimen initially, and thereafter keep it fixed in position, taking micrometer readings of the specimen at four points along the bar. These readings were used to compute the actual position of the point of effective tangency, this position in turn being used when computing the proportional limit and modulus of elasticity. After a time sufficient data were obtained to justify the use of mean values for the position of the point of tangency. This

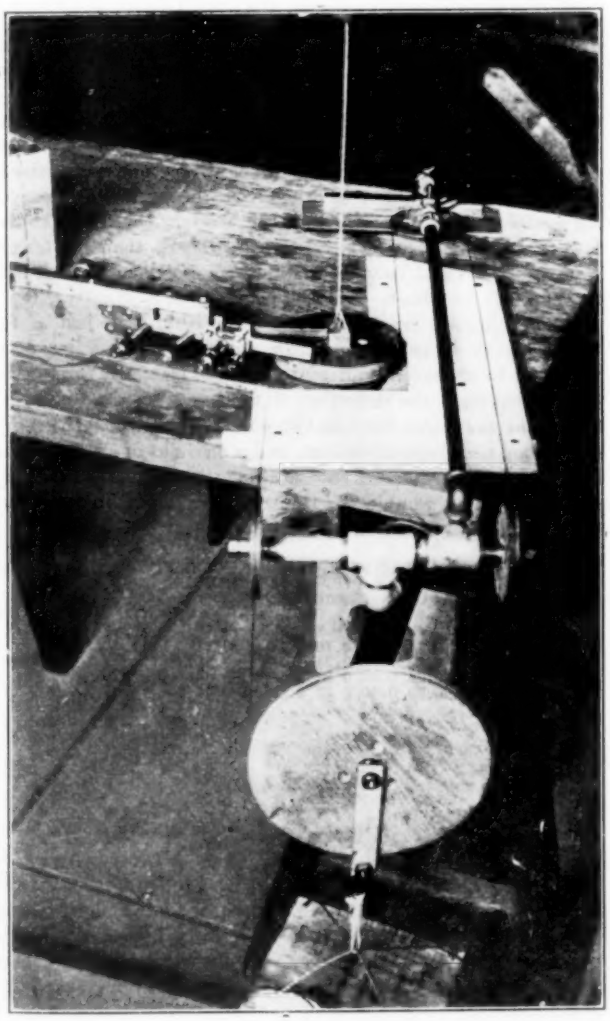

Fig. 10 Another View of Apparatus Shown in Fig. 9

accelerated the experimental work very much, as it was then necessary to take micrometer readings at only one point on the bar for each loading, and a large amount of laborious computation was avoided.

The resultant error in hysteresis loss and in proportional limit can be shown to be well within the range of other probable errors. Individual values of the modulus of elasticity may be affected by ± 2 per cent through uncertainty as to the exact position of this point of effective tangency, while the error of the mean value of several runs would be negligible. An effort was made

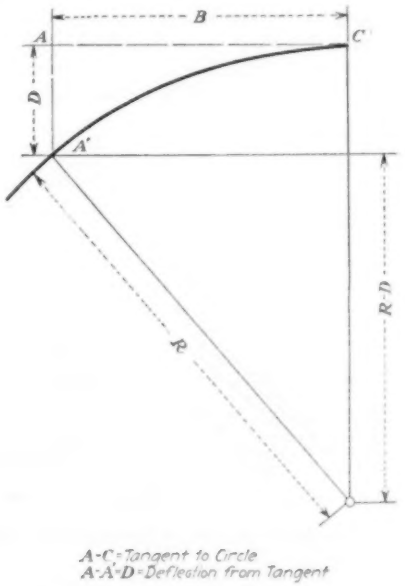

Fig. 11 Elements of Circular Arc

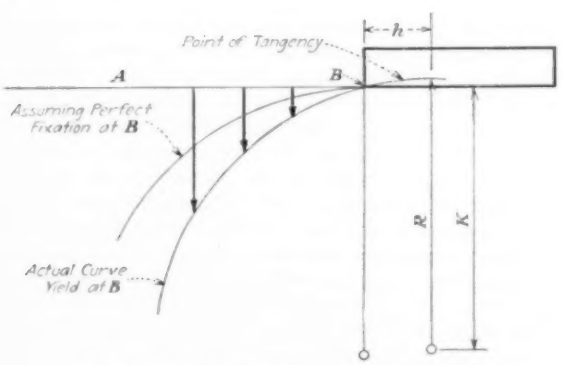

Fig. 12 Position of Point of Tangency

to correlate this variation in point of effective tangency with other factors, but it was apparently independent of the magnitude of load applied, being governed more by slight variations in the shape of the bar itself and in the way the clamping plates were tightened.

Operation of Bend-Test Apparatus

Before carrying out the bend-test experiments it was necessary to adjust the micrometer mount so that it was parallel to the face of the fixed block to which the test bar was clamped, and to measure the distances from the points from which the deflections were measured to the edge of the clamping block. This latter point, as has been previously pointed out, was very nearly the point of tangency.

A straight steel bar was supported by wooden blocks in the position to be later occupied by the test bars, and clamped against the vertical face of the fixed block. The leg of a 12-in. micrometer caliper was used for this purpose as it was straight and stiff enough to eliminate the possibility of any lateral displacement. The micrometer mount was adjusted by means of the

tangent screw until it was parallel to the straight bar, measuring the distance between the micrometer mount and straight bar with Johansson gage blocks. Micrometer readings were taken and these values later used as the "zero" readings.

The distance between the depth-gage rods and micrometer-head spindles and the distance between the first micrometer head and the clamping block were measured with gage blocks. From these dimensions and the diameters of the rods and spindles the distances between the edge of the clamping block and the

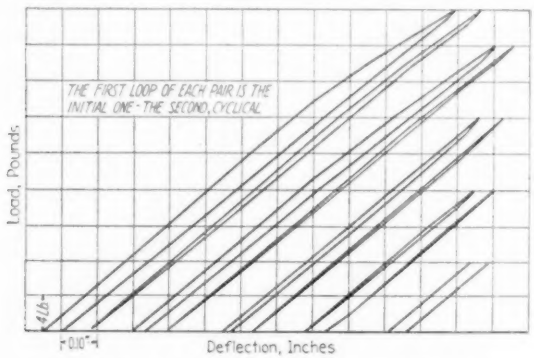

FIG. 13 FLEXURAL LOAD-DEFLECTION LOOPS

edge of the rod or spindle nearest to the block were determined. These distances were:

Measuring point.....	0	1	2
Distance in inches.....	0.337	2 535	4.483

The diameter of the torque disk was 6.02 in. and that of disk plus cord was 6.08 in. so that the effective diameter was 6.05 in.

The first step in making a bend test was to wash out any dust that might have collected in the pulley bearings and to make sure that they worked freely. The test bar was then clamped in place with the flat side vertical and the longitudinal axis parallel to the base plate. In tightening up the clamping-block bolts, care was taken to draw the block into as nearly uniform bearing as possible against the test bar. Micrometer readings were then taken, and a comparison with the readings taken on the straight bar indicated the amount by which the test bar deviated from a straight line. The torque disk was slipped into place on the free end of the bar and leveled up. It was necessary to see that both cords left the disk at the same elevation in order to insure that no torsion was applied to the test bar.

For most of the test runs the loads were applied in 4-lb. increments, this load causing an increase of 10,000 lb. per sq. in. in the stress in the outer fibers of the bar. The weights used were correct to the nearest 0.01 lb. or better. In putting on or removing the weights it was not feasible to do it so smoothly that the bar would gradually move from one load position to the next. Instead there was a fairly rapid movement of the bar, followed by a second or two of oscillation about the equilibrium position for the load. Thus when the bar was being loaded it might reach its equilibrium position from either side of that point. This would tend to prevent the friction in the pulleys from consistently making the deflections too small as the loads increased, and too large as they decreased. Duplicate readings of deflections, moving the load up or down, checked within 0.001 in.

After applying each load it was necessary to move the radius arm a small distance so that the cords leaving the torque disk would be parallel. Readings were taken at all of the micrometers for the first few bars tested, but later only the micrometer located 4.483 in. from the clamping block was used. While this did not give complete data as the first system, it saved a great deal of time. The point of contact was determined by the closing of an electrical circuit. The gap between the end of the micrometer and the test bar was connected in series with a 22.5-volt battery, a head phone, and a 100,000-ohm resistance. At first a condenser was used across the gap, but there was not much sparking and its use was discontinued. With this system the point of contact could be determined, as shown by duplicate readings, as closely as the micrometer could be read, i.e., to 0.0002 in. Readings were not duplicated unless an error was suspected at the time the reading was taken. Ten to fifteen seconds usually elapsed between the time the bar was loaded and the reading taken, this interval being taken up by the time required to adjust the radius arm and to set the micrometer. With two operators working it took 20 min. to run a cycle from 0 lb. to 72 lb. and back. This required 35 readings, so that the total time per reading was about 34 sec. When a single operator was working, a little more than twice this time was required.

RESULTS OF BEND TESTS

Typical load-deflection curves taken from bend tests are given in Fig. 13. The loops there shown are very similar to the hysteresis loops in the tensile stress-strain diagrams. The proportional-limit values are typically less definite than for the tension tests. A reasonable value for the cyclical condition seems to be 110,000 to 125,000 lb. per sq. in., as indicated in Table 4. Values of a lower proportional limit and an upper pseudo-proportional limit are given in Table 7 as taken from the stress-strain curves for initial loading, but generally the bend in the curve at the lower proportional limit was much less sharp than for tensile tests, and the exact value of the lower proportional limit is correspondingly uncertain.

For the load-deflection curves for the bend test, just as for the hysteresis loops in the tensile stress-strain diagrams, it is necessary to use several different moduli of elasticity in order to exactly represent the deflection of the bar. In place of doing this, a line was drawn between two points that bisected the width of the loop near top and bottom, and a modulus of elasticity was computed which would give deflections that would fall on this median line and would thus be reasonably close to the actual deflection.[7]

TABLE 4 CYCLICAL HYSTERESIS—SUCCESSIVE RUNS MADE ON DIFFERENT BARS

Maximum stress	Cyclical hysteresis, in-lb. per cu. in. — Experimental values	Mean	Reverse bends[1]	Median modulus of elasticity

[1] Second set of runs made on the same bar, but with bar bending in opposite direction, to reverse the direction of stresses.

The values obtained for this median modulus of elasticity in bending averaged 30,300,000 lb. per sq. in. for 12 initial load-deflection loops, and 30,800,000 lb. per sq. in. for the corresponding cyclical loops. There was a maximum variation of 2.6 per cent from these mean values, with an average variation of 0.9 per cent.

The hysteresis values obtained for the bend-test bars are shown in Figs. 14 and 15. The maximum apparent stress (computed from $SI = CM$) in the outer fibers has been plotted on the x-axis, and the energy loss in inch-pounds per cubic inch on the y-axis. The latter value was obtained by dividing the total loss in a given length of the bar by the volume of the bar included in that length

[7] For method of computation, see Appendix No. 2.

The solid line in Fig. 14 represents the energy loss for bars in a cyclical condition, i.e., when no added set is noticed during the running of a load cycle. The individual points have been plotted to show the range in energy loss for several different bars tested at each of several maximum stresses. This curve apparently shows a slight break at somewhere between 130,000 and 150,000 lb. per sq. in., which is about the upper proportional limit in tension. For the lower portion of the curve $E_0 = 1.183 \times 10^{-13} \times S^{2.80}$, and for the upper portion $E_0 = 2.52 \times 10^{-17} \times S^{3.30}$, where E_0 is the energy loss in inch-pounds per cubic inch, and S the maximum fiber stress in the extreme fiber. Detailed values are given in Table 4.

The dotted line in Fig. 14 shows the energy loss in the first cycle and is really a measure of the set produced in that cycle more than of hysteresis loss. At a point between the virgin

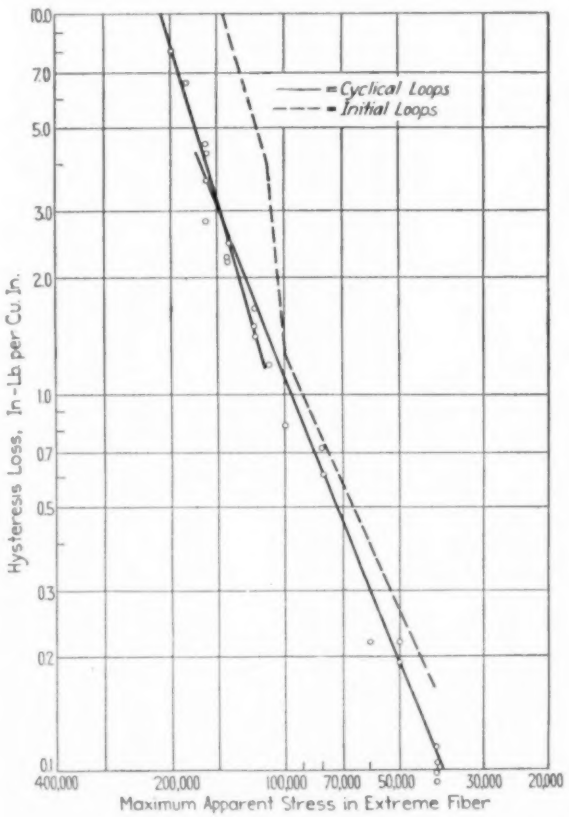

FIG. 14 FLEXURAL HYSTERESIS LOSS

proportional limit and the proportional limit as found in tension, it is seen to take a sudden increase, the initial loops showing naturally a greater proportionate loss above the proportional limit.

Certain of these bars were later reversed in position and retested in such a way that the center of curvature in bending was placed on the other side of the bar. In this way those fibers which had previously adjusted themselves to a cyclical condition of stress in compression were now compelled to adjust themselves to cyclical conditions in tension, and vice versa. The range of load in each case was from zero to the same maximum load as previously used. The resulting hysteresis values were but little, if any, greater for the reverse bend than for the initial conditions.

This was true even for bars loaded well beyond the proportional limit, with nominal maximum stresses of 200,000 lb. per sq. in.

Bar No. 33 was run through 10 cycles at 40,000 lb. per sq. in. maximum stress, then through 10 cycles at 60,000 lb., and by similar steps up to 120,000 lb. per sq. in. For the higher stresses more than 10 cycles were used to put the bar in a cyclical state. The results are shown in Fig. 15 and in Table 5.

Heat treating the bars at 335 deg. cent. by packing them in sand at that temperature and allowing them to cool very slowly

TABLE 5 CYCLICAL HYSTERESIS—SUCCESSIVE RUNS AT INCREASING LOADS MADE ON SAME BARS

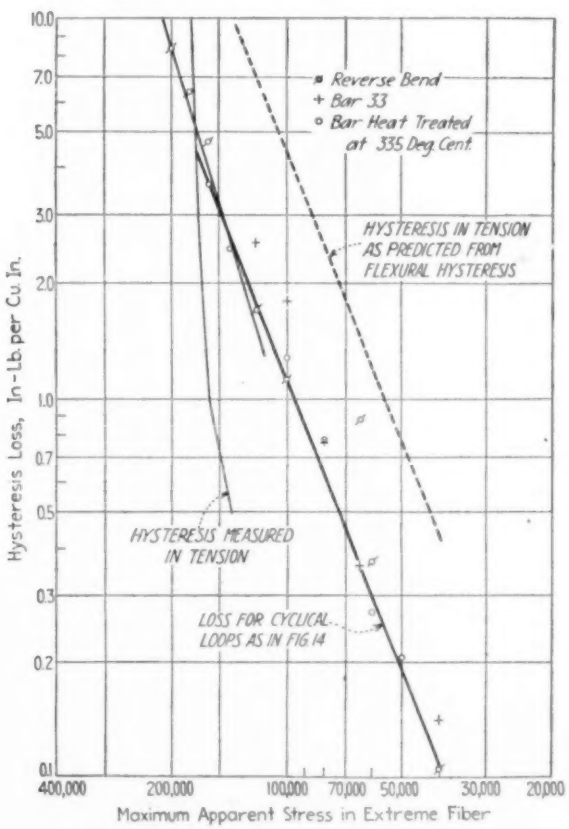

FIG. 15 FLEXURAL AND TENSILE HYSTERESIS LOSS

had no appreciable effect on the hysteresis loss. Fig. 15 shows the results obtained with a bar that was so treated.

An extended series of experiments were carried out to find out whether the hysteresis loss depended on the limits between which the cycle was run as well as on the stress range in the cycle.

Bars which had at first been tested between load limits of 0 and P were loaded and unloaded until they were in the cyclical state in the successive ranges 0 to $\frac{1}{2}P$, $\frac{1}{2}P$ to P, and $\frac{1}{4}P$ to $\frac{3}{4}P$. The hysteresis losses in these successive ranges are given in Table 6. There is evidently a definite progressive increase in hysteresis as the position of the center of the stress range is raised, the hysteresis for a load range $\frac{1}{2}P$ to P being approximately double that for a load range 0 to $\frac{1}{2}P$. The loss in the middle range lies between that in the other two.

Set and Elastic Afterworking in Bending

For ranges of stress above the virgin proportional limit of the material, the permanent set of the bar tends to increase under successive applications of loading, and to approach a certain maximum value corresponding to a cyclical condition in the bar. The relation between set and number of load cycles is given in Fig. 16, while Fig. 17 shows the relation between maximum stress and set. These values represent the permanent set in inches in the bar as measured by a micrometer at 4 53 in. from the edge of the clamping block.

At least 90 per cent of the total set is produced in the first 10 cycles, the rate of increase being comparatively slow after that. For the higher stresses the bar seems to lose its cyclical condition with a period of rest. Bar No. 38 (maximum apparent stress 200,000) had reached a state of nearly constant set at cycle 60, but after a 17-day rest it showed a sudden increase of 30 per cent in set. Bar No. 46 (maximum apparent stress 180,000) in the reverse-bend test showed the same effect, but to a less marked degree. Between cycles 50 and 64 it showed little increase in

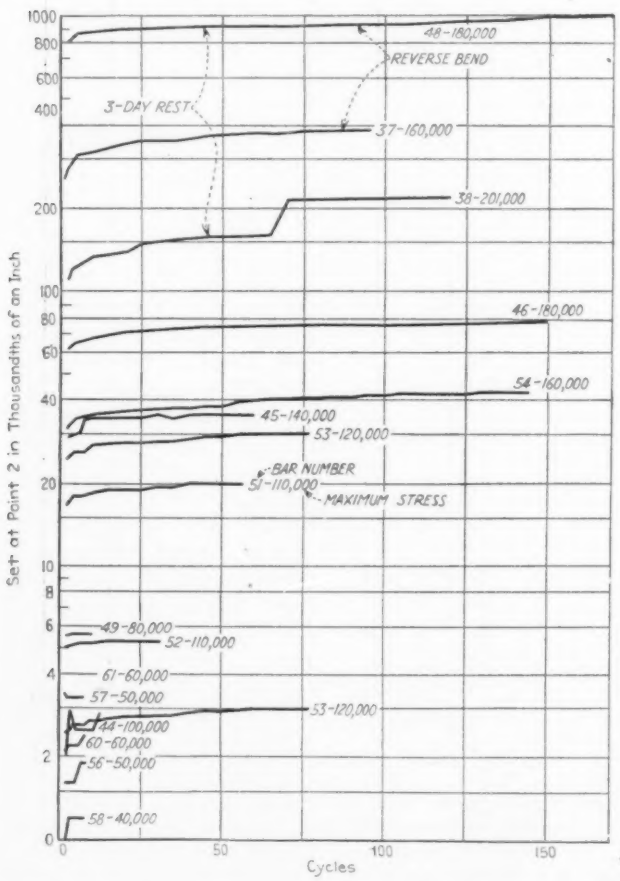

Fig. 16 Influence of Stress Repetition on Flexural Set

set, but after a three-day rest period it was necessary to put the bar through 100 more cycles before the set again became constant.

The set increases with the stress as shown in Fig. 17. At the lower loads the points are widely scattered. Some of these discrepancies may be due to the fact that the bars were not perfectly straight to begin with. There is a definite increase in the amount of set and in the rate of its increase above a stress of 155,000 lb. per sq. in.

The reverse-bend tests showed a more uniform relation between set and stress (Fig. 17). Below a stress of 155,000 the set increases as the 2.27 power of the stress and is 7 to 8 times as great as that in the direct bend test. The break in the curve takes place at 155,000 as it did in the direct-bend tests, but is a much sharper break. There is a little doubt as to the reliability

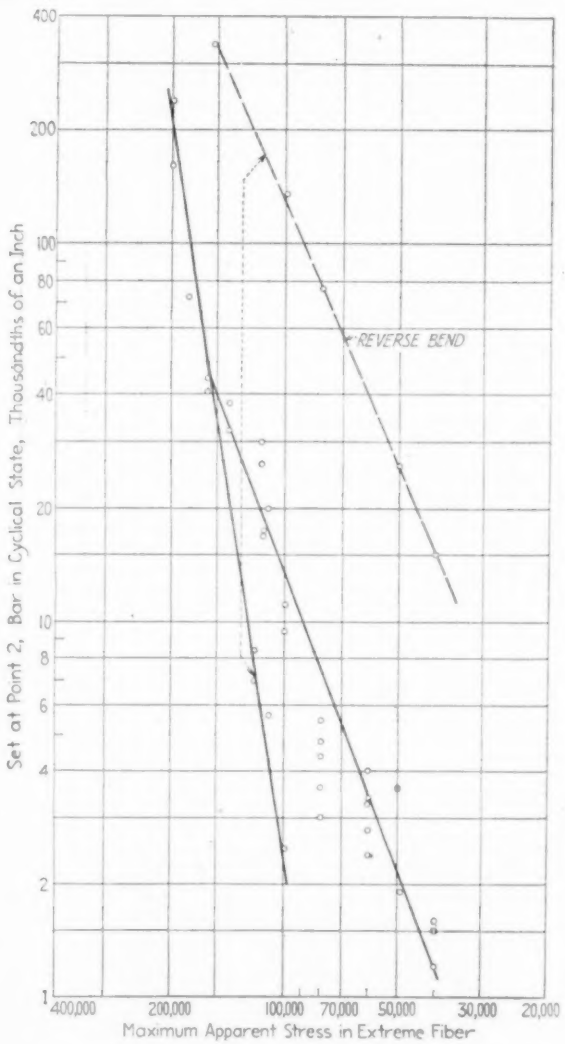

Fig. 17 Permanent Set at Cyclical State in Bending

of this part of the curve as it depends on one point only, but it would be expected that there would be more set above the yield point in the reverse bend than in the direct bend.

A study of the set and hysteresis results shows that if several bars are tested to the same maximum load the bars with the smaller amounts of set tend to show the lower cyclical hysteresis values, and that those with the larger sets will show the higher cyclical hysteresis values. This was true in the sets of bars tested to a maximum stress of 40,000, 80,000 and 120,000 lb. per sq. in. No conclusion could be drawn from those stressed to 60,000 and 100,000 lb. per sq. in., and this relation did not hold for the group of bars stressed at 50,000 lb. per sq. in.

The tendency of an overstressed bar to return to its original position during a period of rest at zero load has been called "elastic afterworking." For bars stressed beyond 150,000 lb. per sq. in. this elastic afterworking caused a reduction in set

varying from 0.0005 in. to 0.0014 in. during periods of rest varying from 1 to 16 hours.

Loads giving stresses as low as 40,000 or 50,000 lb. caused a yield or increase in set of 0.0002 in. and 0.0010 in., respectively, when applied continuously for a 15-hour period. The bars had previously undergone load cycles to maximum apparent stresses of 160,000 and 200,000 lb. per sq. in., respectively.

The increase in set was very noticeable when the bar was loaded for a period at stresses above the proportional limit. A bar loaded to 160,000 lb. per sq. in. for 15 hours showed an increase in set of 0.0460 in. Another bar loaded to 200,000 lb. per sq. in. yielded 0.0140 in. during a load period of 75 min.

Summary and Discussion

The real value of these experimental results of course can be most definitely brought out by making practical applications. The most immediate application lies probably in a study of true stress distributions in bending, as far as they affect the selection of proper unit stresses, and as they indicate the effect of internal stresses caused by various methods of manufacture.

Let us visualize what actually occurs in a round or rectangular bar as it is being bent. The fibers on the concave side are being shortened; on the convex side they are being lengthened; and the rate of shortening or lengthening is proportional to their distance from some central, unaffected, row of fibers called the neutral axis or neutral plane. The next step in the usual computation is to assume that unit stress is proportional to unit strain, and that therefore the unit stress is proportional to distance from the neutral axis, whence follows easily the well-known formula $S = Mc/I$. There also follow two less well-known but very convenient formulas:

$$M = EI\,(1/R_2 - 1/R_1)$$
$$S = Ec\,(1/R_2 - 1/R_1)$$

where R_1 is the radius of curvature of the center line of the bar at that particular point before applying load, and R_2 the radius of curvature at the same point after the load has been applied. E is the modulus of elasticity, usually assumed to have the same value as that obtained in a tensile or compressive test.

Any material placed under compression, and so caused to shorten longitudinally, tends to expand laterally in both directions. Consequently, as the compression fibers on the concave side of the bar expand laterally, while the tension fibers on the convex side contract laterally, the cross-section of the piece tends to warp, the face of a rectangular strip becoming concave in a direction at right angles to the main curvature of the piece. This effect is often spoken of as "anticlastic" curvature. Saint Venant in 1856 was the first to call attention to it. Love in his "Mathematical Theory of Elasticity," Prescott in his "Applied Elasticity," and Timoshenko and Lessells in their work of the same title all treat it in detail. Its presence can be forcibly called to one's attention by the simple experiment of gripping one end of a small rectangular steel bar in a vise, and then bending the bar into a small-radius circle.

There are three results from this tendency to lateral expansion:

(1) The distance from neutral axis to extreme fiber becomes greater on the compression side, and less on the tension side. A slight shift of the neutral axis may result, which has no particular importance.

(2) The lateral curvature, if allowed to occur freely, causes a change in the shape of the cross-section with a resultant gradual slight increase in the moment of inertia, and so in the apparent stiffness of the bar. The resulting lateral radius of curvature would equal the major radius of curvature divided by Poisson's ratio for the material.

(3) In wide, thin strips the lateral curvature is restrained or entirely prevented because of the arching action in the material which comes into play as soon as the lateral distortion begins. On the compression side of the material this is equivalent to introducing a hypothetical lateral compressive force which pushes the fibers back to their original width, simultaneously causing expansion at right angles to this (lateral) direction, forcing the fibers to increase in length parallel to the length of the bar, and so reducing the effective unit strain of the extreme fibers. As a result the bar deflects less under the applied loading, and its apparent modulus of elasticity is increased. In the limiting case, with a bar of infinite width in proportion to its thickness, the stiffness will go up in the ratio 1 to $1/(-\sigma^2)$, where σ = Poisson's ratio. For $\sigma = 0.27$, the resulting increase is 8 per cent. In the experimental work here described, the average value of the modulus of elasticity in tension was 29,700,000 lb. per sq. in., and in bending, 30,800,000 lb. per sq. in., an increase in stiffness of 3.7 per cent for bars $^1/_8$ in. thick by $^1/_2$ in. wide, with rounded corners. In Fig. 18 the discrepancy below the proportional limits, between the stress-strain curves in bending and in tension, is due to this cause.

This increased stiffness comes into play as soon as the bar begins to deflect, whereas the increase in stiffness due to the change in shape, noted under (2) above, comes into play only gradually as the bar deflects, and ordinarily factor (3) is much more important than factor (2). As a result, a wide, thin strip will show a greater stiffness in bending than a piece of square cross-section, and the latter a slightly higher stiffness than a round rod, all being made of identical material.

Returning to the main theme, imagine that the rod is still further bent, so that the extreme fibers pass beyond the proportional limit. The unit strain still remains proportional to the distance from the neutral axis, but the unit stress is no longer proportional to this distance. If, as in this experimental work, the radius of curvature of the bar is known, the true unit strain in the extreme fiber may be found, and then from a tensile stress-strain curve, or more correctly from such a curve corrected for the anticlastic effect, the true unit stress in the extreme fiber may be read off. The ordinarily used bending formulas are of course not valid for this case. For the particular case shown in Fig. 18, under the highest loading, the unit stress as computed by the formula $S = Ec\,(1/R_2 - 1/R_1)$ was 217,000 lb. per sq. in.; and by the formula $S = Mc/I$, it was 203,000 lb. per sq. in.; whereas the true maximum unit stress was only 176,000 lb. per sq. in.

Other methods of determining the true value of the unit stress in the extreme fiber may be used. One very engaging and theoretically exact method for bars of rectangular cross-section has been suggested by L. Prandtl. Take readings of load and deflection while the bar is being loaded. Compute the resulting unit stress and unit strain, using the formula $S = Mc/I$. Plot this stress-strain curve, and draw a straight line tangent to this curve, at the desired load point, as shown in Fig. 18. Read off the unit stress at the intersection of this line with the axis of zero strain, and subtract one-third of it from the nominal unit stress to obtain the true value.

The after-effects of an overstrain of this nature are more important than the immediate effect. These after-effects take the form of (*a*) a permanent set, or curvature, in the bar as a whole; (*b*) a permanent elevation of the effective proportional limit of the overstressed fibers; and (*c*) an introduction of trapped internal stresses throughout the entire width of the bar. The first effect is more or less obvious. The methods of prophesying its quantitative magnitude will be more evident after a study of the other two effects.

The character of the second effect may be visualized by a study of the typical stress-strain curves in tension and in bending for loads beyond the proportional limit, shown in Figs. 3 and 13.

The elastic return for loads beyond the virgin proportional limit is evidently not perfect. That is to say, the return line is not perfectly straight. Certain time-lag effects exist, and there are some other departures from perfect proportionality. Even after the load has been removed and reapplied a sufficient number of times so that cyclical conditions are approached, the stress-strain lines are still not perfectly straight, and a hysteresis loop remains. On the other hand, if the bar is held loaded for even a moderate length of time, so giving time for the deformation to occur, the stress-strain line on unloading will be so nearly straight that the bends may be averaged out, and a mean modulus-of-elasticity value used. In other words, although the extreme fibers did not behave elastically throughout the entire loading period, they will behave essentially elastically during the entire unloading period, and during future loading and unloading periods, particularly if future load values are kept moderately below the initial load.

The decrease in unit stress during unloading, measured at various points across the depth of the bar, will therefore be proportional to the distance of these points from the neutral axis, and will be accurately given by the usual elastic theory ($S = Mc/I$ formula). Thus in Fig. 19[8] the true stress in the extreme fiber, loaded, was 174,000 lb. per sq. in. tension; the decrease in stress by the formula given was 221,000 lb. per sq. in.; and the trapped stress in the extreme fiber with the load removed, was 47,000 lb. per sq. in. compression. If now this bar is again bent in the same direction, this trapped stress operates to relieve conditions, so that the true stress will be 47,000 lb. per sq. in. less than the computed value, while on bending in the opposite direction, the true stresses are 47,000 lb. greater than the computed values. This of course is the theoretical reason for the caution never to load a spring so as to cause it to uncoil under the load.

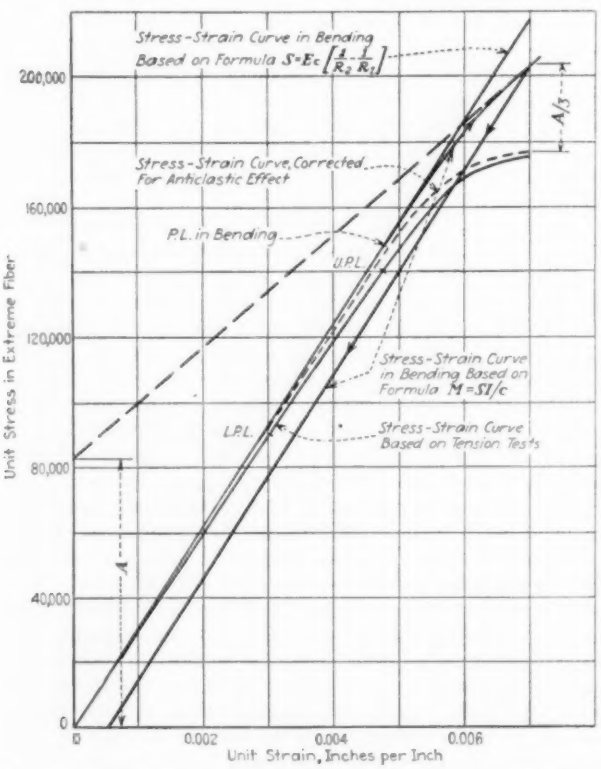

FIG. 18 · STRESS DISTRIBUTION IN BEAM LOADED BEYOND PROPORTIONAL LIMIT

Within the interior of the bar, conditions are analogous. At a point half-way between the neutral axis and the extreme fiber, the decrease in stress is 110,500 lb. As this is less than the true stress in the loaded condition at that point, the residual trapped stress at that point on unloading is one of tension. The true unloaded stress condition across the width of the bar is given by the dotted line in Fig. 19. The usual equations for equilibrium must be complied with by that dotted line: the total tension must just balance the total compression, and the moment of the forces acting clockwise about the neutral axis must balance the moment of the counterclockwise forces. This last condition determines the amount of permanent set remaining in the bar.

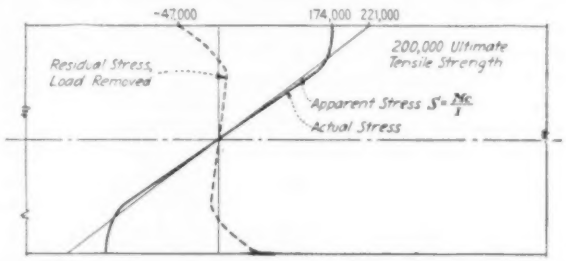

FIG. 19 TRAPPED STRESSES FROM FLEXURAL OVERSTRAIN

With modifications, therefore, it will furnish theoretical reasons for the amount of recoil of helical or power springs on winding, and should furnish an explanation for the occasional erratic behavior of different lots of wire which makes it difficult to comply with close specifications for size of coil. Some phases of these practical cases are more difficult to handle, as the wire is under tension as well as bending while being wound. The future program as outlined calls for a detailed study of this and of the simple case, applying the results directly to different types of wire. It also calls for an experimental study of certain approximations in this theory, particularly the effect of time lag and of elastic after-recovery.

The usual beam formula $S = Mc/I$ is properly limited to beams which are straight or nearly so. The error introduced through applying it to bars of appreciable curvature has so far been neglected. For the range of ratio between radius of curvature and thickness of piece which was used in this experimental work, this neglect is allowable, as the error will not exceed 0.5 per cent.

The magnitude of the internal friction or hysteresis loss in the material is best shown in Fig. 15. This figure is a logarithmic chart using as abscissa the hysteresis loss in inch-pounds per cubic inch of material corresponding to a single stress cycle starting at zero, rising to the maximum stress in the extreme fiber corresponding to the ordinate, then returning to zero. Before measuring these loop areas the material had been put through from fifty to one hundred or more stress cycles of this same magnitude, until further cycles caused no further increase in set, in order to avoid the effect of "initial set." The bending results show no signs of any break in the curve opposite the virgin proportional limit in tension, hysteresis being present even for light loads, and steadily and uniformly increasing as the load increases up to a stress approaching 150,000 lb. per sq. in. At this point there is a slight and not any too clearly indicated break in the line. The lower part of this line may be represented by the formula

$$\text{Hysteresis} = 1.183 \times 10^{-13} \times (\text{max. stress})^{3.6}$$

The upper part has a slope which indicates an exponent of 3.3. This compares fairly closely with the exponent of 3.0 given by

[8] This figure is based on a different bar and on greater loads than those used in Fig. 18, so that numerical values do not agree.

G. H. Keulegan of the U. S. Bureau of Standards (see Bibliography, Nos. 14 and 15). Mr. Keulegan worked with Armco iron, and with low unit stresses, a fraction only of the stresses indicated on Fig. 15. An extension of his curve upward, corrected for the fact that he worked with cantilever loading, whereas the bars here tested had moments of uniform magnitude over their length, came some distance above the author's experimental results, indicating that the hysteresis losses in the spring steel were approximately one-fourth of those in Armco iron. Not much reliance should be placed on this figure, as the stress ranges used in the experimental work do not at all overlap, and too much extrapolation of formulas is needed to permit of the comparison. Other experimenters have used coefficients ranging from 2 to 3, but very little work has been done at stresses approaching those used in the work here reported.

TABLE 6 RELATIVE HYSTERESIS IN DIFFERENT PARTS OF LOAD RANGE

Maximum stress	Range 0–P	0–$\frac{1}{2}P$	$\frac{1}{4}P$–$\frac{3}{4}P$	$\frac{1}{2}P$–P
		Hysteresis, in-lb. per cu. in.		
80,000	0.60	0.11	0.18	0.24
80,000	0.66	0.14	0.15	0.28
120,000	1.40	0.28	0.52	0.62
120,000	1.50	0.41	0.55	0.62
160,000	3.76	0.64	0.90	1.18
160,000	4.45	0.64	1.09	1.15
201,000	8.11	1.24	1.68	2.55

TABLE 7 PROPORTIONAL LIMITS IN BENDING

Bar No.	Maximum stress —1000 lb. per sq. in—	Initial loop L.p.l.	Initial loop U.p.l.	Cyclical loop Cycle No.	Cyclical loop P.l.
36	120	50	...	83	>120
41	120	80	110	97	>120
59	140	95	110	98	...

46	180	120	150	107	125

TABLE 8 COMPARISON BETWEEN HYSTERESIS IN TENSION AND IN FLEXURE

Apparent stress, 1000 lb.	Flexural hysteresis	Conversion factor, $n+1$	Tensile hysteresis based on bend test	Measured tensile hysteresis
180	5.7	4.3	24.5	14.0
160	4.0	4.3	17.2	1.0
140	2.55	3.6	9.2	0.5
80	0.66	3.6	2.4	0.0

From the experimental work (see Table 6) there seems very definite evidence that for a given total range of stress the magnitude of the hysteresis increases rapidly as the minimum stress in the range increases in value.

Attention should be drawn to the results for tensional hysteresis, shown by the upper line in Fig. 15. For stress ranges below 160,000 lb. per sq. in., the energy loss corresponded to a mean width of loop of not over 0.000005 in. per inch of length. Above this stress as the yield point of the material was approached the hysteresis loss increased sharply. No formula is given, but the slope of the line as drawn suggests that the hysteresis varies as the 20th power of the stress. These values represent conditions after the bars had been loaded and unloaded in tension a sufficient number of times so that the increase in set per cycle was appreciably below the width of the loop. Data are on file covering the progressive decrease in hysteresis loss as the bars approach cyclical conditions. A typical case is shown in Fig. 6.

Comparison cannot be made directly between hysteresis in tension and in flexure, as the whole volume of the bar is stressed equally in tension, whereas only the extreme fibers in bending receive the stated maximum stress. For an energy loss in bending varying as the 2.6 power of the maximum stress, the expected loss in tension, for the same maximum stress, would be $n + 1$ or 3.6 times as great. The actual measured values were much lower as indicated by Table 8. This suggests that some factor is present in flexure which causes hysteresis to be a more important factor in it than in tensile stress. Further study of this topic is planned.

EFFECT OF PITCH ANGLE ON HELICAL-SPRING DEFLECTIONS AND STRESSES

AS A PRELIMINARY step to more detailed work on torsional conditions of stress, an investigation was made of the numerical effect of various approximations tacitly made in the ordinary design of helical springs, in order to be able to allow for them. The most prominent of these approximations is the assumption ordinarily made that the pitch angle of the spring is negligible, and that consequently in tension and compression springs the torsional stresses only need be allowed for, the bending stresses and deflections being ignored. A corresponding error occurs in formulas for helical springs used in torsion, where customarily bending stresses only are considered and torsional stresses and their effects are neglected.

Corrected formulas for these cases, making proper correction for the pitch angle, have long been known. They have been summarized here. Results are given in more easily available form in Fig. 20. These charts show for various values of the pitch angle the percentage correction which must be applied to the results of the usual formulas to make correction for the effect of the pitch angle. The pitch angle ϕ used in these formulas is the angle which the center line of the wire in the coil

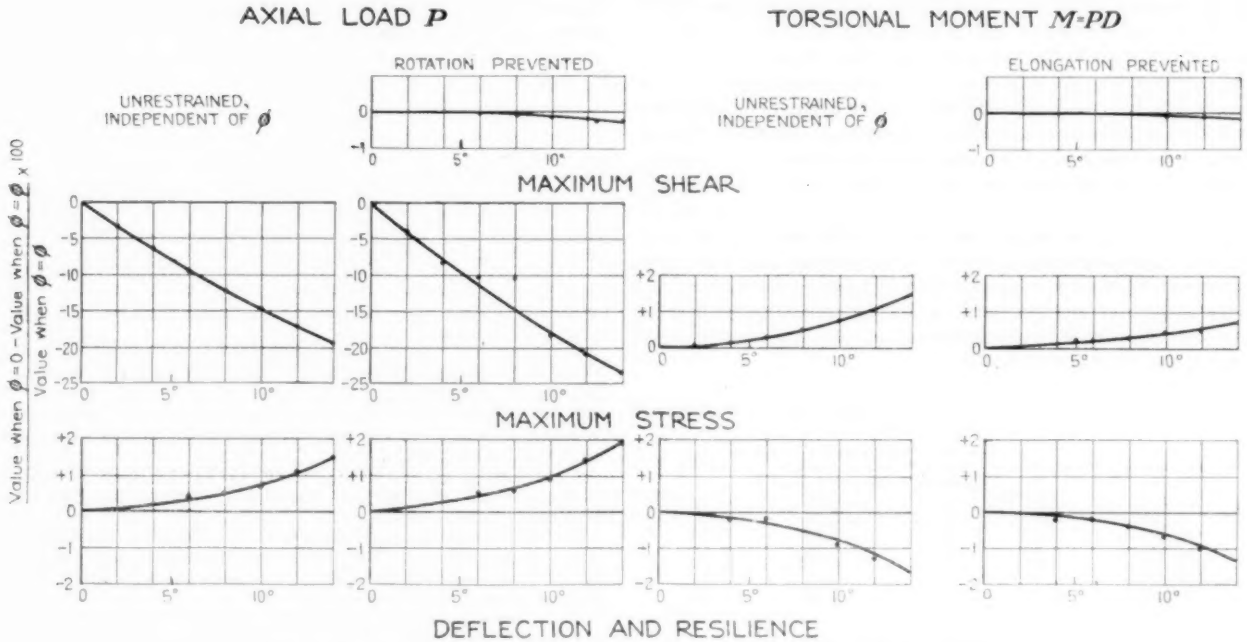

FIG. 20 EFFECT OF PITCH ANGLE ON HELICAL SPRINGS OF CIRCULAR SECTION

would make with a plane perpendicular to the axis of the coil. It is given numerically by the statement that $\tan \phi = p/\pi D$, where p = pitch or distance between center lines of consecutive wires, measured parallel to axis of coil, and D = diameter of coil, center line to center line of wires. Other items in the notation are as follows:

- P = axial load on springs, in pounds, considered + when it stretches spring
- M = torsional moment in inch-pounds applied from outside upon spring, considered + when it tends to bring coils closer together
- M_t = resulting torsional moment in wire of spring
- M_b = resulting bending moment in wire of spring
- F = linear deflection of spring, inches
- t = angular deflection in radians
- E = modulus of elasticity in bending, lb. per sq. in.
- G = modulus of elasticity in shear, lb. per sq. in.
- I = moment of inertia of wire
- I_p = polar moment of inertia of wire
- d = diameter of wire, inches
- L = total length of effective portion of the wire in the spring.

I—Springs Carrying Axial Load P[9]

1 *End Unrestrained* (Free to rotate as well as to move axially):

$$M_t = PD \cos \phi \qquad S_s = \frac{16\ PD \cos \phi}{\pi d^3}$$

$$M_b = -PD \sin \phi \qquad S_b = \frac{32\ PD \sin \phi}{\pi\ d^3}$$

$$\text{Maximum Stress} = \frac{S_b}{2} + \sqrt{S_s^2 + \left(\frac{S_b}{2}\right)^2} = \frac{16\ PD}{\pi\ d^3}\ (1 + \sin \phi)$$

$$\text{Minimum Stress} = \frac{S_b}{2} - \sqrt{S_s^2 + \left(\frac{S_b}{2}\right)^2}$$

$$\text{Maximum Shear} = \frac{\text{Max.} - \text{Min.}}{2} = \sqrt{S_s^2 + \left(\frac{S_b}{2}\right)^2} = \frac{16\ PD}{\pi\ d^3}$$

$$F = \frac{32}{\pi\ d^4} PD^2L \left(\frac{\cos^2 \phi}{G} + \frac{2 \sin^2 \phi}{E}\right)$$

$$t = \frac{32}{\pi\ d^4} PDL \sin \phi \cos \phi \left(\frac{1}{G} - \frac{2}{E}\right)$$

$$W = \frac{PF}{2}$$

2 *End Restrained* (so that relative rotation of ends is prevented):

$$\text{Moment caused by } P = \frac{-PD \sin \phi \cos \phi\ (E - 2G)}{E \sin^2 \phi + 2G \cos^2 \phi}$$

$$M_t = \frac{-PD \sin^2 \phi \cos \phi\ (E - 2G)}{E \sin^2 \phi + 2G \cos^2 \phi} + PD \cos \phi \qquad S_s = \frac{16\ M_t}{\pi\ d^3}$$

$$M_b = \frac{-PD \sin \phi \cos^2 \phi\ (E - 2G)}{E \sin^2 \phi + 2G \cos^2 \phi} - PD \sin \phi \qquad S_b = \frac{32\ M_b}{\pi\ d^3}$$

$$\text{Maximum Shear} = \frac{16}{\pi\ d^3} \sqrt{M_t^2 + M_b^2}$$

$$= \frac{16\ PD}{\pi\ d^3} \sqrt{1 + \left[\frac{(E - 2G)(\sin \phi \cos \phi)}{E \sin^2 \phi + 2G \cos^2 \phi}\right]^2}$$

$$\text{Maximum Stress} = \frac{16\ M_b}{\pi\ d^3} + \text{Maximum Shear}$$

$$F = \frac{32\ PD^2L}{\pi\ d^4} \left[\frac{\cos^2 \phi}{G} + \frac{2 \sin^2 \phi}{E} - \frac{(\sin \phi \cos \phi)^2 \left(\frac{E}{2} - G\right)^2}{\frac{E^2G}{4} \sin^2 \phi + \frac{EG^2}{2} \cos^2 \phi}\right]$$

$$W = \frac{PF}{2}$$

[9] In the formulas given on this page for springs carrying axial load, the term D should be taken as representing the center-line radius of the coil, rather than the center-line diameter.

II—Springs Transmitting Moment M

1 *End Unrestrained* (Free to elongate as well as to rotate):

$$M_t = M \sin \phi \qquad S_s = \frac{16\,M \sin \phi}{\pi\, d^3}$$

$$M_b = M \cos \phi \qquad S_b = \frac{32\,M \cos \phi}{\pi\, d^3}$$

$$\text{Maximum Stress} = \frac{16\,M}{\pi\, d^3}(\cos \phi + 1)$$

$$\text{Maximum Shear} = \frac{16\,M}{\pi\, d^3}$$

$$F = \frac{32}{\pi\, d^4} RLM \sin \phi \cos \phi \left(\frac{1}{G} - \frac{2}{E}\right)$$

$$t = \frac{32\,ML}{\pi\, d^4}\left(\frac{\sin^2 \phi}{G} + \frac{2 \cos^2 \phi}{E}\right) \qquad W = \frac{Mt}{2}$$

2 *End Restrained* (Change of length of coil prevented):

$$M_t = M \sin \phi - M\left[\frac{\sin \phi \cos^2 \phi\,(E - 2G)}{E \cos^2 \phi + 2G \sin^2 \phi}\right]; \qquad S_s = \frac{16\,M_t}{\pi\, d^3}$$

$$M_b = M \cos \phi + M\left[\frac{\sin^2 \phi \cos \phi\,(E - 2G)}{E \cos^2 \phi + 2G \sin^2 \phi}\right]; \qquad S_s = \frac{32\,M_b}{\pi\, d^3}$$

$$\text{Maximum Shear} = \frac{16}{\pi\, d^3}\sqrt{M_t^2 + M_b^2}$$

$$= \frac{16\,M}{\pi\, d^3}\left[1 + \left\{\frac{(E - 2G) \sin \phi \cos \phi}{E \cos^2 \phi + 2G \sin^2 \phi}\right\}^2\right]^{1/2}$$

$$\text{Maximum Stress} = \frac{16\,M_b}{\pi\, d^3} + \text{Maximum Shear}$$

$$t = \frac{32ML}{\pi\, d^4}\left[\frac{\sin^2 \phi}{G} + \frac{2 \cos^2 \phi}{E} - \frac{2(\sin \phi \cos \phi)^2\left(\frac{E}{2} - G\right)^2}{\frac{E^2 G \cos^2 \phi}{2} + EG^2 \sin^2 \phi}\right]$$

$$W = t\,\frac{Mt}{2}$$

Appendix No. 2

FORMULAS AND METHODS OF COMPUTATION

I—Method Used in Locating Effective Position of Point of Tangency of Strip

THE equation of a circle whose center is not at the origin of a system of rectangular coordinates is

$$(x - h)^2 + (y - k)^2 = R^2$$

where h and k are the coordinates of the center of the circle and R is its radius. If the coordinates of three points on the circle are measured, the x's being the distance from the micrometer to point B (see Fig. 12) and the y's the deflections measured by the micrometers, the values of h, k, and R can be found from the solution of the three simultaneous equations

$$(x_1 - h)^2 + (y_1 - k)^2 = R^2$$
$$(x_2 - h)^2 + (y_2 - k)^2 = R^2$$
$$(x_3 - h)^2 + (y_3 - k)^2 = R^2$$

Actually it was found to be more convenient to put the equations in the form

$$K + 2x_1h + 2y_1k = x_1^2 + y_1^2$$
$$K + 2x_2h + 2y_2k = x_2^2 + y_2^2$$
$$K + 2x_3h + 2y_3k = x_3^2 + y_3^2$$

where $K = R^2 - h^2 - k^2$, solve for h, k, and K, and then find R. The difference between k and R gave the y-coordinate of the point of tangency, so that it was necessary to compute values to five significant figures in order to obtain this distance to the nearest 0.001 in.

II—Method of Computing Flexural-Hysteresis Loss

The hysteresis loss during a given load cycle equals the difference between the work done on the bar while it is being loaded and the work returned by the bar during the unloading. If a gradually increasing moment M is applied to a bar the work done is $Md\theta$, where θ is the angular change at the point where the moment is applied. Plotting an M-θ curve the area between the curve and the axis will give the work done on the bar if θ represents the angular change for an increasing load, and will give the work returned by the bar when θ represents

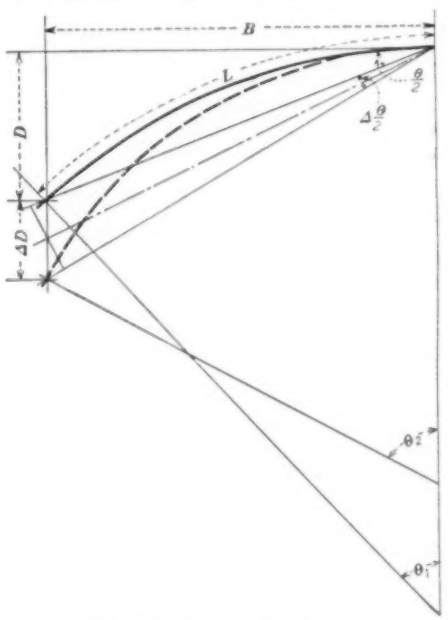

Fig. 21 Relation Between ΔD and $\Delta\theta$

the angular change for a decreasing load. The area of the loop formed between these two curves, which is analogous to the loop of a stress-strain curve as M is proportional to stress and θ to strain, gives the loss of energy during the load cycle. By plotting a M-$\Delta\theta$ curve, where $\Delta\theta$ is the difference in angle for increasing and decreasing loads, we have in effect greatly increased the scale of the plot. The area under the M-$\Delta\theta$ curve also represents the energy loss and can readily be obtained using a planimeter. Computations were greatly shortened by using a load-deflection difference curve in place of the M-$\Delta\theta$ curve.

The relation between $\Delta\theta$ and the deflection difference is seen from Fig. 21 to be

$$\Delta\theta = 2\Delta(\theta/2) = \frac{2\,\Delta D \cos(\theta/2)}{B/\cos(\theta/2)} = \Delta D\left[\frac{2 \cos^2(\theta/2)}{B}\right]$$

This figure also shows that as the bar is deflected the length between the point at which the deflection is measured and the fixed end increases. In other words, the deflection difference,

ΔD for $\theta = 30$ deg. is a measure of the loss of energy in a slightly greater length of bar than it is when $\theta = 10$ deg. In order to obtain the loss of energy in a constant length B, $\Delta\theta$ will have to be divided by L/B. The deflection difference for a given load, multiplied by $\frac{(2/B)(\cos^2[\theta/2])}{L/B}$, will give the value of $\Delta\theta$ for a length of bar B. A curve showing the variation of this factor with the magnitude of the deflection is shown in Fig. 22. The largest values of hysteresis, and consequently of $\Delta\theta$, are found at about half the maximum load in the cycle, so that the correction factor corresponding to the half-load deflection is relatively the most important. At 32 lb. load the deflection is

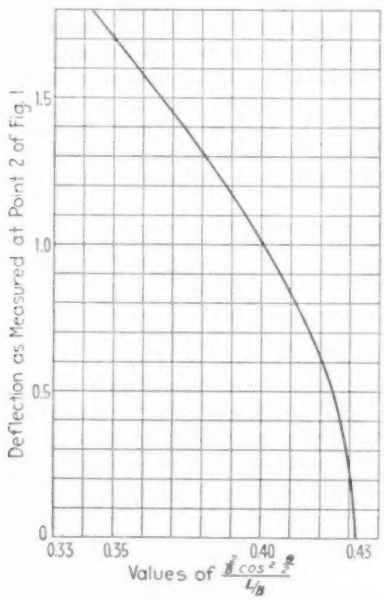

FIG. 22 CURVE GIVING FACTOR FOR OBTAINING $\Delta\theta$ FROM ΔD

0.50 in., so that up to 64 lb. the factor 0.424 is used. The deflection at half the maximum load of 80 lb. is 0.85 in., and it is seen from the curve that the corresponding factor is 0.408. Using these average factors for load up to 64 lb. and between 64 and 80 lb. rather than multiplying each value of ΔD by its exact factor to obtain $\Delta\theta$, introduces an error not greater than 4 per cent, which is less than the experimental differences and saves a great deal of time.

B_1 = 4.48 in. to edge of clamping block.
B_2 = 4.63 in. to point of tangency. Use $B = 4.55$ in.
Effective diameter of torque disk = 3.02 in.
Average area of test bar = 0.0596 sq. in.

Loss of energy in inch-pounds per cubic inch equals area of deflection-difference–load curve multiplied by 4.73 for loads to 64 lb. or 4.56 for loads above 64 lb.

$$\frac{3.02 \times 0.424}{4.55 \times 0.0596} = 4.73 \qquad \frac{3.02 \times 0.408}{4.55 \times 0.0596} = 4.56$$

III—MODULUS-OF-ELASTICITY COMPUTATIONS IN BENDING

It was much more convenient to plot load deflection curves in bending, and to study these directly, than to compute unit stress and unit strain values so that the usual stress strain curve could be plotted. This had the disadvantage that modulus of elasticity values could not be directly obtained from the graph.

As a result the median modulus of elasticity had to be computed from the expression $M_2 - M_1 = EI(1/R_2 - 1/R_1)$, where M_2 and M_1 were the bending moments applied to the bar under the upper and lower loads and R_2 and R_1 the resulting radii of curvature in the bar. These values of radius of curvature were obtained from the relation $R = B^2/2D + D/2$, where D is the measured deflection and B the perpendicular distance from the line along which the deflection was measured, to the effective point of tangency. This effective point was taken as being 0.15 in. inside of the edge of the clamping block, that being its average position, determined as already described.

Inserting numerical values in these equations,

$M = 3.02\,P$, where P = load applied to pulley system.
$I = 0.0000745$ (inches)^4 $\qquad B = 4.63$ in.

$$E = 40{,}540\,\frac{P_2 - P_1}{1/R_2 - 1/R_1}$$

Appendix No. 3

DETERMINATION OF SHAPE AND MOMENT OF INERTIA OF BAR CROSS-SECTION

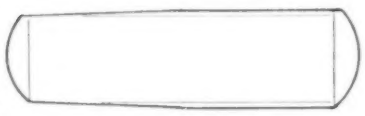
THE material used throughout this investigation was the usual flat rolled wire, nominally $^1/_8$ in. by $^1/_2$ in. in cross-section. Due to the method of manufacture, the shape was roughly rectangular, with sides very nearly parallel, but with rounded ends. Consideration was given to the possibility of having the sides and edges of the wire carefully ground so as to make the shape truly rectangular.

This plan did not appear to be desirable, because of the possibility of drawing the temper of the surface skin of metal during the grinding operation, and because of the fact that the grinding operation was almost certain to draw these thin bars slightly out of true, so requiring later straightening.

As an alternative, the shape of the cross-section of the bar was carefully studied and the corresponding moment of inertia computed. In doing this, thin sections were cut from the bar and glued on a glass plate. Using a projector, the shadows of these sections were thrown on a screen and traced. The magnification was about 55 diameters. These tracings are shown in Figs. 23 and 24. It is seen that the curves traced lie a little outside of the true circular segment. The moment of inertia of a circular segment is 15 per cent greater than that for a parabolic segment, both having the same chord and rise. (This might not be true for a different ratio of chord to rise.) It was estimated that the moment of inertia of the actual segment would be larger than that of the circular segment, and the moment of inertia has been taken as 30 per cent larger than that of the parabolic segment. *This is slightly less than the moment of inertia of one-half of an ellipse. If t is the thickness of the specimen and a the ordinate of the vertex of the segment, the moments of inertia are as follows:

Parabola	$0.0334\,at^3$
Ellipse	$0.0490\,at^3$
Value used	$0.0435\,at^3$

On this basis the segments contributed 7 per cent to the total moment of inertia of the section.



To check up the uniformity of cross-section of the bar, the thickness at each edge and at the center and the maximum width at inch intervals along the length were measured with a micrometer caliper. The width of the flat portion of the bar was measured with a micrometer microscope. The results of these measurements are given in Table 9.

The moment of inertia is very sensitive to any variation in the thickness of the bar, an error of 0.001 in. in thickness causing a 3 per cent error in moment of inertia, and for this reason the thickness had to be carefully measured.

TABLE 9 SUMMARY OF MEASUREMENTS OF 12-IN. BARS

FIG. 23 CROSS-SECTIONS OF WIRE

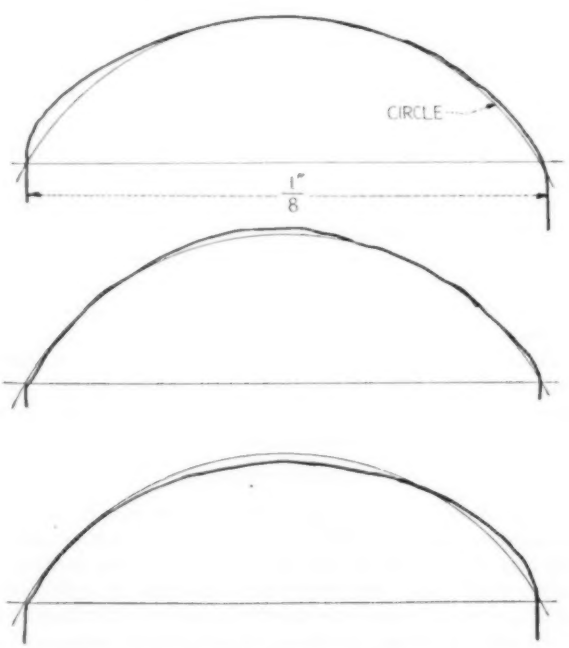

FIG. 24 TRACINGS OF PROJECTED SECTIONS OF WIRE

In computing the moments of inertia, the section was divided up into two rectangles and two segments as shown in the lower diagram of Fig. 23. The dimensions were determined from the mean thicknesses and widths previously mentioned. The greatest difference in the moments of inertia of the first five bars as computed from their mean dimensions was 0.7 per cent.

Taking bar No. 5, in which there was the greatest variation in section, it was found that the moment of inertia at the largest section was 1.5 per cent greater than the moment of inertia at the smallest section.

DETERMINATION OF AREA OF CROSS-SECTION

By using its weight and specific gravity, the average area of a bar can be found sufficiently, accurately and much more expeditiously than by using the mean of the dimensions taken at each inch along the length of the bar as was done in determining moment of inertia. The following values of specific gravity were determined by the usual methods of weighing in air and in water, making the necessary corrections:

Run	Specimen A	Specimen B
1	7.811	7.806
2	7.821	7.820
3	7.826	7.834
Mean	7.819	7.820
Max. deviation from mean, per cent	0.10	0.18

The bars were weighed on a laboratory balance, and the lengths measured to the nearest 0.01 in.

As a check, certain of the bars were ground down to a rectangular cross-section so that their areas could be accurately determined by linear measurements. The areas were then also determined by weighing as above described. The results of the two methods agreed within 0.2 per cent.

As illustrating the uniformity in size of the bar as received, the following measurements, taken on three groups of bars, may be of interest:

Group	No. of bars	Mean area	Maximum variation from mean, per cent
1 As rolled	9	0.05956	0.44
2 As rolled	5	0.05955	0.29
3 Ground to rectangular section	7	0.04956	0.22

Discussion

BENJAMIN LIEBOWITZ.[10] The preliminary results seem to justify more intensive investigation. Apparently, one of the greatest needs is for more sensitive and accurate extensometers. In spite of the excellence of Professor Sayre's instrument, it appears that perhaps nothing short of interferometer measurements will suffice for the extreme delicacy required in the direct-stress tests. The use of interferometers in engineering investigations is not new, but their application to strain measurements may involve considerable difficulties.

For the experiments in flexure no such extremes are necessary. Here the difficulty seems to be largely that of eliminating the effect of the clamped end. Any one who has ever tried to make built-up tuning forks knows how serious this influence can be. The nature of these experiments makes it all the more important to eliminate any possible doubt on this point. The clamped-end effect might perhaps be avoided by having a free instead of a fixed micrometer mount, and by using it after the fashion of a lensmaker's spherometer over the middle regions of the specimen.

If the result is substantiated that hysteresis in flexure is much greater than in direct stress, it may afford a partial insight into the fact that fatigue-stress limits are higher in flexure than in direct loading. For hysteresis, like any other frictional force, opposes internal motion of the specimen so that under a given cyclic load the cyclic yield or strain should be less. Thus hysteresis may exert a supporting influence which, under some circumstances, may offset its destructive effect. On the other

[10] New York, N. Y. Mem. A.S.M.E.

hand, for a given strain range, the fatigue limits in direct stress should be higher than in flexure, for the effect of hysteresis in that case is to increase the effective range of stress imposed on the specimen in flexure.

Another aspect of hysteresis may be mentioned, viz., its ability to function as a damping means. This can be shown strikingly by spreading the tines of an ordinary tuning fork, and then restoring it to its original shape. A marked reduction in tone volume results, but the effect is only temporary as the fork regains its original volume in a few hours or days. Hysteresis from this viewpoint may turn out to be a real ally in certain branches of engineering, e.g., crankshaft design.

One of the very interesting aspects of the paper is the emphasis which the authors have placed on the "cyclical state." It has always seemed to me curious and significant that there should be such a thing as a cyclical state, at least in the sense that in changing from one stress cycle to another, the specimen must in each instance develop a new cyclical state. In a report which the writer read before this committee in 1926, and which was published in the *Journal* of the Society of Automotive Engineers, a "hypothesis of minimum hysteresis" was suggested according to which the hysteresis in the cyclical state will in general be a minimum, and certain evidence from the literature in support thereof was adduced. The implication of this hypothesis is that in an acyclic fatigue test, the average hysteresis for a given maximum-stress range would be greater than in a corresponding cyclical test, and presumably therefore the fatigue life shorter or the non-fatiguing stress range lower. One experiment in particular which is mentioned in this report has a bearing on this point, viz., where the specimen was subjected in succession to the stress ranges O-$\frac{1}{2}P$, $\frac{1}{2}P$-P, and $\frac{1}{4}P$-$\frac{3}{4}P$. The writer would like to ask the authors, when the specimen was in the cyclical state $\frac{1}{2}P$-P and the range was then changed to $\frac{1}{4}P$-$\frac{3}{4}P$, did the hysteresis temporarily increase before the cyclical state in the new range was reached?

G. H. Keulegan[11] and W. G. Brombacher.[11] That portion of the report on elastic hysteresis and other elastic defects, such as elastic afterworking, are of particular interest. The experimental results obtained by Messrs. Sayre and Hoadley on the values of the elastic hysteresis when the bars are subjected to tension stresses are unexpected and, as they state, should be considered tentative until all possible sources of error are eliminated. In this connection the writers would like to suggest the possibility of the masking of the small values of the hysteresis which would be expected at the lower values of the stress, by errors in the measurement of the stress. No discussion is given in the report of the testing machine, the method of its calibration, or the method adopted for measuring the applied loads. Is the $\frac{1}{6}$ per cent error mentioned one of precision or accuracy? These features have very likely been given consideration by the authors, and it is hoped that they will be given a place in their final discussion.

The experiments appear to show that the tensile hysteresis is zero at a maximum stress of 80,000 lb. per sq. in. This result is in some measure contradicted by Hopkinson and Williams[12] who obtained a smooth curve for the energy loss per unit volume per cycle when plotted against the maximum stress range. The specimen was of low-carbon steel with a tensile strength of about 67,000 lb. per sq. in. The specimen was subjected to reversed stresses ranging from 23,000 to about 66,000 lb. per sq. in. Their results show the energy loss proportional to the fourth power of the fiber stress.

[11] Bureau of Standards, Washington, D. C.

[12] "The Elastic Hysteresis of Steel," Proc. Royal Soc. of London, 1912.

The relation between flexural hysteresis loss and the maximum apparent stress in the extreme fiber plotted in Fig. 14 shows a break or discontinuity in the curve at the yield point. As pointed out by the authors, the maximum stresses in bending are not likely to exceed the values of those at the yield point (see Fig. 19).

It therefore follows that there is no significance in plotting hysteresis loss against apparent stress for values of the stress above the yield point. It might be fairer to plot all of these values against the yield-point stress. It is evident that the static or cyclical hysteresis loss should increase as the stresses are increased above the yield point, since the average values of the stress also increase. The analysis of the complicated phenomena occurring at stresses above the yield point is a difficult matter. A prime necessity is an accurate knowledge of the stress distribution at each loading.

It would be of considerable interest to users of springs in precision instruments to know the ratio of the average or maximum value of the hysteresis to the total deflection.

G. M. Eaton.[13] The maximum working stress imposed on any part of the material of a spring is always at some place on the surface of the material. This is true of stress resulting either from bending or from torsion. There are three major reasons why the material at the surface of a bar of steel is inferior to material somewhat remote from the surface:

1 The surface of the bar is composed of metal at or adjacent to the longitudinal surface of the ingot, and this surface material is inferior to metal embedded a little further inside of the outer skin of the ingot
2 More or less mechanical imperfection of the surface may occur as a direct result of the rolling operation
3 Surface decarbonization probably occurs in some measure in every heat cycle to which spring steel is subjected.

This is a very insidious enemy to spring life, because the decarbonized material does not respond to heat treatment and yet the surface material is subjected to the maximum working stress.

Fatigue failures of steel springs almost invariably start at some surface imperfection, as a minute crack. Once this crack is started, its leading ends are the seat of heavy stress concentrations, so that the little incipient crack progresses into material which is amply strong to resist the stress which would exist if the concentration of stress mentioned did not exist.

This brief discussion has been made to lead up to the suggestion that the special research committee add to their agenda the investigation of the influence of the condition of the surface of the stock on the service performance and life of steel springs.

Authors' Closure

M. F. Sayre. I quite agree with Dr. Liebowitz that more sensitive and accurate measurements of elongation are needed, and I am hoping that we shall be able to obtain this result in our uture work. Any such increase in precision of extensometer measurements of course also involves added care in measurement of the applied loading, in control of temperature variations, and in the removal of frictional drag or lost motion at the points of attachment between the extensometer and the specimen and at joints in the extensometer. I am inclined to think that this last difficulty in particular has been the cause of errors in some hysteresis results in the past.

I have not found it easy to develop an extensometer which will use interferometer methods. The difficulty lies in the fact that it is desirable to provide for a total range of measurement of

[13] Engineer, Molybdenum Corporation of America, Pittsburgh, Pa. Mem. A.S.M.E.

some five thousandths of an inch. Each interference ring or band represents only ten to fifteen millionths of an inch, so that it would be necessary to keep count of possibly five hundred bands as they passed the field of view, in order to get results over the full range. This would mean indefinite delay of course in doing the work, and also a likelihood of inaccuracy in counting the rings.

The testing machine was an Amsler 30,000-lb.-capacity machine which had been calibrated about a month before the tests were made, under the supervision of a mechanic from the Amsler plant in Switzerland, using an Amsler calibration box. I was present at the time, and saw the calibration carried out. The $^1/_6$ per cent error mentioned represented the largest discrepancy found in this calibration. As a matter of fact, in that part of the work where precision was most needed (the measurement of hysteresis loss), accuracy depended upon being able to take extensometer readings at the same actual load on the ascending and descending branches of the stress-strain loop. The precision of this work consequently depended upon the sensitivity of the machine, and not upon the absolute value of the individual loads.

Internal friction is often a highly desirable feature in that it serves to dissipate energy, and so to damp out vibrations. Theoretically, as Dr. Liebowitz mentions, it should also operate to resist internal motion in such a way that for a given cyclic load, the cyclic yield or strain would be less. Quantitatively, however, the internal friction is ordinarily so small that I doubt whether this second factor would be of much numerical importance.

I should like to say a word about the question of stress concentrations on the surface of the specimen. There has been some foreign work done on studies of salt crystals under tension. The crystal was placed under load, the lower half of the crystal being in running water and the upper half in air. Under these circumstances, rupture occurred each time in the open air until the part in the water had been dissolved down to one-twentieth of the area of the part in air.

Apparently the unit strength of the crystal in water was twenty times the unit strength of the same crystal in air. The strength in water was not so far different from the high strength which theoretically, based on surface-tension values, it should attain. The low strength in air was interpreted as due to the effect of very minute surface cracks which had little time or opportunity to form in water, where the surface was constantly being dissolved away. This thoroughly agrees with Mr. Eaton's suggestion that the character of the surface metal is highly important, but also suggests that a thin layer of soft decarburized material on the surface of a spring may not be entirely undesirable, as this ductile metal would be less likely to be affected by these small cracks or flaws.

Paper APM-51-17: Stresses in Heavy, Closely Coiled Helical Springs, by A. M. Wahl (Discussion)

W. M. Austin.[1] In the writer's discussion of Mr. Wahl's paper, there are certain errors that should be corrected. The writer also submits a further simplification of his formulas, and a table and curves of the correction factors to be applied to the old formulas.

Referring to page 197 of APM-51-17, Equations [43] and [44] should read:

$$W = \frac{2\pi Sa^2(1-v)}{v^3(1+uv)(1+u)}\left[\left(1-\sqrt{1-v^2}\right)\left(\frac{2}{3}+u^2v^2+2uv\right) - uv^3 - \frac{v^2}{3}\sqrt{1-v^2}\right] \quad [43]$$

$$W = \frac{\pi d^2 S(1-v)}{2v^3(1+uv)(1+u)}\left[\left(1-\sqrt{1-v^2}\right)\left(\frac{2}{3}+u^2v^2+2uv\right) - uv^3 - \frac{v^2}{3}\sqrt{1-v^2}\right] \quad [44]$$

On page 198, expression [45] should read:

$$\frac{\pi(1-v)}{2v^3(1+uv)(1+u)}\left[\left(1-\sqrt{1-v^2}\right)\left(\frac{2}{3}+u^2v^2+2uv\right) - uv^3 - \frac{v^2}{3}\sqrt{1-v^2}\right]$$

can be reduced to

$$\pi\left[\frac{1}{8}v - \frac{5}{32}v^2 + \frac{37}{384}v^3 - \frac{133}{1536}v^4 + \frac{127}{2048}v^5 - \frac{4079}{73728}v^6 + \frac{4061}{98{,}304}v^7 + \ldots\right] \quad [45]$$

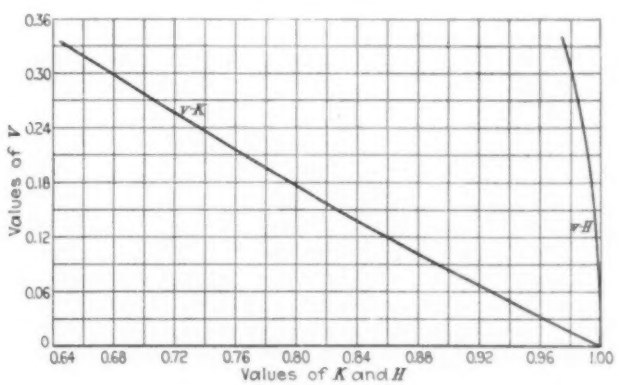
Equation [46] should read:

$$F = \frac{2\pi S(1-v)(1+uv)r}{G(v+uv)} = \frac{2\pi S(1-v)(1+uv)a}{G(v+uv)v} = \frac{\pi(1-v)(1+uv)d}{G(1+u)v^2} = \frac{\pi dS}{G}\left[\frac{1}{v^2} - \frac{1\frac{1}{4}}{v} + \frac{9}{16} - \frac{83}{192}v + \frac{155}{768}v^2 - \frac{403}{3072}v^3 + \frac{3168}{36{,}864}v^4 - \ldots + \ldots\right] \quad [46]$$

[1] Engineer, Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

For comparison with the formulas given in most of the handbooks, Equation [44] can be transformed to:

$$W = \frac{\pi d^2 S}{8D}\left[1 - 1\tfrac{1}{4}v + \frac{37}{48}v^2 - \frac{133}{192}v^3 + \frac{127}{256}v^4 - \frac{4079}{9216}v^5 + \frac{4061}{12{,}288}v^6 \ldots\ldots\right]$$



and Equation [46] can be changed to:

$$F = \frac{8WD^3}{Gd^4}\left[1 - \frac{5}{24}v^2 - \frac{77}{576}v^4 - \frac{4219}{110{,}592}v^6 \ldots\ldots\right]$$

If we denote by K the expression in the brackets in the formula for W, and by H the expression in the brackets in the formula for F, then we can calculate the values of K and H for various values of v. Table 1 shows the results of such a calculation for values of v from 0.335 to 0.000. The rate of change of K and H with respect to v varies so gradually that for intermediate values of v the values of K and H can be obtained by interpolation.

TABLE 1 VALUES OF K AND H FOR VARIOUS VALUES OF v

v	K	H	v	K	H	v	K	H
0.335	0.645	0.974	0.250	0.726	0.986	0.140	0.838	0.996
0.330	0.651	0.975	0.245	0.731	0.987	0.130	0.849	0.996

0.320	0.660	0.977	0.235	0.741	0.988	0.110	0.871	0.997
0.315	0.665	0.978	0.230	0.746	0.989	0.100	0.882	0.998
0.310	0.669	0.978	0.225	0.751	0.989	0.090	0.893	0.998
0.305	0.674	0.979	0.220	0.756	0.990	0.080	0.905	0.999
0.300	0.679	0.980	0.215	0.761	0.990	0.070	0.916	0.999
0.295	0.683	0.981	0.210	0.766	0.991	0.060	0.928	0.999
0.290	0.688	0.982	0.205	0.771	0.991	0.050	0.940	0.999
0.285	0.693	0.982	0.200	0.776	0.992	0.040	0.951	0.999
0.280	0.698	0.983	0.195	0.781	0.992	0.030	0.963	0.999
0.275	0.702	0.983	0.190	0.786	0.992	0.020	0.975	0.999
0.270	0.707	0.984	0.180	0.796	0.993	0.010	0.987	0.999
0.265	0.712	0.985	0.170	0.807	0.994	0.005	0.994	0.999
0.260	0.717	0.985	0.160	0.817	0.995	0.000	1.000	1.000
0.255	0.722	0.986	0.150	0.827	0.995	....	....	....

The accompanying curves v-K and v-H, Fig. 1, are plotted from the values of v, K, and H in the table. Values of K and H for larger values of v could easily have been calculated, but there is an old rule that springs having a wire diameter more than 1/3 of the mean diameter of the coil are not economical. This rule is no doubt the result of long experience. It also seems to be proved correct by the results of this and other analyses.

One thing is worthy of note, namely, that for the largest value of v in the table the variation in deflection from the "usual formula" is only 2.6 per cent, which corresponds to a variation in mean diameter of only 0.87 per cent. It must be remembered that this deflection formula holds good only for springs that have no internal stresses when free. Surging compression springs to a lower free height than that at which they were tempered

introduces other variables of which no account is taken in this formula.

While the correction factors in the brackets have been determined analytically to the sixth power of v, it will be observed that the sixth power is required only for the larger values of v in order to get K and H correct to the third place. In calculating the table, whenever a term became too small to affect the third place it was neglected. This reduced the time of calculation to less than half of what it would be if the sixth powers were used in each case.

Foreword

THE Power division of the American Society of Mechanical Engineers is pleased to present the following papers which include all those presented at the Fourth Midwest Power Engineering Conference held in Chicago, Ill., February 12 to 15, 1929.

The meeting was sponsored and endorsed by the local sections, regional, and professional divisions of the American Society of Civil Engineers, American Institute of Mining Engineers, American Institute of Electrical Engineers, American Society of Mechanical Engineers, American Society of Refrigerating Engineers, American Society of Heating and Ventilating Engineers, National Electric Light Association, National Safety Council, and Western Society of Engineers.

During the last four years, the engineering societies of Chicago have been cooperating to provide a broader viewpoint of advances made in the power industry. Engineering conferences have been held, but there has been no ready means of publishing the papers. This year the A.S.M.E. decided to print the papers presented at the fourth conference as a part of its transactions. Circulation of these presentations through this publication should stimulate additional interest and provide discussion for future power conferences, that will serve further to clarify the issues involved.

The papers presented during the four days over which the conference extended, discussed power problems and ways in which the power resources of the country may be developed best for the benefit of the people and the industries. Separate sessions were devoted to power-plant substructure problems; metallurgical and chemical problems; electrical-engineering problems; heating, ventilating, and refrigeration problems; power-plant operation, and power-plant economies. Able authorities discussed various phases of the power situation, covering not only, the larger and broader viewpoint, but also specific and technical viewpoints as to what is being done in the power industry and probable future developments. The papers are arranged in the order in which they were presented and the table of contents shows the sessions into which the papers were grouped.

In reading the various papers, one is impressed with the attention being given to improved design and construction of power plants, to practices that result in added economies in power production and to better use of equipment now available. Metallurgical and chemical research has added much of value to power-plant maintenance and to provide higher grade materials for construction. Heating and ventilating problems are being solved to provide better operation of equipment and the refrigeration field is proving an added extent for power supply.

Power Development

Engineering Advancement Depends on Progress Made in Many Sciences

By W. L. ABBOTT,[1] CHICAGO, ILL.

LIFE is change. When a city stops changing it stops growing, and when it ceases to grow it begins to die. Throughout the ages nature has been changing its animal forms and mankind has been continually changing its customs, costumes, religions, languages, laws, and governments; but the swiftest changes of all are now taking place and the practice of engineering is no exception.

It is true that not all changes are for the best. Nature makes something new only when she makes a mistake, and of those mistakes all except one in 10,000 are failures. Although she discards and disowns the 9999 mistakes, she cherishes the one success and says that her experiments were profitable.

Whether it was an accumulation of information resulting from a freer exchange of ideas that gradually solidified into a code of engineering, or whether engineering caused a freer exchange of information, we do not know and we cannot say which came first; but, egg or hen, we have learned the simple truth that the more information we give, the more knowledge we all have, and the more knowledge, the greater the progress and prosperity of the world.

It was not until after the freer exchange of information was recognized as good sense that the mechanic arts began their great strides and a profession of scholars was created expressly to form and develop original ideas and to make them known. These scholars, cutting paths in different directions through the wilderness of Nature's unknown laws and facts, developed a great diversity of engineering sciences, so great in number and so different in sphere that no one can follow all, and yet the whole are based on common fundamentals and each is so dependent on the others that many of those branches are represented here in our power program, and by their diversity in nature and their unity in purpose make this conference a success.

Such apparently unrelated subjects as substructure, Metallurgy, telemetering, heating and refrigeration, insurance, and sight-seeing among the molecules and atoms all find their appropriate places in our discussions of the great and comprehensive theme of power, whose development and utilization we are here to promote. Our friends farther down the avenue are displaying the latest styles in equipment for that purpose. We and they are here because of the great and increasing demands of civilization for some means to drive its wheels faster and faster, at ever lessening cost and with increasing benefit to man.

Power which once was obtainable in sufficient quantities from a slave or two or an ox or two is now demanded in amounts which would have appeared absurd to the users of a generation back—absurd because there was no demand for such quantities of power as are considered commonplace in this day, when nation vies with nation in its production and use. Excepting one or two small "hydro" countries, we lead all nations in the amounts of power used per capita. Therefore, we smugly assert that the use of power by a people in its industries and daily affairs is an index of that people's wealth, enterprise, industry, intelligence, mental alertness, good looks, etc.

While conceding all of that, to be agreeable, let us keep in mind that in this race we of America are favored with a great fundamental endowment of fuel, which accounts for much of our superiority in the use of power, and this fuel we are using with greater lavishness than efficiency. Great as that store of fuel is, it is limited in amount and cannot last as long as the human race will, and during this severe winter we shiver to think of the possible condition of the race with no coal left. Surely we can be rich in fuel and not spendthrifts of it, and if in using this wealth we do not employ all reasonable means to realize its last heat unit, we are squandering the heritage of our posterity.

It is true that immense strides have been made in efficiency since the day of the flueless cylindrical boiler, generating steam at or near atmospheric pressure, to be condensed by a jet of water in the cylinder of the slow-moving pumping engine. It is true that, the country over, scarcely half as much coal is now required to develop a unit of power as was needed twenty years ago, but today after 200 years of steam engineering, with the thermal efficiency of our best power plants under 25 per cent, we should blush rather than boast.

In this presidential address at the opening of the midwest Power Engineering Conference, it would be appropriate to list the more striking developments which have taken place during the past year, but upon consideration and advice I conclude that there have been no such striking developments during the past year nor during any preceding year. I might as properly take you into a great forest and ask which of those trees grew last year. None of them grew last year. All were growing. So with engineering. Progress made yesterday was but slight refinement of the development of last year, and that improvement was due to knowledge based on the accumulations of previous generations and centuries.

The airplane, whose continued roar is now heard over our flying fields, is a marvel of strength, power, and adaptation and a monument to the knowledge and ingenuity of its designer, but he could not have known how to start his design without the tragic experiences of flaming coffins and other wartime flying failures and successes. The building of those war planes was made possible by the Wright brothers at Kitty Hawk. They profited by the work of Langley on the Potomac, and he by the principles laid down by Chanute after his soaring flights in the Indiana dunes. All of this work were useless without the internal combustion engine of Dr. Otto. Back of Otto were electric ignition, engine design, thermodynamics, chemistry, metallurgy, and so on.

The steam turbine of today bears little resemblance to its immediate ancestors, which were exhibited by de Laval and Parsons at the Columbian Exposition, but the efficient, powerful giants that now drive most of the world cannot deny their rude parentage, and those toy turbines of thirty-five years ago have a direct lineage harking back twenty centuries to Hero of Alexandria. Neither the steam turbine nor the aeroplane were created; they "just grew up," with their roots in the deep past.

What is true of these modern marvels is true of all such marvels, now, here, or yet to be. None of them spring fully developed from any brain. They are dependent on too many different arts for any one discoverer or inventor to encompass, and each must wait for the work of others.

A marching column of soldiers advances by moving synchro-

nously first its left feet, then its right. But not so with engineering. It is rather like the progress of a so-called 1000-legged worm that advances the front foot on one side, and before that is set down the foot next behind is being moved, and in turn the one behind that; the wave of activity moving back to the last leg, but by the time the fifth or sixth foot is lifted the first one has been put down and is again in motion. Meanwhile the same action is taking place with the legs on the other side and the body moves forward, but the final movement of the last leg was made possible by the movement of the first one some time earlier, and further advancement of the first leg must wait until the whole body moves, not due to the performance of any one foot, but because they all, as a part of the whole, have taken some mincing steps.

It is so with engineering advancement, which can only take place with progress in many sciences dependent on each other for light. Regarding engineering development during the past year, I can say only that the advancement of the arts has followed closely that of the sciences and waits further scientific progress. Today we are using our coal a little more efficiently, due to better furnaces and hotter fires; but we are moving slowly, waiting for better refractories; steam temperatures and pressures a little higher, but waiting for better boiler steel; transmission voltages a little higher, but waiting for better insulation. And so it is all along the line, each waiting for the one ahead to make further advance possible, and when one moves all move. Step by step, we are improving by adopting new ideas of value, and improving by discarding old ones that time has made uncouth; progress from year to year hardly perceptible, but from one decade to the next astounding.

These changes are going on in every country, for change is the order of the day, and comfort, prosperity, happiness, and pride of leadership are the stakes for which the various nationals contend.

The game is for scientists and engineers, but the winnings are for all.

Details of Design and Construction of the Stream-Flow Power Plant

By H. G. ROBY,[1] CHICAGO, ILL.

DESIGN requirements of any engineering structure are usually conflicting. The success of a design depends to a large extent on the good judgment used by the engineer in giving proper weight to the different requirements, and in working out a satisfactory compromise between them. This is particularly true in the design of low-head water-power plants.

A fundamental necessity is a low cost of construction. Unless the cost is low, the project will not be undertaken. In order to secure this, the designer attempts to hold as small as possible the quantities of excavation and of concrete called for by his plans. The tendency is to reduce the center-to-center spacing of the units, and to hold down the general dimensions, both in plan and in elevation.

The result of narrow and shallow water passages, however, is to speed up the water passing through the plant. A high velocity causes too great loss of head at the intake, due to turbulence and back eddies, and leaves too large a residuum of energy in the water as it is discharged from the power plant. For the best hydraulic conditions the plant should be ample in general dimensions, with deep and wide water passages. The good design finds the best middle ground between these extreme requirements.

Another conflict in requirements lies in the fact that the substructure is both a conduit for the water and a foundation for the machinery and building.

The passages carrying the water to and away from the wheel should be unobstructed. The discharge from the turbine in particular should be clear, as the water is being discharged at a high velocity, and in a whirl. But in order to carry down to the foundation the weight of the generating equipment, the weight of the building itself, and of the water in the scroll chamber, it is necessary to insert piers and columns which cut up the flow, causing turbulence, and loss of efficiency. It is quite remarkable that, with the diverse requirements to be met, the designers of water wheels and the designers of power stations have been able to work out arrangements which, even under low heads and while handling large volumes of water, give water wheels in place efficiencies up to 90 per cent.

There are limits beyond which experience has shown it is not desirable to go in speeding up the flow of the water through the power plant. A velocity through the entrance racks of 2 ft. per sec., or a little more, and a discharge velocity of about 4 ft. per sec. at the downstream line of the power plant has been quite generally adopted.

At Louisville, Kentucky, a new hydro station has recently been put into operation, which has a maximum head of 37 ft. The plant is equipped with eight units, each having a capacity of 10,000 kw. The water quantity required at full gate is nearly 4000 sec. ft. per unit or 31,000 sec. ft. for the entire installation. This is about four times the flow now being drawn from Lake Michigan through the Chicago River. The units are spaced 58 ft. centers except where there are expansion joints, where they are 64 ft. centers, and the total length of the power house is 508 ft.

The depth of the water at the entrance racks is 38 ft., and at the downstream line of the plant it is 24 ft. at lowest tailwater. It is seen from this that overall dimensions of low-head plants become large, in spite of the designer's constant effort to keep them down.

One of the important advances in water-power practice in recent years is the adoption of the propeller-type or high-speed runner. It is probable that for heads up to 50 or 60 ft. this type of runner will supplant entirely the Francis type which has been in use for 75 years. The large increase in speed of the propeller type makes possible the use of a much smaller generator, and this in turn permits the width of the power station to be cut down. In the first installations, this saving in cost was offset somewhat by a lower efficiency at part-gate or part-load operation. The latest improvement in the propeller design is an arrangement by which the pitch of the propeller blades may be changed to conform to the change in gate-opening or of head. By adjusting the wheel to the condition of flow at any given time, the efficiency is maintained at a high level, and the disadvantage of this type as compared with the Francis type is removed entirely.

Another advantage of the propeller type is its ability to keep up to speed under a much wider range of heads than the older model. At Louisville, this feature was particularly valuable. The tailwater rise at Louisville amounts to 65 ft. For only 75 or 80 days in the year does the water below the power house remain at the low-water stage. A Francis-type wheel, designed for 37 ft. head, would fail to maintain speed when the head was reduced to about 17 ft. With the propeller type, the plant at Louisville has been operated with heads varying from 37 ft. down to 7½ ft. The average head for the year is about 27 ft. It is estimated that the output of this plant is 10 per cent greater than it would have been if the Francis wheel had been adopted.

At Louisville, the dam was built for the United States Government, primarily for the improvement of navigation. There are two ways for vessels to pass the dam. Except for about 20 days in the year, they go through the canal and lock, paralleling the river at this point. At extreme flood the lock is drowned out, a pass is opened in the dam, and the vessels follow the natural channel of the river. Upbound vessels could not navigate the pass through the dam unless the drop from the upper to lower water level was kept small. Thirty-six hundred feet of removable dam, 10 ft. high, and 860 ft. of removable pass, 14 ft. high, make it possible to hold the upper pool at a fixed gage, while increasing the discharge through the dam and while the lower pool is rising to within a foot of the upper pool. After all of the removable dam and pass are taken out, the upper and lower pool continue to rise together. As I have stated, the maximum difference in level is 37 ft., and the tailwater at maximum flood rises 65 ft. The upper pool therefore rises 28 ft. at maximum flood.

This great variation in water levels necessitated a rather unusual design of the power station. Allowing for possible floods greater than recorded, the level of the entrances to the plant was placed 69 ft. above low tailwater. The head-works platform was placed a few feet above normal upper pool, but the gantry crane and all other features of the head works were designed so that the platform could be flooded to a depth of 29 ft.

[1] Assistant Hydraulic Engineer, Byllesby Engineering & Management Corp., Chicago, Ill.

Presented at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

In order to save concrete, the generators were placed on a floor 16 ft. below the entrance level. Even with the depression of the generator foundations, the main shafts, extending from the bottoms of the runners to the exciters above the generators, are 67 ft. long.

In addition to the unusual height of the substructure, several other features were injected into the design by the wide water-level variation. At maximum flood, the upward pressure on the turbine cover plate and on the roof of the scroll chamber become very large, amounting to 7,500,000 lb. for each 58 ft. unit. This uplift had to be counterbalanced by the weight of the building and machinery above the scroll-case roof, or there would have been a tendency for the upper part of the structure to float away. This limited the amount of coring out that could be practiced in the effort to keep down the concrete yardage.

For most of the year the turbines operate submerged. Leakage around the turbine shafts and around the pins operating the gate guides cannot be led directly to tailwater, as the tailwater is usually higher than the points of leakage. A sump had to be provided, to which the leakage is led by a drain running the full length of the power house and from which it is pumped over the high wall, the top of which is above possible flood level.

The preparation of the construction program required a careful study of the probable behavior of the river. The cofferdam around the power house site was built to a level 26 ft. above low water. It was designed so that it could be overtopped without damage, and unwatered quickly after having been flooded. It was expected that this high freeboard would give a working season from June 1 to November 1 for the excavation work, and for building the substructure up to an elevation high enough to permit the work to proceed during the winter and spring floods. There had not been a flood that would have interfered with this program since 1898, but as usual the season of 1926 was one of those unusual high-water seasons. The cofferdam was overtopped in August, which is the month of lowest average flow.

The construction schedule for the dam, which is 8650 ft. long, was arranged on the principle that it would be cheapest to build cofferdams to meet only moderate high water, and to work at a high rate of speed during the period when the comparatively low cofferdams would hold out the river. Following that scheme, a large part of the dam, over a mile in length and amounting to 50,000 cu. yd. of concrete, was built in 40 days.

FSP-51-3

Power-Plant Substructure Problems

By J. C. SANDERSON,[1] CHICAGO, ILL.

Varying conditions that are encountered in power-plant substructures are illustrated by discussing the problems that arose in the construction of four power plants at Mexico City, Pekin, Ill., Cincinnati, Ohio, and Chicago, Ill. The first was on soil of low bearing capacity, the second in water-bearing sand with a special cofferdam construction, the third required a deep foundation on water-bearing gravel, and the fourth was on a clay foundation.

SUBSTRUCTURE design is based almost entirely on the experience and judgment of the designer. There is no satisfactory method of determining the bearing capacity nor the lateral thrust of soil. At power-plant sites, which are of necessity near lakes or rivers, the character of the soil may be so variable in kind and quality that the information gained from borings or test pits may be worse than useless. In porous material water may be a difficult problem to handle, particularly where the variation from low to high water is considerable.

The difficulties of power-plant foundations do not consist so much of devising means for supporting heavy loads on unsatisfactory soils as in avoiding unequal settlements between the various parts of the building. Unequal settlement may mean a broken steam or water line or a high-speed machine out of level.

To illustrate some of the diverse conditions that may be encountered in power-plant foundations, we shall consider the foundations of four power plants built recently. The first is on a soil of low bearing capacity, the second in a water-bearing sand with a special cofferdam construction, the third a deep foundation on water-bearing gravel where the variation between low and high water is 64 ft., and the fourth on a clay foundation in Chicago.

The first plant is located in Mexico City which is near the center of an approximately circular level valley some fifty miles in diameter and encircled completely by high mountains. In the fifteenth century the Spaniards cut a tunnel through the mountains, lowering the water to its present level. The entire valley is supposed to have been a deep lake that has through the centuries been filled with alluvial mud, volcanic ash, and clay.

The thickness of the present top crust floating on this sea of mud cannot be determined as the water content increases with the depth to at least 50 per cent of the volume. This crust will stand a fair test load, but when a considerable area is loaded the settlement is as a basin, with the low point near the center of the load.

It is not practicable to use piles as the material gets softer with the depth. In most of the valley it is 1000 ft. or more to hard bottom. On account of the basin form of settlement, the heaviest bearing comes at the outer edges of the foundation and the lightest bearing at the center. After a careful study of existing buildings it was decided to adopt an average load of 850 lb., a maximum load at the edge of the footing of 1000 lb., and a minimum load of 520-lb. per sq. ft. at the center.

The foundation was designed as a light concrete barge with longitudinal and transverse steel trusses. These trusses took up the entire basement story. The bottom slab is 10 in., the deck or boiler room floor 6 in., and the sides 8 in.

The footing was extended at the west end of the building to bring the center of gravity of the foundation to the center of gravity of the load. The boiler loads and other concentrated loads were carried to the trusses by steel beams. On account of the unit bearing varying from the center of the load there was some difficulty in apportioning the load properly between the longitudinal and transverse trusses.

The old boiler room was torn down and the new boiler room constructed alongside the existing turbine room. The new foundation could not be carried below the bottom of the turbine room wall. Much of the interior of the turbine room was torn out and a new turbine foundation built on the same principle as the boiler room. Clearance was allowed around all pipes from the boiler room to the turbine room. There was no rigid connection made between the two buildings.

In preparing the site for the new boiler room some old boilers were dismantled. It was found that a turbine foundation nearby settled. When the new work was finished the turbine foundation had returned practically to the original elevation. The power station was completed about a year ago and has gone through a number of light earth shocks with no noticeable settlement.

The Powerton plant which is the second to be considered is on the Illinois river about three miles south of Pekin, Illinois. The plant site is about $^1/_2$ mile east of the river on ground 9 ft. above the flood plane. The top soil to a depth of 4 ft. to 6 ft. is a mixture of light clay and sand. Below this is a deep bed of sand and fine gravel. The plant is about 100 yd. from a deep sand and gravel pit in which the water level is nominally river level.

The lower point of the condenser pit is at extreme low water or 25 ft. below high water. The foundation is a concrete mat on the sand with a difference of 22.5 ft. between the bottom of the mat in the boiler room and condenser pit. The river level was nominally 20 ft. above the bottom of the condenser pit during the entire time the foundation was being installed. Inasmuch as the boiler-room foundations were in sand some 20 ft. above the pit bottom, we could not afford to lose sand during the installation of the deep footing.

The work was installed by excavating the entire site to the bottom of the boiler-room mat. Steel sheet piling was then driven around the entire area, approximately 120 ft. × 145 ft. on the neat line of the concrete. Inside the sheeting and about 1 ft. clear of the sheeting we drove 12-ft. to 18-ft. I-beams on 2 ft. 2-in. centers. These beams carried the earth thrust during the installation of the pit as well as after the pit was completed. The bracing was framed on the sand about 20 ft. above the bottom of the pit, and was spaced to give approximately 20-ft. dredging pockets. A concrete filler was cast between the I-beams and the sheeting for about 4 ft. from the top. When this concrete set, the bracing was tightened up with steel wedges to the extent of forcing the sheeting back into the bank. There was no bracing installed below this top set. When the excavation was completed there was nominally 20 ft. head room below the bracing. Wooden piles at intersections supported it.

As the excavation progressed the concrete filler between I-beams and sheeting was installed in 7-ft. sections. The I-beam had a 12-ft. plate riveted on the bottom to increase the bearing capacity. Two sumps about 5 ft. below the bottom kept the excavation dry. All reinforcing and concrete were placed in the dry. After the bottom was poured the I-beams were encased

---

Presented at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

in concrete by pouring a solid wall around them. The beams were designed to carry the entire earth thrust. The concrete is used for the protection of the beams and for watertightness of the wall. Driving the sheeting on the neat line saved the outside form as well as the excavation of the three or four feet of space usually left between the concrete and sheeting. The ample head room, below the bracing, reduced materially, the cost of installing the reinforcing and concrete. The entire cofferdam, 572 lineal feet, was driven with a variation of less than 2 in. from the theoretical line.

After installing the basement floor the bracing was removed and the steel sheeting pulled. As the sheeting was pulled the space left was puddled with sand. We have had no settlement in the boiler-room floor that was cast next to, but free of, the pit walls.

During the progress of the work a check was made twice a day to be sure that the I-beams were not being forced in at the bottom. There never was any evidence of yielding. The sheeting was driven 10 ft. below the bottom of the pit and the I-beams 12 ft. The beams were probably driven farther than necessary, but as this was the first time the method had been used it was decided to take ample bearing area. There was some question as to the action of a saturated sand under lateral pressure. There was no evidence of the sand being displaced.

When the cofferdam was designed the groundwater was assumed at 15 ft. above the bottom. During construction the river level was actually 20 ft. above the bottom. Pipes were sunk at various distances from the pit and the elevation of groundwater was determined. The groundwater had a grade of practically 2 per cent and the elevation just outside the cofferdam was approximately half-way between the river level and the bottom of the excavation.

The intake crib on this job was built up partly on planking ways just above lake level and dredged about 30 ft. to position. The outside dimensions are 66.5 ft. × 67.25 ft. It was landed within 2 in. of the theoretical position and nominal level. Alternate screen partition walls were omitted to give larger dredging pockets. After the crib was sunk to proper depth the bottom was poured through the water with a bottom-dump bucket. When the sealing concrete had set, the water was pumped out and the inside finished in the dry.

The third power plant, at Columbia, is located on the west side of the Ohio River near North Bend, about twenty miles down river from Cincinnati, Ohio. The plant site was about 15 ft. below extreme high water. The variation between high and low water at the site is 64 ft. The soil is a light sandy clay on a thick bed of sand and gravel, about 45 ft. below grade. As an experiment we tried to install two piers by the Chicago well method. This was a failure on account of a water-bearing sand about 25 ft. below the surface. The pressure was so great at this depth that the lagging was pushed in until the hole was an ellipse. This same difficulty was encountered in putting in the intake and discharge tunnels. The earth thrust was much heavier at 25 ft. below the surface than at 40 ft. Several piers were installed with steel sheeting. The sheeting was braced as the excavation proceeded, then the pier cast dry. This method was slow and expensive. The sheeting was very hard to pull on account of the length and the very heavy pressure. Most of the piers were dredged down as was the condenser pit. The process was nominally the same for piers and pit.

The pier site was prepared by digging a hole 12 ft. to 15 ft. deep by open dredging. The steel cutting edge was leveled up on planks, forms were set up and about 12 ft. of pier poured. When this concrete was about 7 days old the pier was sunk by dredging the material from the inside. After the pier had been lowered to ground level another 12 ft. section was poured and the process repeated. When the pier reached gravel the bottom was leveled. A diver was sent down to inspect the bottom. The concrete seal was poured through the water and a cap put on the top, leaving the hollow pier partly filled with water. During the process of sinking it was necessary to keep a close check on the center line of the pier and see that it was vertical.

The condenser pit, on account of its size (77 ft. interior diameter) required close attention to assure that it was kept vertical and to exact position. Provision had been made for a maximum variation of 1 ft. in location. The pit was landed 2 in. out of level and 4 in. off center. The concrete seal of about 2000 yd. was made as a continuous pour.

The bottom was poured through some 20 ft. of water, starting at the center, pouring the full depth of the seal, and working toward the outside. The seal was figured without reinforcing for 2500 lb. per sq. ft. net when the pit was pumped out. The condenser pit was reinforced for the thrust of the sealing plug acting as a dome. The piers and condenser pit were also reinforced for shear and distortion.

Piers and condenser pit were made heavy enough to overcome a skin friction of 300 lb. per sq. ft. There were no material difficulties encountered as all piers were sunk without jetting or loading.

The fourth plant, Crawford Avenue of the Commonwealth Edison Company, is located on the drainage canal at Crawford Avenue, Chicago.

The soil is a blue clay, increasing in hardness with the depth. Hardpan is encountered at 25 ft. to 30 ft. below grade. The building walls and columns are carried on caissons founded on the hardpan. The caissons were sunk by the Chicago well method. There were no difficulties encountered in the installation except that the clay was quite hard toward the bottom. The turbine foundations, however, are mat footings on the clay. It would have been expensive to sink a number of lightly loaded caissons for turbine foundations. If fewer fully loaded caissons had been sunk, there would have been required as heavy a mat as for a spread footing. The mat foundation for the turbine was made strong enough to insure that the entire foundation for a machine would stay in one plane. If this is accomplished a slight settlement causes no trouble, even though the settlement is out of level. All of the piping connected to the machine was made sufficiently flexible to accommodate a slight change in elevation. There has been no noticeable settlement in any of the six machines now installed in this station.

Design and Construction of Substructures of Steam Power Stations

By P. E. STEVENS,[1] CHICAGO, ILL.

This paper discusses the substructures used under varying conditions in several localities. One located in an old river bed required the solution of many difficult problems. Another located 350 ft. from a river bank was constructed on a site which was overflowed to a depth of several feet during high-water stages. Still another developed an interesting method for solving the problem of wet excavation through pit and tunnel work.

NECESSITY for locating power stations adjacent to a plentiful supply of water makes wet excavation a usual condition, and the considerable differences in elevation at which foundation supports must be provided add complications to the task. These problems must be faced in order that there may be no limitation placed upon the design of those features of the plant having to do with the efficient production of commercial power, and the proper solution must be regarded as a contribution to that most desirable condition, a low operating cost.

The loads to be sustained by steam-power-plant foundations include very heavy concentrations from equipment in addition to the weight of the building. For example, a steel stack 18 ft. in diameter and 200 ft. high, will weigh, with its lining, about 900,000 lb. Such a stack will commonly rest upon a steel structure 70 to 90 ft. high above the foundations. In addition to the stack this steel structure will carry a boiler weighing 750,000 lb. with water walls, superheaters, insulating enclosure, etc., making the total weight of equipment on four columns a matter of 2,110,000 lb. In one case the columns carrying the stack deliver a concentration of 2,330,000 lb. to the foundation, while other boiler-room columns carry a total load of 840,000 lb. each. In the turbine room are found other heavy units of equipment. A very common size turbo-generator of 30,000 kw. capacity will weigh, with its steel support, about 600,000 lb. A condenser for such a unit will weigh about 400,000 lb. when filled with water. To take care of the concentrations of load found under the boiler room columns the desirability of developing a high intensity of reaction from the soil is apparent. Even where the soil is relatively dry and would afford a safe support for an ordinary manufacturing plant of similar dimensions, the concentrations from equipment and the necessity for substantial freedom from settlement make the use of piling advisable.

An excellent illustration of conditions characteristic of steam power plant substructures is found in the Hibridge station of the Northern States Power Company, St. Paul, Minnesota. The plant is located in the old river bed about 150 ft. from the present bank of the Mississippi river from which it derives its supply of cooling water. Low water in the river is approximately 20 ft. below the general surface of the ground and the maximum recorded high water was nearly 21 ft. above low water. The power plant occupies a building 168 by 205 ft. in plan and about 95 ft. in height. Additional areas are occupied by the coal receiving hoppers, a switching annex and an office. The building is surmounted by two self supporting steel stacks, 18 ft. by 200 ft. reaching a height of 330 ft. above the lowest footing. A general elevation for the basement floor was established at about 3 ft. above high water with a pit 40 ft. by 176 ft. in plan and 23 ft. deep for the condensers. The floor of the condenser pit is 9 in. above low water. The circulating water tunnels are below this level, making the deepest excavation about 13 ft. below low water or 31 ft. below the surface of the ground. The general elevation for column footings is approximately 19 ft. above low water so that the extreme variation in elevation of foundation levels is 32 ft. The coal pit, 40 ft. in width and extending 126 ft. along one end of the building, has its floor 1 ft. 3 in. below low water involving an excavation about 23 ft.

The subterranean survey indicated soft silt to a depth of 19 ft. or approximate low water, with groundwater at a depth of about 8 ft. Below this a 20-ft. stratum of soft clay and sand was found, beneath which a very firm sand was indicated. The footings were designed for McArthur pedestal piles to rest on the sand stratum at a depth of about 40 ft., or 20 ft. below low water. The small, shallow pits for walls and column footings were excavated by hand in open cut. For the deeper pits, steel sheet piling was driven and the material taken out by means of bucket and derrick.

Two steel stiff-leg derricks were placed to cover the heavy work and four pile drivers were used in driving the steel sheeting and the McArthur shells. The concrete plant comprised a ¾-cu. yd. mixer with overhead material hoppers and adjacent stock piles, with a stiff-leg derrick to handle the stock. Concrete was distributed by means of hopper cars running on narrow-gage industrial track.

Upon attempting to pull the casing from the piles under the condenser pit it was found impossible to do so without destroying it. It became necessary to change the design and to use a much larger number of wood piles instead of the concrete piles contemplated in the original plans. In some areas the depth of the soft ground was found to be greater than the limit of penetration of the McArthur shells, and in order to develop the desired bearing value a combination wood and concrete pile was resorted to. After sinking the steel shell to its full depth the plunger was withdrawn and a wood pile was dropped into the tube. The wood pile was then driven its full length below the tube, a concrete bulb was formed about the top of the wood pile, and the concrete pile completed in the usual manner.

The difficulties encountered at the station just described might well be contrasted with the relative simplicity of the construction problem at another plant about a mile farther up the river. The site is on what was once an island and the ground was only a few feet above low water. The relative elevation of the floor of the condenser pit is about the same, but the entire basement floor was placed a few feet above the condenser-pit floor. In the absence of a survey, a soft subsoil was anticipated and a contract let for driving wood piles with a penetration of not less than 20 ft. below the cut-off. Upon opening the excavation, a dense sand and gravel was found, into which piles could be jetted only about 12 ft. The entire excavation was kept dry with one 8-in. pump, and the only difficulty resulted from the engineer's insistence upon a real effort being made to meet the piling specification for a penetration of 20 ft.

In the Riverbank Station of the Oklahoma Gas and Electric

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Company located about 350 ft. from the bank of the Arkansas River near Muskogee, we find a difference in level of various footings of 51 ft. The river has a high-water record approximately 37 ft. above its low-water stage, overflowing the site of the station to a depth of several feet. The building is 102 ft. by 175 ft. in plan and about 85 ft. in height above the basement floor. Two steel stacks, 14 ft. by 201 ft., give a total structural height above the lowest footing of 323 ft. The boiler-room basement and the turbine-room floor are 5 ft. above high water with the turbine-room basement 18 ft. lower and a condenser pit 34 ft. by 51 ft. in plan, extending to a depth of 23 ft. below the basement floor. Beneath the floor of the condenser pit which is about 1 ft. above low water, there is a valve pit 5 ft. 6 in. deep and circulating-water tunnels 6 ft. 0 in. in height, making the bottom of the excavation 13 ft. 6 in. below low water or about 35 ft. below the surface of the ground. A coal-receiving pit 24 by 37 ft. is also provided having a floor at a depth of 28 ft. 6 in. below the main floor involving an excavation about 20 ft. deep.

The soil underlying the site consists of 15 to 20 ft. of light sandy loam resting upon a stratum of wet sand and gravel about 17 to 25 ft. in depth, beneath which was found some brown shale and some oil-sand stone. This survey showed groundwater to be from 5 to 11 ft. above low water level.

The footings under the turbine-room columns are about 20 ft. above low water and those under the boiler-room columns about 18 ft. higher. These rest on McArthur pedestal piles designed to have a bearing value of 30 tons each. The coal-receiving hopper and pit and the condenser pit have no piles under them. The smallest footing carries 90 tons and the largest 600 tons.

Excavation was made largely in open cut, steel sheet piling being used only for the deeper pits. Material was shoveled into skips and buckets to be hoisted out by derricks. A steel guyed derrick, two steel stiff-leg derricks, and a wood stiff-leg derrick were placed to cover the work, and a revolving crane traveling on the railroad track was found valuable in handling cars and placing unloaded material to advantage. Concrete was distributed from a steel tower equipped with a boom for handling the spout.

Conditions of unusual difficulty were encountered in the substructure work for the Waterside station of the Louisville Gas and Electric Company on the banks of the Ohio River at Louisville. The erratic behavior of this river is well known. At this location its low-water shore line is about 580 ft. from the station and 37 ft. below the basement floor. Its rise to maximum high water is 45 ft., flooding the streets adjacent to the station. The oldest section of this plant was built in 1914 and it was extended in 1916 and 1924. It now occupies a building 182 by 322 ft. in plan and about 72 ft. high. From the bottom of the deepest concrete work to the top of the steel stacks is 322 ft. The general basement is about 8 ft. below high water. Pits are provided for the several condensers, as well as an ash pit 24 by 225 ft. in plan and 28 ft. deep. The bottom of the ash pit is about 16 ft. above low water. A screen house 35 by 51 ft. in plan is located on the station property about 480 ft. from the low-water shore line and connected with the plant, and with gratings in the river bottom by tunnels.

The condenser pit and the screen well were each constructed above ground as a caisson of reinforced concrete, open at top and bottom, and provided with a cutting edge of steel. As the reinforced-concrete walls and bracing were constructed the material within the cutting edge was excavated by means of a clam-shell bucket operated through the open wells of the caisson, thus permitting the structure to sink. The concrete was built up to its full vertical dimension before the cutting edge reached the desired depth. Additional weight to overcome the increasing friction of sinking was provided by loading with sand in large bins constructed on top of the concrete.

The footings of the 1916 extension are on McArthur pedestal piles resting on a stratum of firm gravel at approximately low-water level. For the 1924 extension it was decided to use a precast concrete pile of hexagonal cross-section tapering from 9 in. to 16 in. in diameter and 50 ft. long, reinforced with 6 bars $^3/_4$ in. square, and provided with a $2^1/_2$ in. jetting pipe in the center, reduced to $1^1/_2$ in. at the tip.

The discharge tunnel has its outlet in the river bed just below low water at a distance of about 480 ft. from the screen house. The intake tunnel extends beneath the river to a point about 590 ft. from the screen house. These two tunnels are in one concrete structure one above the other. They were constructed in a cofferdam of sheet piling, and the difficulties encountered would furnish material for a paper of many pages.

A relatively simple foundation layout was met with in the Horseshoe Lake station of the Oklahoma Gas and Electric Company near Harrah, Oklahoma. The site is about 120 ft. from the shore of Horseshoe Lake. This lake is an old river channel, now cut off from the new channel except at freshet stages, and is subject to a rise of about 12 ft. above present lake level, which has been raised 6 ft. by the construction of dams since the original plant was built in 1927. To this building which was 163 by 134 ft. in plan was added an extension 163 by 60 ft. in 1927. The turbine-room basement floor was placed 3 ft. below present lake level and the floor of the condenser pit 2 ft. 6 in. lower. The height from the basement to the roof is 114 ft., above which are two stacks, 11 ft. 8 in. by 73 ft. 6 in., the total height above the lowest footing being about 205 ft. Below the basement floor there is a sump, a clear water tank, and tunnels for cooling water, making the deepest excavation about 20 ft. below lake level.

A coal pit, 48 by 34 ft. in plan and 28 ft. deep, has its bearing on piles at a depth of 16 ft. below lake level. The floor of the screen well, located at the shore of the lake, is 16 ft. below lake level and the intake tunnel continues at this depth to the pump connection.

In the 1923 installation, the top of the piling under the turbine room was about at low water, and under the boiler room about 6 ft. higher. For these foundations precast concrete was used while the lower footings under the coal pits and cooling-water tunnels were placed on wood piles. In 1923, the lake level had been raised 6 ft. and wood piles were used for the entire addition.

Pit excavation was limited by means of steel sheet piling. A stream from a pipe nozzle was used to loosen the earth and sluice it to the suction pipe of a centrifugal pump, through which the water-suspended material was lifted to the surface and piped to the fill, by means of which the ground adjacent to the building was raised to a level about 1 ft. above high water.

The principal equipment included two steel, stiff-leg derricks, a pile driver, and a concrete plant consisting of a $^3/_4$ cu. yd. mixer served by wheeling in buggies from a stock pile to the batch hopper above the mixer. Concrete was distributed by spouting from a tower adjacent to the mixer, supplemented by the use of two-wheel buggies.

A very interesting method of solving the problem of wet excavation was employed in the pit and tunnel work for the steam power plant of the San Diego Consolidated Gas & Electric Company at San Diego, California. The station is located about 1100 ft. from the shore of San Diego Bay, an arm of the Pacific Ocean, from which it takes its cooling water. Extreme tidal range in the bay is $9^1/_2$ ft. A street leading from the water front and passing the plant has a grade of from 5.3 to 6.8 ft. above high water.

This station was built in 1910 and in 1921 the necessity for

additional generating capacity became manifest. Again in 1925 the growth in demand for power foreshadowed the need for a much larger circulating-water capacity, and in 1928 the station building was enlarged to its present dimensions of 179 by 167 ft. for the older portion, and 122 by 89 ft. for the new extension, which gives the building an L-shape. The basement of the turbine room in the old portion is about 9 ft. above low water and the earlier condenser pit about 2 ft. above low water. In 1922, additional tunnels were constructed under the boiler room at a depth of 27 ft. below the floor requiring excavation about 17 ft. below adjoining footings.

The soil is a fine sandy clay which is as hard as brick when dry and quite fluid when wet. A shallow trench was excavated through the boiler-room floor and in this were built the three longitudinal walls and roof of the tunnel, together with the end chambers for connection to the existing tunnels in the street alongside the station, and for the pump connections within the building. The tunnels were surmounted by longitudinal walls to prevent any possible caving from the sides. The entire structure 14 ft. 6 in. wide, about 200 ft. long, and 29 ft. high was sunk to its permanent elevation by excavating from the inside under compressed air. Excavated material was "blown" out through pipes and deposited on the roof of the tunnels between the extended side walls, providing the necessary weight for sinking. Wet concrete for the floor was introduced through a pipe having a hopper above ground giving sufficient head to overcome the air pressure.

When it became necessary in 1925 to increase the tunnel capacity, a new twin tunnel having two water ways, 4 ft. by 8 ft. 6 in., was sunk to a depth of 26 to 28 ft. below grade or 12 ft. below low water. This tunnel is about 1156 ft. in length and was sunk in four sections varying from about 200 to 373 ft. in length. The same method was used except that instead of retaining walls of concrete surmounting the tunnels, timber walls were used.

The new screen-house foundation which was a part of this work is 29 by 32 ft. in plan, and extends to a depth of 36 ft. below low water, or 8 ft. below the depth to which the harbor is to be dredged. From this depth up to about 10 ft. below low water is a concrete base constructed with 3 longitudinal and 4 cross-walls 3 ft. in thickness, forming 6 wells about 7 by 10 ft. in plan, and open at the bottom. Each wall is provided with a steel-protected cutting edge. Above the top of this base the middle longitudinal wall is omitted, thus providing three wells for the screens. The total height of this substructure from the cutting edge to the operating floor is 49 ft.

A cofferdam of steel sheet piling was driven, the bottom inside leveled off, and the concrete structure started in the dry, at a depth of about 10 ft. below low water. About 16 ft. of the structure was built up when dredging inside the wells was started. No important difficulty was experienced in sinking the foundation to its intended depth by this process of dredging, sinking, and building up. Upon completion of the sinking the 6 wells in the base were filled with sand to a depth of about 12 ft. below low water. An effort was made to pump out the structure in order to pour the 24-in. floor slab at the bottom of the screen wells. This was unsuccessful and the slab was poured under water by using a 4-in. tube or tremie pipe. The other interior construction below water level was then completed without further difficulty.

FSP-51-5

Metals Used in Power Plants

By A. E. WHITE,[1] ANN ARBOR, MICH.

This paper deals with metallurgy as applied to power plants. It is divided into two major sections, one concerning the metals used in this field, together with special processes for producing certain desired results, while the other considers the tests applied to metals in order to determine their suitability for the various required applications.

The metals considered in the first section are divided into two groups, ferrous and non-ferrous. Under ferrous metals, cast iron, wrought iron, plain carbon steels, and certain selected alloy steels are considered. The metals in the non-ferrous group considered are copper, lead, brass, bronze, babbitt, and monel. Special emphasis is placed on the field of use of each of these materials in power-plant work rather than on their characteristics. The special processes considered in the first section are welding, plating, and nitriding.

In the second section, the tests applied to metals made to determine their suitability for power-plant use are discussed. Among the tests considered are surface examination, including both visual and macroscopic, tensile tests, impact tests, hardness tests, metallographic examination, magnetic tests, X-ray examination, strain determinations, heat tests, fatigue tests, corrosion tests, corrosion, fatigue tests, and high-temperature tests.

MATERIALS AND SPECIAL PROCESSES

THE chief ferrous metals used in power plants a few years ago were cast iron, wrought iron, and steel. Cast iron was used for many parts, particularly tuyeres, and as the casing for many power-plant units such as pumps, turbines, and various parts of condenser assemblies. As power plants went to higher operating pressures and temperatures, cast iron found less and less use. It is generally recognized that its chief outstanding asset is its cheapness, but in most instances it possesses no remarkable properties which would warrant its use over and above all other available materials. It is not intended to suggest that cast iron be stricken from the list of power-plant materials, as in cases of ordinary service it may have a perfectly proper field. It resists oxidation and corrosion to a greater degree than does ordinary steel. There are various grades of cast iron on the market for some of which outstanding claims are made by producers. Representations of this type should be taken with due caution.

One of the major characteristics of cast iron is growth under temperature. If an iron is made containing less than 0.50 per cent silicon and approximately one per cent of manganese, with around 3 per cent of carbon, growth will not take place. It should be pointed out that an iron of this composition is not machinable. Very marked improvements in the compositions of cast iron have been made through the addition of alloys, though these improvements have been largely in the matter of strength and machinability rather than a manifestation of any characteristics particularly applicable to power plants.

Wrought Iron. In the early days of power plants wrought iron was used extensively for boiler tubes. It now has little application in this field, however, it is being used to a degree as tube stock for economizers, in view of the fact that it is felt by some to possess greater resistance than does steel to the corrosive conditions which exist in economizers, as well as for other purposes.

Plain Carbon Steel. Plain carbon steel is used in power plants in cast, rolled, and forged conditions.

Cast Steel. Cast steel is used extensively in power plants, particularly in valve parts and fittings. Some of the fittings in modern stations weigh as much as 10,000 lb. and, in consequence, present real manufacturing difficulties. Most castings, in fact all of the important ones, used in power plants are made by the electric-furnace process. They are usually furnished in the annealed or normalized condition. Designers of power plants can be particularly helpful if they will observe a number of general precautions in the design of castings. Some of these are (1) the use of suitable fillets, (2) the maintenance, so far as it is possible, of the same thickness of metal throughout the cross-section of the casting, (3) the control of the total weight of the casting so as to keep it as much under 10,000 lb. as possible.

The foundryman can also help the casting situation very materially by observing certain practices: (1) He should control the density and porosity of the core closely and of the mould proper. (2) He should use risers of proper size and should have them properly located. In no case should a riser be less than 35 per cent of the weight of the casting, and it would be better practice to make it 50 per cent of the casting weight. (3) He should employ a proper pouring temperature and use a steel which has been killed thoroughly. (4) He should refrain from shaking out the casting until such time as there would be no possibility of the formation of surface cracks, and (5) he should bring the casting to heat slowly in the annealing and normalizing treatments and should refrain from cooling it under such rapid or uneven conditions as will produce strain.

Rolled Steel. Power plants are large users of rolled steel. The framework of most of the buildings and the reinforcing bars used in the concrete are all rolled material. Satisfactory standard specifications for the use of this material are available and, therefore, need not be discussed.

A very considerable amount of rolled material is used in the form of tubes which are of both the welded and seamless types. There is a general trend toward the use of seamless pipe since it is felt generally to be safer than welded pipe, though for many purposes welded pipe is acceptable. At the present time, a very high grade of welding is being done. Until recently, it was not possible to obtain seamless pipe beyond 6 in. diameter, except in relatively short lengths. With the advent of new types of piercing mills, however, one can obtain seamless pipe up to about 24 in. diameter in almost any desired length. A few years ago, plain carbon steel was about the only type of steel which could be obtained in a seamless condition. This situation is changed so that it is now possible to obtain seamless tubing, not only of plain carbon steel, but also of such alloys as stainless iron, Enduro (17 to 18 per cent chromium) and the high-chrome nickel alloys, though in all of these latter instances the carbon content in the metals is low, usually under 0.10 per cent.

This tubular material is used as boiler tubes, economizer tubes, superheater tubes, and fittings. In fact, it is used most generally in the boiler and turbine rooms, particularly in the former.

Forged Steel. The major uses of forged steel in power plants are in turbine shafts and turbine disks. Modern turbine shafts, because of their large sizes, call for particular care in manufacture. The ingots from which the forgings are to be made must be sup-

[1] Director, Department of Engineering Research, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

Presented at the Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

plied with a riser of suitable size, and the forging operation must be performed to prevent the development of cracks in the metal. It is the author's opinion that, wherever the procedure is possible, an improvement in this metal is brought about by upsetting. Likewise, particularly in the case of large forgings, it is extremely

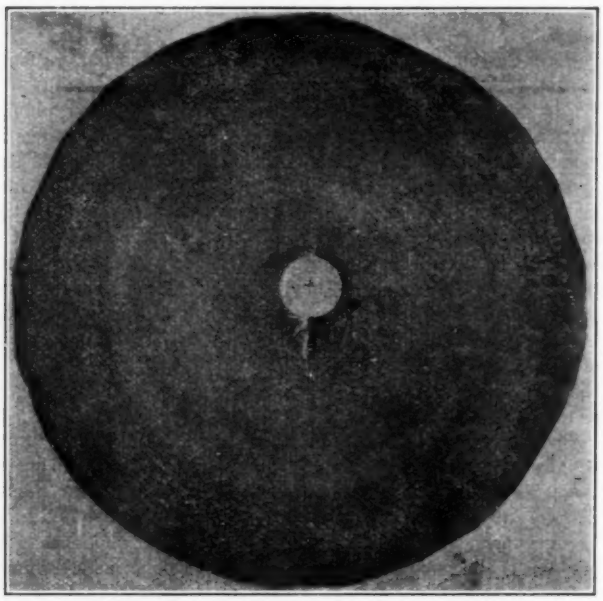

FIG. 1 SULPHUR PRINTS OF TWO CARBON STEELS

[(*a*) Above, an acceptable type as regards sulphide inclusions; (*b*) below, an unsatisfactory type regarding sulphide inclusions.]

important to bring the forging to heat slowly so that the metal may be the same temperature from center to surface.

Alloy Steel. The list of alloy steels which might be discussed in connection with power-plant uses would make several papers in itself. The author has, for the sake of brevity, arbitrarily selected seven steels. These are 3½ per cent nickel; a low-chromium, low-nickel; a low-chromium, low-tungsten; an 8 per cent chromium, 8 per cent tungsten; stainless iron, containing 12 to 14 per cent chromium; Enduro, containing about 18 per cent chromium; and a chromium-nickel alloy steel containing 19 per cent chromium and 8 per cent nickel.

The 3½ per cent nickel steel is used mainly for turbine disks, and in some cases for turbine shafts. It is preferred to plain carbon steel because of its higher strength and greater resistance to oxidation. The Chapman Valve Manufacturing Company has advocated chromium-nickel steel for castings for some time. Its uses give castings which have higher strength than is the case with plain carbon steel. Mr. Malcolm, metallurgist for the above company, was the first to bring to the attention of the public the value of a low-chrome, low-tungsten alloy; for high-temperature service.

Investigations made in the laboratories of the University of Michigan indicate that an alloy of 8 per cent chromium and 8 per cent tungsten has stability characteristics greater than those of the low-chromium, low-tungsten alloy, although it must be recognized that the greater the amount of chromium and tungsten present, the greater the difficulty with which forming and machining operations can be performed.

Stainless iron is used quite extensively for turbine blades. This is a metal which carries from 12 to 14 per cent chromium and under 0.10 per cent carbon. As turbine blades are one of the crucial parts in the power plant, considerable study has been given to the proper selection and design of blades. None of the manufacturers feel that the problem has been solved entirely, though, with the recent improvement in the design of the blades and the greater care which is being given to the selection of the stock, less difficulty should be encountered with this part than has been the case in the past.

With the trend toward higher operating temperatures, designing engineers have sought for a material acceptable for use in superheaters. It was soon recognized that plain carbon steel was not satisfactory. Stainless-iron tubes were then used, and this was followed by a stock made of Enduro. This material unfortunately appears to develop brittleness when held at around 1000 deg. fahr. (358 deg. cent.) for a long time and its use for this purpose, because of this weakness, has been discontinued.

An alloy made up of about 19 per cent chromium and 8 per cent nickel is now being used, for this particular composition. It manifests superior stability at elevated temperatures, as well as greater resistance to oxidation than does plain carbon steel.

Non-Ferrous Metals. Large quantities of non-ferrous metals are used in power plants. Chief among these are copper, lead, brass, bronze, babbitt, and monel. Copper, is employed mainly in the generator and transmission lines. It is a metal used in a high state of purity. Lead is used also in very large quantities as a covering for transmission cables. For this purpose it is used either as a pure metal or as an alloy carrying small quantities of antimony or possibly tin.

Brass is used in very large quantities in the condensers. There are three major types of this metal in use. One, which is known as Muntz metal is composed of about 62 per cent copper and about 38 per cent zinc; another type consists of 70 per cent copper and 30 per cent zinc; and the third, known as Admiralty, is made of 70 per cent copper, 29 per cent zinc, and one per cent tin. Consideration is also being given to nickel and Adnic tubes, although both of these latter types are in the process of development.

Bronzes are used in parts of impeller blades, and to a degree for heavy-duty bearings. Babbitts are used extensively for bearings. Monel, is made up of about two parts of nickel to one part of copper. One of its important uses was for turbine blades, and in this field it is still used, though a large proportion of the blades in modern turbines are made out of stainless iron.

Welding. The use of welding in power-plant construction is

receiving greater and greater attention daily. Engineers are yet fearful of poor welds and, unfortunately, no outstanding commercial method has been disclosed to date for the inspection of power-plant material after it has been welded. Yet improvements in the art of welding are being made constantly so that the welds of today are vastly superior to the welds that were made five years ago. With this improvement in welding, it is believed that all forward-looking engineers will give greater and greater consideration to the use of this method for joining together metal sections.

Plating. Very little plating has been done for power-plant parts. This is an operation which will in the future doubtless receive greater consideration than has been given it in the past. A recent use of plating has been made by the Detroit Edison Company at the Trenton Channel plant in nickel plating the valve stems of a number of important valves. A plating of $^3/_{16}$ in. thickness was put on the stems. As far as the author is aware, this is the thickest plate that has been used commercially. Over six months of work was necessary in order to work out methods for performing satisfactorily this operation.

Chromium plating also offers possibilities, though it should be recognized that it has not worked out satisfactorily from the standpoint of protecting the metals against oxidation at elevated temperatures. This failure is doubtless due to the fact that most chromium plate is exceedingly thin, and in consequence porous, and the gases, therefore, have an opportunity to get through the chromium to the base metal. It is possible to thicken chromium plate so as to obviate this condition. So far as the author is aware, however, this has not been done to date.

Nitriding. Nitriding is a process which aims to produce a very hard surface on steels, especially on certain alloy steels. It consists in subjecting steels containing special-alloying elements such as aluminum, chromium, molybdenum, and vanadium to an atmosphere of ammonia at a temperature in the neighborhood of 950 deg. fahr. (510 deg. cent.) for a period of from 12 to 90 hr.

One of the advantages of this process lies in the fact that the steel is heat treated previous to the nitriding process and no heat treatment, therefore, is necessary after the nitriding to give the case its hardness. This eliminates the warpage and scale often obtained in the other processes for producing hard surfaces. Another advantage of the process is the extremely hard surface obtained. Hardness values estimated at 1000 Brinell are secured. Application of this treatment has been made by the Chapman Valve Manufacturing Company, and possibly by others, for the hardening of their valve discs and seats.

METHODS OF TESTING

A very large number of types of tests are in use for the examination of materials used in power plants. Some of the most important ones will be discussed.. These include tests to determine surface characteristics, tensile properties, hardness, metallographic characteristics, the existence of blowholes, and sand pits (using X-ray), strain, and a few others.

Surface Characteristics

Practically all steel used in power plants is subjected to a surface inspection to determine the surface characteristics. This inspection consists of several supplementary processes including visual inspection, sulphur-print tests, and macroscopic examination.

Visual Inspection. Most surface inspection is of a visual type. No purchaser of metals will accept material which is badly scaled or pitted, or which is in a badly oxidized condition. The use of the periscope in this connection is gaining in popularity for examining tubular sections, especially in the examination of such materials as condenser tubes, boiler tubes, and the bore of turbine shafts. In this latter connection, the periscope test is a most important one, for if the material under examination discloses any cracks or other defects, rejection of the stock usually follows.

Sulphur Prints. The use of sulphur prints is also increasing since these give indications of segregations, particularly of sulphides. Fig. 1 shows two sulphur prints, one of steel of an acceptable type from this standpoint, and the other of a steel manifesting an undue number of sulphide inclusions. In the case of large forgings, sulphur prints are more and more coming into use for the purpose of determining the chemical center of the metal, for it is obvious that in a mass of metal, which is rotating at high speeds, less distortion and strain become manifest if the chemical and mechanical centers of the mass are in the same section.

Macroscopic Examination. The macroscopic test for steel is

Fig. 2 Macrograph of Half a Disk From Turbine Shaft

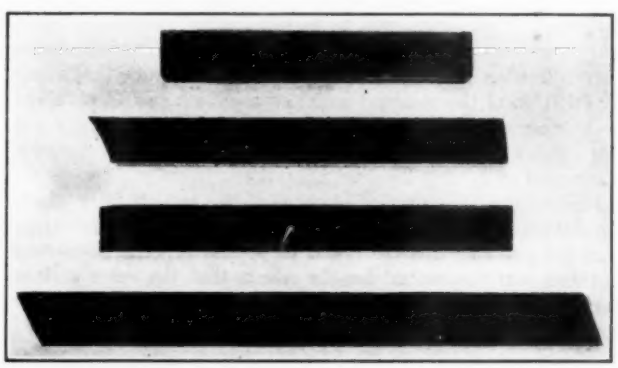

Fig. 3 Macrographs of Specimens From Seventh Stage of a Turbine Shaft

increasing in use in view of the fact that it too gives an indication of segregation, as well as flow lines, which result from forging or other mechanical forming operations. Figs. 2 and 3 show the results of a macroscopic etch on sections from a large turbine shaft. Fig. 2 is one-half of a cross-section of a turbine shaft. Fig. 3 is made up of four sections cut from a turbine shaft and illustrates the effect of the etch on the different faces. These examples are given, not as examples of good macroscopic characteristics, but rather, to indicate what a macroscopic test will disclose. Material to be acceptable from a macroscopic test should disclose a surface similar to that found on the outer face of Fig. 2. Yet it must be recognized, that the extent to which it is possible mechanically to work metal will affect, to a very considerable degree, the nature of the surface which will be obtained from a macroscopic etch. Material, which has not been appreciably worked will by its very nature disclose a more unsatisfactory surface from the standpoint of a macroscopic etch, than will material which has undergone an appreciable degree of mechanical reduction.

Tensile Tests

The method most commonly employed in the inspection of metals is the one involving the tensile test. This test gives values

for the proportional limit, elastic limit, yield point, maximum tensile strength, per cent elongation, and per cent reduction of area. The proportional limit, elastic limit, and yield point are greatly confused values, though within recent years, testing engineers have had a higher regard for the differences than was true with their predecessors. The proportional limit is usually accepted as that value at which the strain ceases to be proportional to the stress, as obtained by plotted results. The elastic limit is likewise looked upon as that value at which the strain ceases to be proportional to the stress, although it is obtained by a release of the load and is the value secured when a strain just begins to manifest itself upon the release of the load. As a rule the elastic limit is somewhat higher than the proportional limit. The modern tendency is to favor the use of the proportional limit rather than the elastic limit. The yield point is a rapid means of finding the load at which the strain ceases to be proportional to the stress. It is usually secured by means of the drop of the beam of the testing machine, or by means of the use of dividers employed for detecting a permanent set. It is the method most frequently used in commercial practice, though it gives values a few thousand pounds higher than does the proportional or elastic limit.

It is highly important in the case of rolled and forged stock, to take cognizance of the direction of the fibers; that is, whether the test sections are in line with, or perpendicular to, the direction of working. Sections taken parallel to the direction of work always show an equal, and usually a higher, reduction-of-area and elongation value, than do the sections taken at right angles to the direction of work. The author is of the opinion that a better criterion of the material under examination can be obtained by transverse-test sections than by longitudinal sections, for if there is any weakness in the stock it will be better disclosed by a transverse- than by a longitudinal-test specimen.

Furthermore, the proper selection of the section from which the test specimen is taken is highly important. Usually, sections near the outer surface are found to possess superior properties to those near the center, for the reason that the outer surface has been in a position to benefit to a greater degree, than has the center from mechanical work and the advantages to be derived from heating and cooling. As an illustration of these statements the results of four tensile tests made on a large forging are given in Table 1. One of the sections in Table 1 is transverse and the other three are longitudinal. The transverse section shows abnormally low elongation and reduction-of-area values, a part of which condition is attributed to the presence of snowflakes in the steel, though had the steel been free from this condition, it is doubtful if the elongation, as measured over two inches would have exceeded 20 per cent, and the reduction of area 3 per cent. It should also be noted that the elongation and reduction-of-area values for the longitudinal section, taken adjacent to the center are low. This is, without doubt, due to the unsatisfactory nature of the material. However, in comparison with these low values one should note the high values of the longitudinal sections, taken near and at the edge, where the metal had received all the possible benefits of work and the improvement due to heating and cooling. The elongation and reduction-of-area values for these two sections are normal and indicative of satisfactory material. Yet, with all the marked difference in the elongation and reduction-of-area values, there is not the same noticeable variation in the proportional limit, yield-point, or tensile-strength values, though, to be sure, the values for the transverse section are under those for the longitudinal. Such differences as are given in this table do not always exist, though it is seldom that transverse sections possess as good properties as do longitudinal sections, particularly with respect to elongation and reduction-of-area values.

TABLE 1 PHYSICAL TESTS ON SPECIMENS FROM LARGE FORGING

Specimen No.	Direction of specimen	Location	Treatment	Proportional limit, lb. per sq. in.	Yield point, lb. per sq. in.	Tensile strength, lb. per sq. in.	Elongation in 2 in., per cent	Reduction of area, per cent
1	Transverse	From center to outer edge	As received	30,000	40,000	63,825	7.0	8.52
2	Longitudinal	Near center	As received	40,000	55,000	76,450	11.5	18.82
3	Longitudinal	Between center and outer edge	As received	35,000	37,500	72,500	32.5	54.93
4	Longitudinal	Near outer edge	As received	35,000	40,000	72,500	32.5	59.59

Impact Tests

Impact tests of various types have been used for a number of years, although more as a research than as an inspection tool. In fact, it is generally conceded that the methods of preparing test specimens for impact tests play so great a part in the results obtained that the test, as such, has to date found little acceptance as a means of ascertaining the quality of material.

The impact tests are of two types. One is known as bending impact, and the other as tensile impact. The bending-impact type has been the one most frequently used, although there is now a tendency toward a greater use of the tensile impact.

Hardness Tests. A considerable number of methods have been devised for measuring the hardness of metals. The three which have to date found the greatest acceptance are the Scleroscope, Rockwell, and Brinell methods.

Scleroscope Tests. The scleroscope depends upon the principle of measuring the height of rebound of a hardened-steel plunger from the surface of the metal undergoing examination. It lends itself to shop inspection, and possibly that is one of the reasons for its rather general use.

Rockwell Tests. The Rockwell-hardness-testing machine has been on the market but a few years, though it is now finding a large field of usefulness. It operates on the principle of pressing a small ball or a diamond cone into the metal surface under a given load. The hardness of the metal being tested is determined by the depth of penetration. This method, due to its adaptability, is finding quite general use.

Brinell Tests. The Brinell test operates on the same principle as the Rockwell and, in fact, is the older of the two methods. The main objection to its extended use is that the stock has to be brought to it. Likewise, because of the size of the ball used in the test, it cannot be used for testing thin sections.

All of these methods, however, provide a means of testing without destroying. They are especially applicable for determining the quality of heat treatment done on parts such as bolts and nuts.

Metallographic Examination

Though metallographic methods have not been employed to any appreciable extent in specifications, yet they are used very extensively in investigations wherein difficulties are experienced with materials in either their manufacture or use. They are invaluable in determining the nature of constituents, grain size, segregation, inclusions, strains, cavities and blowholes, decarburization, and cracks.

Nature of Constituents. The nature of the constituents disclosed by metallographic examination is, of course, dependent upon the materials undergoing examination. In plain carbon steels, the constituents are usually free iron (ferrite) and carbide of iron, either in a free state or in a state of solution in the iron.

Grain Size. The extent to which the grain size of the above constituents may vary is shown in Fig. 4. In this photomicrograph, which was magnified 100 diameters, ferrite (white) is

shown in varying sizes and the carbide of iron, which in this case is present either as pearlite or sorbite (dark), is also of varying size.

Inclusions. This photomicrograph is also interesting in that it shows a sulphide inclusion (the dove-gray constituent) and a crack, as indicated by the dark streak through the center of the photomicrograph. It will be noted that adjacent to this crack the constituent is mainly ferrite and that the same is likewise fine-grained. Without doubt, the ferrite segregation adjacent to the crack is due to decarburization of the metal which has occurred at this particular spot. Therefore, in this photomicrograph the constituents in the metal are developed, grain size is shown, segregation is in evidence, and decarburization is apparent. Usually, however, most decarburization occurs at the surface of metal, though it is frequently adjacent, as in this case, to cracks.

Brass lends itself exceedingly well to metallographic examination. In Fig. 5 is a photomicrograph of Muntz metal in which the two constituents, the alpha and the beta, are shown. In this

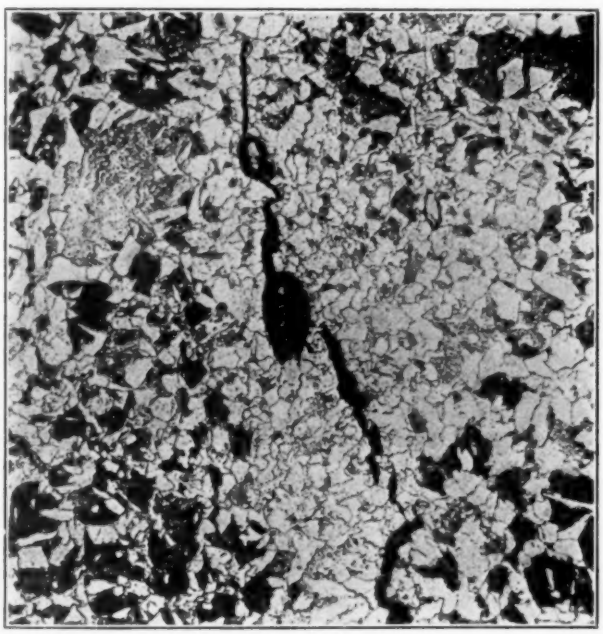

FIG. 4 PHOTOMICROGRAPH OF STEEL SHOWING INCLUSIONS, CRACKS, DECARBURIZATION, ETC.

particular photomicrograph strains are also evidenced by the parallel lines in the various grains.

An entire paper might be written on this subject, but it is believed that enough has been stated to demonstrate the usefulness of this research and inspection method for the examination of metals.

MAGNETIC TESTING

Magnetic testing, although not yet used to any great extent, offers possibilities of being reliable in detecting defects in metals. There are two forms of this test now in use. One consists in subjecting magnetized metals to a bath containing finely divided iron particles in suspension. If a flaw exists in the metal at or near the surface, then the iron particles will be deposited at this point and the defect thus shown.

The second method will discover flaws, not only at the surface, but also in the interior of the metal being tested. This test is not quantitative, but comparative. It consists in placing a perfect specimen in a magnetizing coil and comparing the readings obtained from it with those from exactly similar articles. If a marked variation in readings is obtained, then it is assumed that some foreign material or cavities exist in the section.

X-RAY EXAMINATION

The X-ray method of examining metals is one of rather recent origin. It has been used largely for the inspection of blowholes and sandspots in castings. In fact, the most notable use of the X-ray for this purpose is in connection with the examination of the high-pressure castings for the Weymouth station of the Edison Electric Illuminating Company of Boston. It is the author's understanding that every one of these castings has been examined by means of the X-ray, and that a considerable number of those initially presented for acceptance were rejected because

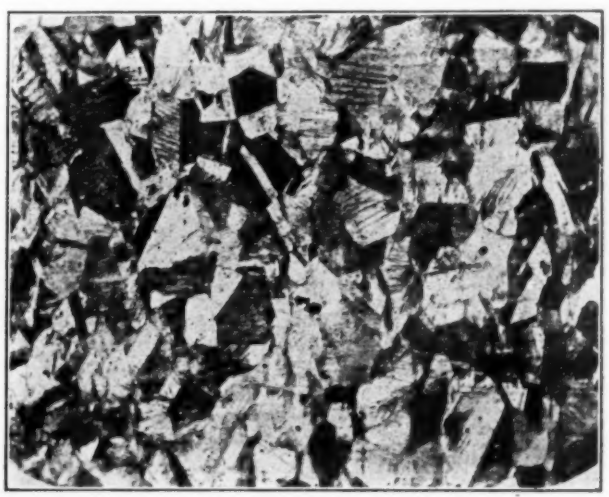

FIG. 5 PHOTOMICROGRAPH OF MUNTZ METAL IN STRAINED CONDITION

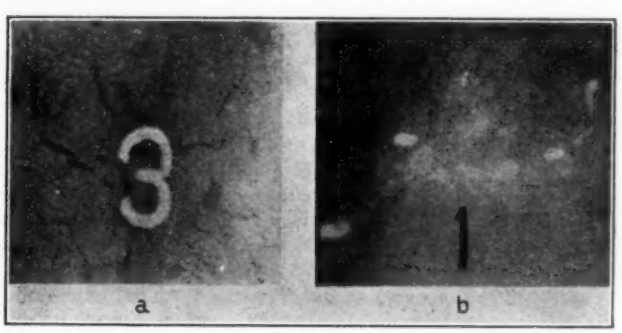

FIG. 6 RADIOGRAPHS OF CAST STEELS
[(*a*) At left, internal cracks; (*b*) at right, blowholes.]

of the presence of blowholes, sandspots and cracks in vital sections. A typical X-ray photograph disclosing some of the above conditions is given in Fig. 6.

In view of the fact that with present equipment it is not now possible to examine sections appreciably over two inches in thickness, it must be recognized that this method of examination is subject to limitations. However, with the development of tubes with higher voltage, it will be possible successfully to examine greater thicknesses of metal.

Another use of the X-ray which is of more recent origin relates to the detection of strains. When a section of metal is examined by the pinhole method, the resultant pattern is made up of con-

centric rings or of spots or striations brighter than the connecting segments. When the pattern is composed of concentric rings, the metal is strain-free [see Fig. 7 (*a*)]. When it is composed of spots or striations brighter than the connecting segments, the presence in the aggregate of large crystal grains or a preferred orientation of the crystal grains (indicative of strains) is manifest [see Figs. 7 (*b*) and 7 (*c*)].

This method of examination was employed on a turbine shaft, which was found to be in a strained condition, and patterns similar to those shown in Figs. 7(*b*) and 7(*c*) were disclosed.

Strain Determinations

It is not always simple to detect the presence of strains in metal, except in cases where the strains are excessive and produce actual rupturing of the crystals. Where such a rupture has taken place, the tensile tests, hardness tests, and metallographic examinations will disclose strains, as well as will the magnetic and X-ray methods. In some cases it is possible to get some criterion of the amount of strain existing in a metal by actual stress measurements. This method was employed in the case of a disk from a turbine shaft which was examined in the "as received" condition and a similar disk after it had been annealed at 1550 deg. fahr. (843 deg. cent.) for the purpose of relieving the stresses. The resultant changes in the amount of the stresses are given in Figs. 8 and 9. Fig. 8 shows the stresses in the disk of metal in the "as received" condition to be of much greater magnitude than those existing in the disk after annealing, as shown in Fig. 9.

Circumferential Stresses at Different Angles

Fig. 8 Disk as Received Fig. 9 Annealed Disk

Heat Testing

A recent development in the examination of turbine shafts is what is known as "heat testing." This test consists in rotating a turbine shaft slowly in a heated chamber. Various temperatures have been employed, although at present most turbine shafts being thus examined are heated to a temperature of approximately 400 deg. cent. (752 deg. fahr.). The deflection of the shaft throughout the heat cycle is noted but greater emphasis is placed on the first and second cold readings. If the deflection from the first hot to the second cold reading is, at any point, in excess of 0.002 in., the acceptability of the shaft is questionable. Most shafts during the heat-test cycle show a movement greater than 0.002 in., although the movement from cold to cold, as stated above, should not be in excess of 0.002 in. A typical turbine-shaft test report is given in Fig. 10, and the set-up for this test is given in Figs. 11 and 12.

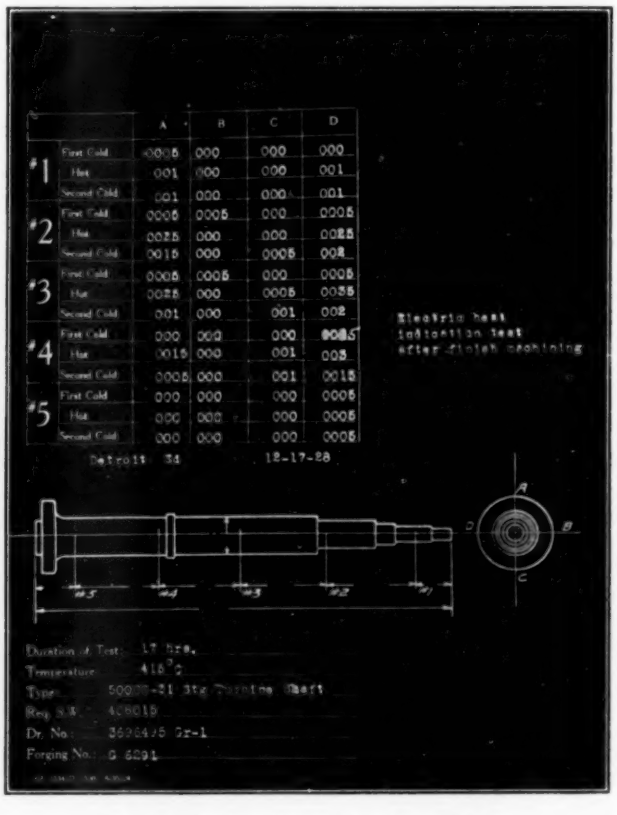

Fig. 10 Turbine-Shaft Heat-Test Report

Fatigue

Within recent years, a considerable amount of interest has been manifest in determining the fatigue characteristics of metals. The outstanding investigations in this country have been under the direction of Professor Moore at the University of Illinois. The larger builders of turbines in the United States have financed a considerable amount of this work, inasmuch as they desired a knowledge of fatigue characteristics of vital parts in prime movers. The results of Professor Moore's work are available through the University of Illinois' bulletins. These, summarized in the briefest of terms, show that the endurance limit for cast iron is about 35 per cent of the tensile strength, the endurance limit for cast steel is about 42 per cent, and the endurance limit for rolled and fabricated steel is about 50 per cent of this strength.

Corrosion

The engineering profession would enthusiastically welcome a short-time corrosion test which would disclose the respective abilities of the metals under consideration to resist corrosion. To date no single test has been developed, which adequately fulfills this purpose. Of the numerous methods which have been

employed for determining the relative resistances of various metals to corrosion, one finds both still and turbulent tests. It seems, however, that something is lacking in the case of all. The greater emphasis is, in consequence, placed on experience rather than on the results of any single test.

Corrosion-Fatigue

The corrosion-fatigue method of testing differs from the usual fatigue test in that the specimen is subjected to the influence of a corroding medium simultaneously with the repeated stress. This, test, although of rather recent origin, is finding wide use and is giving interesting results. Apparently the combined

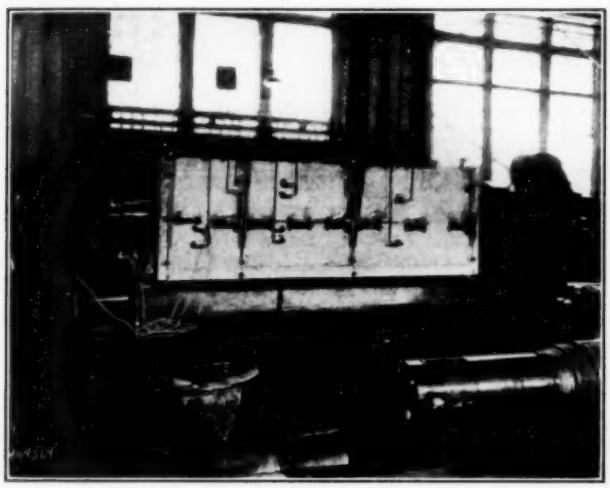

Fig. 11 Set-Up for Heat Tests on Turbine Shafts

action of stress and corrosion produce results entirely different than when these factors are applied separately.

If the stress-cycle graph obtained from this test be compared with one from the usual fatigue test, it will be found that the corrosion-fatigue limit is generally from 40 per cent to 90 per cent of the usual fatigue limit.

High-Temperature Tests

With the trend toward the use of higher operating temperatures in central stations, more information on the properties of metals at elevated temperatures than the central stations now have, is required. Not only should one have information with regard to the properties of metals at elevated temperatures as determined by short-time tests, but likewise information should be obtained with regard to the so-called "creep" characteristics.

Within the past few years a considerable amount of work has been done, both in this country and abroad, on this subject. The field, however, is so new and the number of alloys and the temperatures at which they should be examined are so great, and the time required for a single creep test is so long that the surface of this matter has hardly, as yet, even been scratched. These characteristics are being studied ably by a joint committee sponsored by The American Society of Mechanical Engineers, and the American Society for Testing Materials. Also a considerable number of laboratories have undertaken independent investigations, though many of these laboratories are carrying on activities in cooperation with the above mentioned joint research committee.

The properties of metals at elevated temperatures has been studied extensively in the laboratories of the University of Michigan for the past five years, as the result of grants, that have been made to the University by the Detroit Edison Company. The findings have been published from time to time and are consequently available to the public. Some selected data which have been obtained are given in Figs. 13 to 16.

Fig. 13 gives the data obtained by short-time tensile-strength tests on a 0.13 per cent carbon steel. These data are submitted for this steel, in view of the fact, that it is used so extensively in power plants. It does not possess outstanding properties at elevated temperatures, however, and for that reason it is being superseded by other grades of steel, when maximum stability at elevated temperatures and maximum resistance to oxidation are desired.

Fig. 14 shows the properties of a 19 per cent chromium, 8 per cent nickel alloy steel, when at elevated temperature, as determined by short-time tests. In comparing the data in Fig. 14 with that in Fig. 13, it will be noted that, within the ranges to which these steels are usually subjected, this high-chrome nickel steel has about twice the strength at elevated temperatures that plain carbon steel possesses, and in addition has a high resistance to oxidation.

Fig. 15 is of an eight per cent chromium, eight per cent tungsten

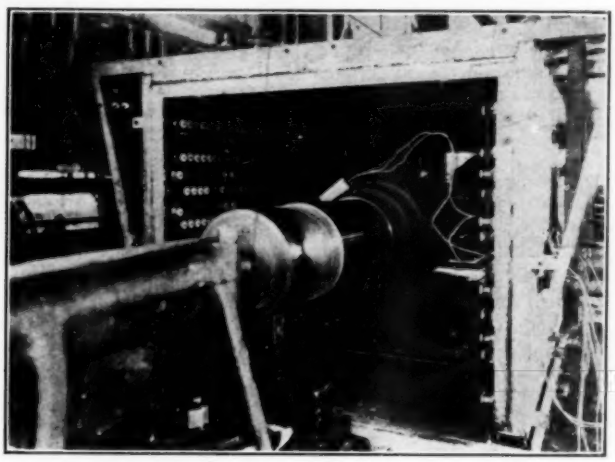

Fig. 12 Set-Up for Heat Tests on Turbine Shafts

steel, when subjected to short-time tensile tests at 1000 deg. fahr. (538 deg. cent.). This figure is included to illustrate the possibilities of heat treatment, since under the conditions of the test a range of proportional-limit values from about 15,000 to 100,000 lb. was secured. Though the 100,000 lb. value was accompanied by negligible ductility, a reasonable degree of ductility is possible by the use of a proper draw. This chart is an example of the possibilities of heat treatment when steels of suitable composition are employed. It is questionable, however, if many steels will show the same response to heat treatment that this particular steel showed. The properties of this particular steel over a range of temperature when tested in an annealed condition are not incorporated here, though they show characteristics, insofar as the proportional limit is concerned, twice those of the high-chrome nickel steel given in Fig. 14.

The laboratory is now engaged in a number of flow or creep tests on various grades of steel. The results obtained on a steel containing 1.43 per cent chromium and 2.19 per cent tungsten are given in Fig. 16. Various loads have been applied to this steel which on a short-time test at the temperature in question showed a proportional limit of 37,500 lb. This steel ruptured with a load of 45,000 lb. at 600 hr. It has been under a load of 40,000 lb. for 1800 hr. and, although to date it has not ruptured, the characteristics of the curve are such that it is expected to break in due time. A further sample was subjected to a load

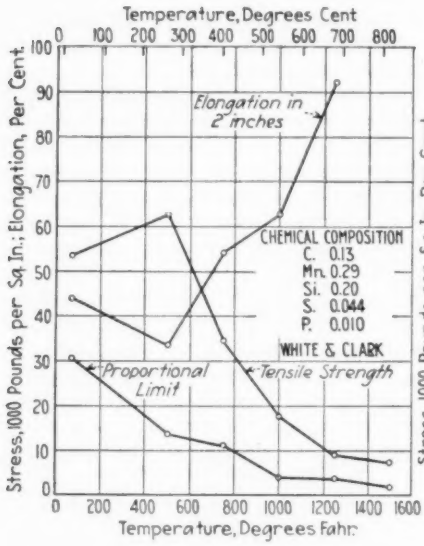

FIG. 13 PROPERTIES OF 0.13 CARBON STEEL AT ELEVATED TEMPERATURES AS DETERMINED BY SHORT-TIME TENSILE TESTS

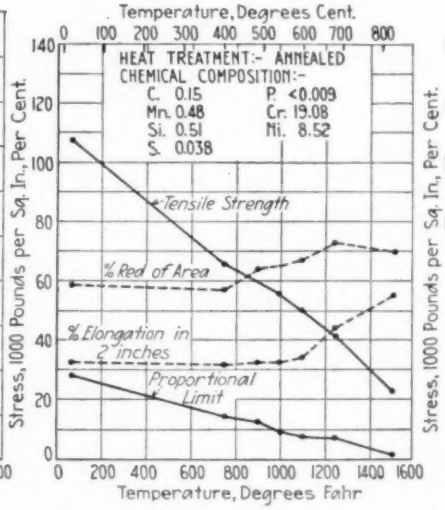

FIG. 14 TENSILE PROPERTIES OF A CHROMIUM-NICKEL STEEL AT ELEVATED TEMPERATURES

of 35,000 lb. but was discontinued after 1320 hr. At the time the test was discontinued the sample had not ruptured, although the curve characteristics indicated that it would break in due time. Further tests are in progress at 30,000 and 20,000 lb., respectively. Each of these tests has been in progress for over 1800 hr., and to date the maximum elongation is under two per cent in the case of the steel subjected to the 30,000 lb. and under one per cent in the case of the steel subjected to the 20,000 lb. load.

CONCLUSION

The foregoing tests and methods of examination are by no means the only ones which may be employed in the inspection of metals for imperfections, defects, and flaws. Likewise, it is recognized that the descriptive details of all of these methods are exceedingly brief. This course was purposely followed in order to keep the paper within reasonable limits, as it was the purpose to give a general birds'-eye view of this field rather than to take up any one item in detail.

The Corrosion Problem as Applied to Power Plants

By H. S. RAWDON[1] and K. H. LOGAN,[2] WASHINGTON, D. C.

WHILE the seriousness of the corrosion problem is generally recognized, it must be admitted that corrosion troubles are of secondary importance, as a rule, rather than primary so far as the main object of the plant is concerned. Nothing in the nature of a systematic study of this problem has been carried out by the Bureau of Standards. Advice on numerous phases of the corrosion problem has frequently been asked, however, and the following discussion relates to only a few of the more salient features of the corrosion problem as it relates both to the inside and the outside of the power plant, that is, to the generating of power and to its transmission.

Corrosion and Water Treatment

The most serious corrosion problems arise in connection with the generation and utilization of steam. It has been known by chemists for years and is now coming to be recognized more generally by engineers that the modern steam boiler is not merely an evaporator wherein takes place the conversion of water into steam, but is in effect an autoclave, the operation of which makes possible the concentration, to a relatively high degree, of impurities initially in solution in the water, together with chemical reactions involving these impurities such that there result very radical changes in the nature of the water within the boiler. The corrosion problem no longer remains the relatively simple one of the corrosion of iron by water, but rather we are confronted with a corrosive attack by substances, the presence of which is ordinarily considered as impossible. In order to ameliorate such conditions, the water is "treated," usually before it enters the boiler, and it may be questioned very seriously whether there is any natural water whatsoever which is entirely suitable for use as feedwater for a boiler without some sort of treatment. The story of boiler corrosion thus becomes inseparably bound up with that of "water treatment," in many respects the two being simply different aspects of the same problem.

Boiler-water treatment, in general, is for the purpose of bettering two conditions, scaling and corrosion. In the past, the former, probably because it gives very tangible evidence of its presence, has received most attention, and too many engineers apparently have been satisfied if the water treatment used controlled this phase of the problem. The other aspect, the control of corrosion, received but scant attention. Conditions have changed, however, and it is quite well recognized now that softening of the feedwater so as to prevent scaling may by no means constitute a complete and satisfactory treatment of the water.

Scaling, that is, the precipitation of insoluble substances resulting from the interaction of impurities present in the water, is usually not considered as a corrosion problem, although the consequences of scaling may at times be more serious than those of simple corrosion. The two problems are not entirely unrelated, however, and so far as corrosion alone is concerned, slight scaling giving rise to a thin, tightly adherent protective coating is to be considered as a distinct advantage.

For convenience of discussion, we may consider "boiler corrosion" as originating from two principal sources, both of which may be regarded as impurities in the water. Corrosion by steam is very limited in extent as compared to corrosion by water and such steam corrosion as does occur is usually reduced very materially by improving the water conditions. Under the influence of the conditions of temperature and pressure prevailing within a boiler many chemical reactions which are ordinarily regarded merely as "paper" reactions occur readily between some of the impurities in the boiler water, giving rise to conditions very favorable to corrosion. A number of natural substances, notably magnesium chloride, present either as such or produced by some preliminary boiler reaction, hydrolyze and actually produce acid in the water, the corrosive action of which upon the steel is accentuated by the prevailing conditions of temperature and pressure. Other salts and also organic impurities may act in like manner. Even traces of the lubricants used may do so. This form of attack may occur almost anywhere in the system but is most severe within the boilers and tubes. The form of the attack, that is, whether it occurs as a gradual and fairly uniform thinning of the tubes, for example, or as surface roughening in the form of pitting and streaking depends in large measure upon accompanying circumstances. The chemical character of the metal, as a rule, does not determine the form or the intensity of the corrosive attack. The only practical means of control of corrosion of this kind depends upon a preliminary chemical treatment of the water so as to insure the complete removal, so far as is practicable, of all those impurities which are either actual or potential corrodents. The subject of water treatment, though still somewhat controversial in a few of its aspects, is well understood and details need not be discussed here.

Of course, in any operating plant the amount of water added daily to the total amount in use within the closed system is only a very small percentage of the total. The greater part of the water is recovered after the steam has served its purpose and is used again. This, of course, serves to reduce enormously the corrosion within the system. Even with water of this character, however, corrosion is not eliminated and the character of the attack which occurs serves to introduce the second type of corrosive impurities in boiler water. These are the dissolved gases—oxygen and carbon dioxide. There is general agreement as to the serious consequences which may result from impurities of this kind. There is, however, decided difference of opinion as to the importance of the role played by oxygen and by carbon dioxide. Speller,[3] an outstanding American authority on corrosion states:

> "Regardless of the theory of corrosion, experience indicates that the oxygen dissolved in water is probably the greatest accelerator of corrosive action in boilers and accessories, and that it should be reduced to a certain minimum depending upon conditions."

On the other hand, Paul,[4] a British authority states: "Oxygen alone, even in the presence of water, has very little if any action

on iron, but—carbonic acid has a very decided corrosive action upon iron." Paul admits, however, that oxygen may accelerate the attack of acids upon iron; he also considers that much of the attack of the carbonic acid is the result of some other carboxylic acid derived from and so closely related to carbonic acid that it is impossible to distinguish between them when they exist in such a dilute state. The reconciliation of such diametrically opposing statements upon such an important subject as this, even though they may seem to be of theoretical rather than immediate practical interest, would be very desirable, indeed. If, as suggested, oxygen in itself is of little or no account but is detrimental only to the extent to which it accelerates the action of some other corrodent which may be present, our concept of the problem may be quite materially modified. It is anticipated that some work now in progress at the Bureau of Standards dealing with the aeration factor in "under-water corrosion" will throw some light upon the relative importance of these two gases when dissolved in water upon the corrosive attack of iron such as occurs within a boiler. Be that as it may, however, it is quite generally admitted, at least in this country, that in addition to the regular water treatment, the elimination of dissolved air from all feedwater (which, of course, removes both oxygen and carbon dioxide) together with a close control of the oxygen content in the water throughout the various units of any steam-generating system is the most efficient and practical way of corrosion control.

Influence of the Character of the Metal

To what extent can the corrosion of boiler and allied equipment be controlled by a wise choice of the material entering into its construction is a question asked repeatedly.

The use of some of the recently developed corrosion-resisting steels is, of course, one means of reducing greatly, if not entirely eliminating, corrosion troubles. Tubes of such steels are now being made commercially, but up to the present their use as boiler tubes has been of decidedly limited extent and is to be regarded still as more or less experimental. Indeed, there seems to be no immediate prospect of any very great extension in this field, and even were such material put into wide use immediately for tubes and other parts, the corrosion problem in equipment already in use would still be a very active one for many years to come.

Variations in the chemical composition of the present-day material for boiler construction, provided, of course, that the material is of good commercial quality such as is required by current specifications, are not the determining factors so far as corrosion is concerned. Results have been published[5] calling attention to the inferior results obtained with low-quality steel. Such cases are exceptional, however. As a rule, serious corrosion is not primarily caused by the composition of the steel used.

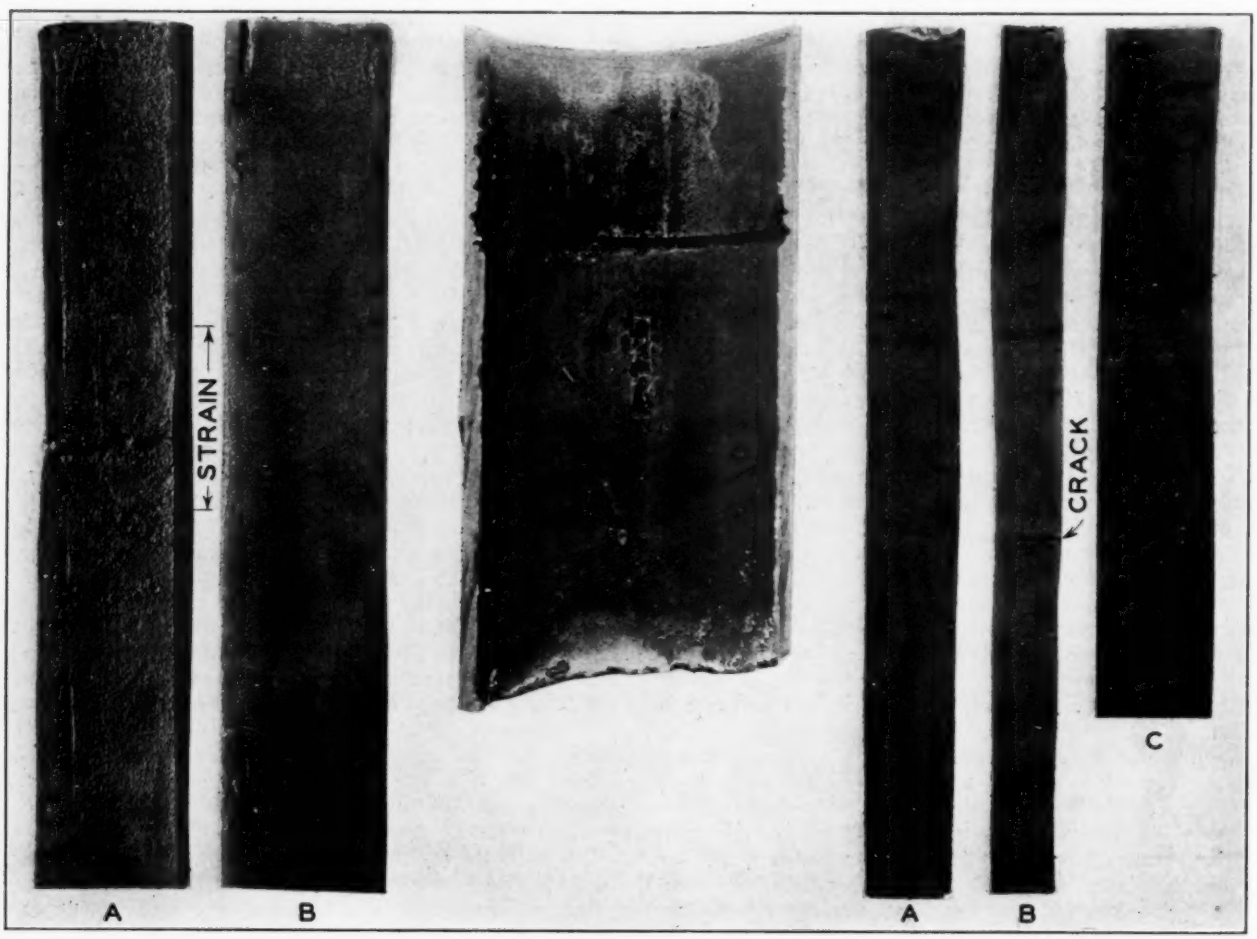

Fig. 1 At Left, Condition of Metal When Annealed End of Tube Was Cold Worked

Fig. 2 In Center, Tube Damaged as a Result of Mistreatment

Fig. 3 At Right, Non-Uniformity of Metal in Tube Resulting From Expansion

[5] G. R. Woodvine and A. L. Roberts, "The Influence of Segregations on Corrosion of Boiler Tubes and Superheaters," *Jl. Iron and Steel Inst.*, 113, p. 219, 1926.

On the other hand, steel, which according to the results of experience should be entirely satisfactory for the purpose, can be made worthless by the "brutal" treatment which it not infrequently receives in the erection of the installation. Corrosion of any metal is greatly accelerated and rendered more serious in its consequences, since it usually results in a localizing of the attack, by any condition which causes non-uniformity in the metal. Cold working by rolling, "expanding," shearing, punching, and the like is one of the most potent sources of trouble from this kind. While excessive cold working is forbidden in some cases, as in the punching of rivet holes, in other cases it is seemingly a necessity, as in the "expanding" of tubes into place. The following cases will illustrate the serious consequences which may ensue from excessive treatment of this kind.

FIG. 4 AT LEFT, CORROSION AT EDGES OF A 3/8-INCH STEEL PLATE

FIG. 5 IN CENTER, DAMAGED END OF A NIPPLE ON A DOWN-TAKE HEADER

FIG. 6 AT RIGHT, CORROSION IN CENTER PORTION OF 3/8-INCH STEEL PLATE

Fig. 1 illustrates the very serious damage resulting from mistreatment of a set of boiler tubes. The tubes failed by localized corrosion a few inches from the end, resulting in perforation within less than a month after installation. The greater part of the tube was in essentially as good condition as at the time of installation. In this particular case, the mechanic who installed the tubes insisted on annealing the ends in a blacksmith's forge evidently to facilitate the "expanding" of the tubes into the end plates. Fig. 2 shows the condition of the metal which resulted when the annealed end was cold worked by the "expanding" process. A zone of very severely deformed metal, as shown by the diagonal strain markings, was formed in that portion of the tube immediately adjacent to the annealed end. The conditions for electrolytic acceleration of the corrosive attack from any source whatever were excellent and the result was the perforation of the tube in this ring of localized corrosion within the course of a few weeks.

In Figs. 3 and 4 is shown the type of corrosion occurring near the edges of a 3/8-in. steel plate and at some distance away from the edge. The strain lines resulting from the shearing of the plate along the edge and extending for a distance of 2 in. into the plate have been revealed by a special etching method. The fact that the course of the corrosion attack has been directed by this strained condition of the metal cannot be disputed. This particular case of corrosion occurred outside of a boiler or heating system. Had it occurred within such a system, however, there is no reason for believing that the character of the attack would have been any different from that shown. In all probability it would have been much more serious than is shown in the figures on account of the favoring conditions of temperature and pressure.

That the foregoing cases are not far removed from actual conditions which may occur in the modern power plant is illustrated by Fig. 5, which depicts a case arising in one of the largest plants of the country in which the corrosion conditions are very carefully controlled and regulated. The illustration shows the damaged end of a nipple on a downtake header which was characteristic of a considerable number of such nipples. The circumferential crack shown, developed after the nipple had been "expanded" into place and the unit put into service. The decided non-uniformity in the working of the metal during the expansion of the tube is apparent from Fig. 6, and the fact that the circumferential crack developed in a zone in which the metal had been excessively rolled is, without doubt, significant as to the cause of the damage.

In the erection of new boilers and accessory units as well as in the replacement of parts in existing plants, the installation of tubes, nipples and the like by cold working the ends (expansion, flaring, and beading) is approved by present-day boiler codes.[6] The seriousness of the damage which may result if the operations are not carried out properly is not usually realized, however. The advisability of using methods which would eliminate such severe treatment of the metal is a matter for serious consideration. Although the damage produced by the cold working may not be immediately apparent and the job may be approved as satisfactory, the conditions may be exceedingly favorable for future trouble, and often all that is required is a corrosive attack

[6] A.S.M.E. Report of Boiler Code Committee, 1918.

of such parts. The only remedy that can be suggested is the old one of "avoiding extremes." Though the cold working may of necessity have to be quite severe, it should be as uniform as possible, both in its operation and in its effect on the metal. Any operation tending to produce abrupt changes in the structural condition of the steel either as changes in the visible structure or that indefinite condition usually referred to as "internal stresses" should be meticulously avoided as potential sources of trouble whenever corrosion is under consideration.

This is particularly true in cases of the so-called "caustic embrittlement" of boiler plate steel, a form of corrosive attack which manifests itself by the formation of cracks in the steel plate which suggest that the metal has undergone a complete change in its properties, from a ductile material to one almost entirely lacking in this characteristic. As a matter of fact, the metal is essentially as ductile as ever. The "embrittlement" has been the result of the action of a corrodent upon the metal while it was under stress. The combination of these two conditions gives rise to the cracking of the metal by the formation of intercrystalline fissuring—a phenomenon which has also been noted with a variety of metals when subjected to stress and corrosion simultaneously. The occurrence of a condition of internal stress such as results from excessive cold working as mentioned previously is very favorable to this type of corrosion.

Information recently published on this subject[7] has served to define quite clearly and unmistakably the conditions under which this form of corrosion may be expected to occur. In the laboratory tests, a stress above the yield point of the steel and a solution of sodium hydroxide of relatively high concentration (300 g. per liter) were necessary in order to produce the effect. An increase in the temperature, however, was found to have the same effect with more dilute solutions. In service, the necessary high stress in most cases is the resultant of the external or service stress and the internal stresses of cold working. The caustic soda results from improper treatment of the water. Although it would appear that this form of corrosion is restricted to certain geographic areas, depending upon the character of the groundwater, the seriousness of the problem is indicated by the recommendations concerning the precautions which should be taken, contained in the Boiler Construction Code for 1926.

Corrosion From Furnace Combustion Products

Corrosion from this source is confined practically to the relatively cooler portions of the furnace systems. The principal combustion products of coal and oil have no corrosive effect whatsoever upon iron or steel at the temperatures prevailing in service. It is the impurities in the fuel, particularly sulphur, to which the trouble can be attributed. Even these products, however, are seriously injurious only to the extent to which condensation occurs. The sulphur in the fuel, upon combustion, gives rise to sulphuric anhydride (SO_3) which may readily combine with other combustion products to form a neutral sulphate which is comparatively harmless. An acid sulphate is often formed and much of the uncombined gas escapes as such without corrosive effect. If the temperature falls to a point which will permit the condensation of moisture, acid is formed. Sooty deposits, if they be present on the inside of the smoke stack or elsewhere, form excellent absorbents for these corrosive gases and also serve to hold the condensed moisture in intimate contact with the metal. Corrosion of these parts, therefore, represents the idle periods of the plant rather than the opposite. Advice concerning the proper steel to use for withstanding this condition has been asked often. The use of special corrosion-resisting steel of the stainless type is, of course, beyond consideration. There is no simple and sure preventive for this type of corrosive attack. Anything of the nature of a paint coating is to be considered only as a palliative and of short-lived usefulness. While no recommendation based upon service can be made, it would seem that, inasmuch as the corrosive attack is essentially that of an acid, steels which have shown themselves to have superior acid-resisting properties under other conditions should, in general, be most suitable for construction work of this kind.

Corrosion Problems Outside the Plant

Distribution of power is attended by corrosion problems as varied and difficult as those encountered within the power plant. If overhead transmission lines are used, both the lines and the towers may be exposed to the attack of corrosive vapors.

Under most conditions copper exposed to the atmosphere develops a thin oxide coating which protects it from further corrosion. When the atmosphere contains ammonia the corrosion is accelerated. Corrosion of copper in an atmosphere containing salt, such as is encountered along the seacoast, is also greater than where the air contains moisture only. Serious corrosion of copper wires and cables occurs occasionally when these are exposed to atmospheres containing large quantities of smoke, as at railway crossings and in the neighborhood of industrial districts.

It seems probable that the presence of sulphur compounds, carbon dioxide, and carbon monoxide in the smoke is harmful. Hard copper is said to corrode more rapidly than soft copper, and stressed copper more rapidly than when not under stress. It is to be expected, therefore, that the corrosion of long-span transmission lines would be somewhat greater than on short-span lines, other conditions being equal.

The use of aluminum instead of copper for transmission wires appears to reduce corrosion problems to some extent. Under most conditions the oxide film which forms rapidly on the surface of aluminum protects the metal from further corrosion. Embrittlement of aluminum wire exposed near the seacoast has been reported. The relative positions of iron and aluminum in the electrochemical series would indicate that the use of an iron core for aluminum cables would set up in the presence of moisture a galvanic potential that would cause the corrosion of the aluminum. Experience indicates that such galvanic action does not occur to a serious extent, and the probable explanation lies in the high resistance of the oxide film on the aluminum.

During the World War, cables of aluminum were put into wide usage in Germany to replace copper and recent reports by a committee of the Deutsches Gesellschaft für Metallkunde on these installations constitute the most recent information on the subject. On the whole, aluminum overhead conditions appear to be satisfactory. In a great many cases no deterioration was found. In other cases serious sagging had occurred and restretching was necessary. Corrosion, when found, was confined almost entirely to the junctions with other metals, but by proper protection of these junctions, it can be eliminated. According to another report, no pronounced corrosive attack was found provided the aluminum was at least 99 to 99.3 per cent pure. It was concluded that the fear of electrolytic corrosion between the aluminum wires and the steel center is groundless.

Transmission towers and fittings are usually protected against corrosion by a coating of zinc. The protection thus obtained results from two causes, the mechanical protection of the zinc layer and the electrochemical action between the zinc and the underlying steel at points where the latter is exposed. Zinc, when exposed to the atmosphere, corrodes slowly on account of the film of zinc oxide that is usually formed. On the other hand, a zinc coating is seldom entirely free from pinholes and thin spots

[7] S. W. Parr and F. G. Straub, "Embrittlement of Boiler Plate," A.S.T.M. 27, Pt. II, p. 52, 1927.

and the potential of zinc with respect to steel is such that the latter is protected at the expense of the former.

Zinc corrodes rather rapidly when in contact with some of the alkali soils of the West and when in contact with wet cement. This results in the corrosion at the base of towers in some regions, but the trouble is not general. Guy wires used for the support of transmission poles are subject to corrosion especially just below the ground line. Heavily galvanized wires resist the action of acid soils considerably better than uncoated steel wires or rods, but in certain regions where the soil is high in salts corrosion of both zinc and steel is rapid. The Bureau of Standards is making a rather extensive study of the action of soils on galvanized and black steel buried underground. The data obtained apply more directly to completely buried materials than to metals such as culverts and guys which are more subject to atmospheric corrosion.

When the power line is put underground, quite a different set of corrosion troubles are encountered. Such lines are usually encased in lead sheaths and are placed in ducts, although lead is not always used and some cables are buried directly in the earth. The Bureau of Standards Soil-Corrosion Investigation includes specimens of parkway cable intended for burial in the earth for street-lighting service and specimens of chemical and antimony-lead cable sheaths. The specimens of parkway cable consist of a rubber-covered conductor encased in a lead sheath. This is wrapped with a layer of jute impregnated with a bituminous material, two layers of galvanized steel tape applied spirally in opposite directions and an outer layer of impregnated jute. The specimens examined most recently had been buried approximately six years. In many soils the steel tape was rusted seriously and a white corrosion product appeared on the lead sheath, but no indications of failure of the sheath have been discovered.

Specimens of lead-cable sheath buried for the same period were removed from 27 soils. In 26 of these locations the antimony lead, such as is now commonly used for telephone-cable sheaths, showed greater loss of weight than the specimens of chemical lead. The average rate of corrosion of the former material was 0.144 oz. per sq. ft. per year, while that of the latter was 0.085 oz. per sq. ft. per year, or but little more than half.

About half of the specimens showed pitting. In several soils the pits were quite deep although in most cases the depth could not be measured accurately because the specimens were not straight. In one or two soils the specimens were punctured.

The distribution of the pits seems to depend on the character of the soil. On some specimens the corrosion is nearly evenly distributed while on others only two or three deep pits will appear. This difference in types of corrosion is illustrated in Fig. 7.

These specimens were buried directly in the ground at depths of from two to four feet. Their conditions are such as to indicate that, unless the rate of corrosion due to soil action has been found to be negligible, it is unwise to bury lead-sheath cables directly in the ground. The results of the Bureau's study tend to confirm the results of a somewhat similar study made at Purdue University several years ago.

Sheaths placed in ducts are subject to less serious corrosion on account of soil conditions although it seems probable that some of the cable trouble attributed to stray current electrolysis has some other origin. The structure of lead is more homogeneous than that of steel and the differences of potential between different points on a lead sheath that can be attributed to non-homogeneity of the metal are small, as is the potential difference between oxidized and bright lead. On this account one might expect little corrosion of lead in a soil or a duct line. It has been shown, however, that differences of potential also are caused by differences in oxygen concentration at different points on the surface of a conductor and since a cable sheath is not in continuous contact with the bottom of a duct and since there is seldom contact except on the sides and bottom, excellent opportunities are afforded for corrosion due to oxygen concentration cells if the sheath is covered with a film of moisture as is frequently the case. Galvanic cells are formed also when the cable passes through different kinds of silt in the duct or from silt in the duct to water in a manhole.

Lead sheaths are destroyed easily by stray-current electrolysis on account of their thin walls. The usual method of preventing electrolytic corrosion is to maintain the sheaths negative to the earth by connecting them directly or indirectly to the negative bus of the source of the stray current. This method is effective in preventing stray-current electrolysis, but it occasionally results in another form of corrosion. In case the current flowing toward the cable passes through earth containing a considerable quantity of salt or lime, electrolysis of this material occurs and

FIG. 7 CORROSION OF LEAD IN SOIL

caustic alkali is formed on the surface of the cable sheath. Such a condition is established when salt water from ice-cream freezers is dumped near duct lines or when the concrete surrounding the duct contains lime and cases are known in which serious corrosion of cable sheaths by alkali transported by the drainage current has occurred. Such corrosion can be identified frequently by the colors of the corrosion product, for while the lead carbonate which usually forms on a sheath is white or gray the corrosion product formed by alkali in the presence of moist air is red or orange in color.

A rather peculiar case of corrosion was observed some time ago on the sheaths of a midwestern power company. Along the bottom of these sheaths was a ridge of soft lead, while on the sides was a thick crust of brick-red corrosion product. The best explanation for this condition that could be found was that since the sheaths were heavily drained electrically, alkali was deposited at the surface of the sheaths at points where the duct line contained water. This alkali dissolved some of the lead during the nightly periods of shutdown of the street-railway

system and at the surface of the water the red corrosion product was formed while on the bottom of the cable lead was deposited from the solution during the daytime by current flowing to the sheath.

A similar case of red alkali corrosion product was observed more recently in an eastern city where the cables were laid in a monolithic concrete duct line. It appears, therefore, that while it is necessary to drain cables electrically in order to protect them against electrolysis, it is wise to limit this drainage in order to minimize alkali corrosion as well as to avoid endangering neighboring structures.

Theoretically it is possible for reinforced concrete building structures to be injured by stray electric currents passing from the reinforcement to the concrete. Actually we know of no well-established case of the failure of reinforced concrete on this account. There are numerous cases of the failure of reinforced concrete on account of the rusting of the reinforcement, but such failures are usually accounted for by poor materials, the addition of salt to the concrete, or the placing of the reinforcement very near the surface of the concrete. There is very little probability that leakage of electricity will result in injury to power plants or other structures.

Use of Power in Chemical Industries

By CHARLES M. A. STINE,[1] WILMINGTON, DEL.

EXCLUDING the metallurgical industries, the total increase in value for material that passed through chemical industries was placed at $6,655,575,000 by the 1925 Bureau of Census Reports, and the value of the products of American industries which have a chemical interest, was $21,000,000,000. Power is conceived by Leonard H. Davis, as potential power existing in coal, oil, gas, or other fuels and in water capable of power development, as actual power such as mechanical or electric, and as utilized power which has been industrially transformed into commercial products. It is interesting to know that fertilizer can be shipped from Muscle Shoals to Saginaw, Mich., at a cost of 1.47 mills per kw-hr. whereas it would cost 1.5 mills per kw-hr. to transmit electricity 100 miles. As further examples of the consumption or transformation and of the distribution of power in the chemical industries, the explosives manufactured in 1925 contained 835,000,000,000 B.t.u., while the industries used over 4,930,632,000,000 B.t.u.

Because of lack of power development, in China 85 workers out of every 100 are needed for producing the necessities of life, whereas in the United States, due to the developed power per capita, 15 workers produce the necessities of life, while the other 85 are left for producing the luxuries and other items making life in the United States so desirable. During a ten-year interval in which progress was hindered by the World War, the power consumed per worker in the production of glass increased 50 per cent, of cement 38 per cent, of leather 25 per cent, and of lime 133 per cent. The importance of the use of power and of mechanical mass production in the economic life is shown by the fact that American industries, using $1^1/_2$ times as much horsepower per wage earner as British industries, turn out $2^1/_2$ to 3 times the production; and similar comparisons might be drawn between the chemical industries.

According to the 1925 Manufacturers' Census Report, those industries concerned with the changes in composition or properties of the raw materials, namely, the chemical industries, used 7,841,875 hp., while the mechanical industries used 6,525,016 hp. The 1927 report listed a total of 6710 chemical and closely allied manufacturing plants as reporting, while about 1400 plants did not report. The aggregate horsepower of the power-generating equipments installed in the 6710 establishments was 2,802,388 hp., and they burned 87,724,883 short tons of bituminous coal and 2,150,018 long tons of anthracite. Of the total primary horsepower, 706,022 consisted of steam engines and 793,784 of steam turbines. Figuring an average of 3.7 lb. of coal per hp-hr., the tonnage of coal burned in hp-hr. amounts to 5,528,600 hp-years for these 85 per cent of the entire establishments of the chemical and allied industries. Moreover, there are no figures at hand showing the amount of power purchased by these establishments. In 1925 the chemical industries spent $200,000,000 for coal, excluding thus the power purchased or the value of water power utilized.

In fifteen large chemical industries from two to seven times as much fuel is burned for process heating as for power generation, according to 1925 figures. One dye manufacturer uses 96 per cent of the steam generated at his plant for process work, 4 per cent for plant heating and purchases all electric energy. Another chemical plant, with an average daily capacity of 1,000,000 lb. of steam in 24 hours, 7 days per week operation, generates its full power load, uses 50 per cent of the live steam directly in processing, 25 per cent for power generation and the remaining 25 per cent for operating pumps, compressors, etc., and the exhaust steam is used for heating buildings and feed water. An explosive manufacturing plant uses 19,000 lb. of steam per day for power generation, 4000 lb. for refrigeration, 4000 lb. for compressed air, and 33,000 lb. for process heating. In a glass manufacturing plant 1,250,000 lb. of steam per day is generated, 30 per cent being for power generation, 25 per cent for process heating and 45 per cent for steam-driven equipment such as compressors and pumps.

The manufacture of synthetic ammonia for the year 1928 amounted to about 25,000 tons, and the fixed nitrogen production of the entire world to about 2000 tons a day or 1200 million lb. a year, which called, according to estimate, for a utilization of a minimum of two and one-half billion hp-hr., the Claude, Casale, Haber-Bosch, and less important ammonia processes being used. In the manufacture of synthetic ammonia, the direct synthesis of ammonia by the manufacture of hydrogen from water-gas consumes somewhere between 3.5 and 5.0 kw-hr. per kg. of fixed nitrogen; in the case of electrolytic hydrogen it is from 15 to 20 kw-hr. and in the case of the arc process as much as 75 to 80 kw-hr., so that the process of producing hydrogen from coke or coal is economically sound. The Linde hydrogen-nitrogen process for the production of fixed nitrogen by the Casale system yields nitrogen at a power cost of only 5.66 kw-hr. per 1000 cu. ft. There is also considerable requirement of power in the liquefaction of air to separate from it the nitrogen, oxygen, helium, argon, neon, krypton and xenon for commercial uses. The manufacture of argon, for example, requires a pressure of 4000 lb. per sq. in. and a temperature reduced to 220 deg. fahr. below zero, the temperature within the still being maintained at about 300 deg. fahr. below zero. In 1925, 1,693,460,000 cu. ft. of oxygen was produced by liquefaction, having a value of about $15,000,000, while the value of the other gases produced from the air was upward of $1,000,000. An interesting development is the production of a refrigerant, solid carbon dioxide snow, by the compression of carbon dioxide with subsequent cooling by expansion, using carbon dioxide from coke or by-product carbon dioxide.

The electrochemical and electrometallurgical industries are the industries most dependent on water power, which consume about 1,250,000 hp. and mostly from hydraulic turbines. An average of about 200,000 kw. capacity is probably a fair estimate of the world's annual purchase of direct current machines for electrolytic service. In the paper and pulp industries one plant generates 750,000 lb. of steam per day, uses 485,000 lb. of live steam for power generation, 175,000 lb. of live steam and 200,000 lb. of exhaust steam for heating buildings, etc. A large book-paper plant generates 5,300,000 lb. of steam per day, 400,000 lb. being for power, and 4,200,000 lb. for process heating. From 2500 to 40,000 gal. of water per ton of paper products is required in manufacturing paper and pulp, and 2 lb. of water must be evaporated for each pound of pulp or paper dried, or 2 tons of coal are needed for every ton of paper.

One petroleum plant uses 11,200,000 lb. of live steam per day and 1,300,000 lb. of exhaust steam for power generation, 9,800,000 lb. of live steam per day and 8,200,000 lb. of exhaust steam for

[1] Chemical Director, E. I. du Pont de Nemours & Co., Inc., Wilmington, Del.

Abstract of an address delivered at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

process heating, and 450,000 lb. per day of live steam and 2,200,000 lb. of exhaust steam for heating the buildings. Another refinery uses 7,000,000 lb. of live steam per day for power generation, 89,000,000 lb. of live steam, and 13,000,000 lb. of exhaust steam for process work, including pumping, more than one gallon of water being converted into steam for every gallon of crude oil. Pumping, grinding, filtering, drying, mixing, centrifuging, combustion, and heat transfer are operations required in the paint, varnish, lacquer, and other chemical industries, the soap industry using one ton of coal to make one ton of soap. A valuable development in the chemical industry is the use of the by-product steam of power generation for process heating.

It is probably not too much to say that the American standard of living is dependent for its continuance largely upon our ability to further perfect our methods for the development of cheap power, after having made comparisons in cost of labor and cost of power in respect to competition in the field of chemical products between our country and foreign countries. The chemical engineer is bound to have an increasing part in the efficient utilization of the resources of fuels. He is interested in the methods of production of the power as well as in the ultimate costs of the finished, delivered power.

X-Ray Applications in Every-Day Engineering Problems

By GEORGE L. CLARK,[1] URBANA, ILL.

APPLICATIONS of X-rays are becoming so numerous and important in the daily life of every man that it seems of interest to take brief account of some of the achievements and possibilities of this great research agent.

What are these remarkably versatile X-rays? In every respect they are identical with ordinary light except that the wave lengths are only $^1/_{10,000}$ as great, on the average, as visible light. They are electromagnetic vibrations propagated as waves or as tiny bundles of radiant energy through space without transference of matter. X-rays, the cosmic rays which come from the far reaches of the universe and are able to penetrate 18 ft. of lead, the gamma rays from radium, the ultra-violet, infra-red, and radio waves are all like light except in wave length.

In all this great range of rays, from those only $^1/_{100,000,000}$ cm. long, to those hundreds of meters long used in radio broadcasting, the human eye is sensitive only to that extremely narrow band we call light. Because X-rays are shorter than light it follows that they are more penetrating, that they should pass through materials opaque to light, and that they should be associated with a finer subdivision of matter than is apparent by examination in visible radiation. As a matter of fact, we find that X-ray wave-lengths are of the same order of magnitude as the sizes of the ultimate atoms of all material things. By means of X-rays as the messenger, therefore, the knowledge of the true unit building blocks of matter and their interrelationships are gained.

Metal castings may be diagnosed for presence of internal gas cavities, sand and slag inclusions, pipe cavities, porosity, cracks, and metal segregation. The result is perfectly sound castings where the safety of human life is demanded such as in high-pressure power plants, oil stills, and aircraft motors. The greatest X-ray laboratory devoted to this subject is located at the Watertown Arsenal in Massachusetts. Some of the other radiographic applications in this country are the examination of welds for soundness, of coal for slate and ash, of minerals for classification, of golf balls for symmetry of the center, of cord tires for adhesion of rubber, of reclaimed rubber for nails and foreign matter, of shells and grenades for proper filling of explosive, of wood particularly when used in airplanes, for wormholes cracks and knots of trees and telephone poles for interior soundness, of logs in veneer manufacturing plants for imbedded nails liable to ruin cutting blades, of walls for hidden pipes and wires, of metal pipes and capillaries for measurement of internal diameters, of clogged gasoline lines, of radio tubes for proper position of electrodes, and of glass and pigments.

If a strip of iron is etched slightly with acid, the crystal grains are seen easily with the eye, each appearing perfectly homogeneous. Under the microscope, however, a homogeneous grain may show a heterogeneous fine structure. One of these microscopic units with X-rays indicates that it in turn is built up of ultimate crystal units. What is this unbelievably small unit crystal of iron—this block which is combined with an enormous number of others just like it to give the crystal grain which the human eye may see? We know it to be a tiny cube with an atom of iron at each corner and one in the center; the cube measures less than $^3/_{100,000,000}$ cm. on a side; it is the last thing that is still solid crystalline iron—its properties are those of the visible crystal grain of iron—it is the ultimate iron. Other metals such as tungsten and chromium have the same type of ultimate cubic architecture, but these have different sizes than that which characterizes iron. Still other metals such as the ductile aluminum, silver, and gold have a different type of crystal unit. The fact that this unit crystal is built in so orderly and perfect a fashion explains why X-rays yield such remarkably fundamental information.

X-rays lead us from information concerning the interior gross structures of material to knowledge of ultimate fine structures far beyond the power of any microscope. Nature has built all solid crystalline matter according to so orderly a plan that all the atoms and molecules are on parallel planes which are spaced at distances which compare with the short wave lengths of X-rays. Thus crystals, each one in its own definite characteristic fashion, diffracts X-rays just as finely ruled lines on glass diffract ordinary light. We are able to deduce the structure and size of the unit crystal cell serving as the architectural pattern which upon multiplication in all directions builds up the visible crystal. We determine the size, shape, and constitution of the single brick in an apparently homogeneous structure hundreds of millions of times larger. If this brick is deformed slightly by stress the X-rays patterns indicate it. If the material is a single crystal grain with all the tiny ultimate units perfectly aligned, or if it is a powder or aggregate of small grains chaotically heaped together, or if it is an aggregate with the grains oriented in a common direction as in asbestos or cotton fibers, or metal wires or rolled sheet, the X-ray patterns are perfectly characteristic. There are some 20 different types of fundamental information which may be ascertained from diffraction data, and these account in the realest sense for the actual behavior of materials.

So rapid has been the growth of this chemical science of X-rays that more than 500 kinds of crystals have been singularly analyzed ranging in complexity from common salt or aluminum to very complex silicate minerals and organic compounds. Prior to X-ray analysis the chemists knowledge of the solid state was decidedly limited and he strove to avoid this by melting or dissolving the substance before he attempted to do anything. Now he is trying to crystallize everything and determine the structure as our knowledge advances of the amazingly orderly forces which hold atoms and molecules in marshaled array in space. We are now thoroughly familiar with the crystalline architecture of most all the useful metals and alloys. We understand that the ductility and malleability of aluminum, copper, gold, silver, and the brittleness and hardness of chromium, tungsten, or molybdenum are properties directly related to the plan of building in the unit crystal. We can picture exactly from the X-ray data how zinc atoms elbow their way into the little unit cubes of copper and literally push the sides of the tiny structure apart to form brass. So, the whole problem of the constitutions and range of stability of metals and alloys is coming to be known and properties predicted definitely. In addition, the processes and results of fabrication and heat treatment, lead us to a new industrial science. When a metal is drawn into a wire or rolled

[1] Professor of Chemistry, University of Illinois, Urbana, Ill.

Abstract of paper presented at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

into a sheet, remarkable changes occur in X-ray patterns. The mechanism of working may be quantitatively deduced; for example, in an aluminum wire every tiny ultimate cube is turned so that the cube diagonals are all parallel to the wire, axis, or in a copper sheet all the little cubes with one atom of copper at each corner and one in the center of each face lie with a cube face in the plane of rolling. All such worked metals are obviously characterized by strongly directional properties, and it is the task of heat treatment to remove this condition, particularly if the metal is to be formed into useful articles. There is no more remarkable achievement of X-rays than the commercial control of annealing which will assure a uniform product of highest quality upon the basis of absolute knowledge of recrystallization processes. With such a control a technique of manufacture inevitably results which involves no greater expense or difficulty.

It is a common belief that heat-treating metals for a long time at low temperatures in order to remove strains and directional properties achieves the same results as annealing for a short time at high temperatures. New X-ray studies show that this precept is far from true, particularly for silver and copper. In the presence of five-hundredths of one per cent of iron the recrystallization temperature of silver is brought down to room temperatures, and all silverware under these circumstances would soon be ruined. As a matter of fact this amount of iron is always present except in very specially refined silver, but its deleterious effects are always offset by the presence of the same slight amount of copper. This curious metallurgical fact, as ancient as silver itself, has come to light after hundreds of years through the agency of X-ray analysis.

Cast steel is characterized by an X-ray pattern which clearly shows a condition of great internal strain, even though it may be free of gross imperfections. The purpose of heat treatment is to relieve this condition, but until now there has been no control method sensitive enough to discover the best annealing technique so that the ideal structure may be obtained. From X-ray data alone it was possible in this laboratory recently to plot regions of equal strain in a large casting, and thus to predict where it would fail or how it should be annealed properly. As a result several large manufacturing plants have based their annealing methods on this scientific research basis instead of empiricism. Similarly, we might describe X-ray studies of the cause and prevention of transverse fissures in steel rails, which have caused so many wrecks, the proper manufacture of electric steel with lowest magnetic loss, the proof of the great superiority in terms of ultimate structure of welds made in a hydrogen atmosphere as compared with the ordinary arc method, the desired structure for aluminum alloys, the changes during metal fatigue, and many other problems. Every metal product which finds usefulness in our daily life is a potential subject for X-ray fine-structure research and then only a single possible field has been touched.

A few representative X-ray studies on non-metallic materials now being made in the laboratory at the University of Illinois and elsewhere include:

Asbestos. A clear differentiation between numerous varieties appearing outwardly the same but differing widely in practical behavior and a method of identifying the mines from various specimens of the same type.

Lime. Discovery of the cause of plasticity and methods to render non-plastic lime useful.

Enamels and Pigments. Composition, particle size, and crystallization as functions of covering power, tint, wear, etc.

Lubrication. A definite knowledge of mechanism in the lining of long grease molecules in successive layers like a pile of carpets, with the pile of each carpet representing the molecules which slide over each other instead of one metal surface on another.

Waxes, Soaps, Alcohols, and Other Organic Compounds. The analysis of crystalline structure, actual measurement of the sizes of molecules, the testing and verification of the structural theories of organic chemistry, as for example, absolutely definite proof of the benzene ring.

Ceramic Materials. Constitution transformations and internal strains as in spark plugs.

Rubber. The discovery that this remarkable substance develops a crystal-like fiber pattern upon stretching (as does also a muscle fiber), analysis of which removes much of the conjecture from our scanty knowledge; the development of a method of stretching rubber 10,000 per cent to threads insoluble in the solvents which usually dissolve rubber easily; and the establishment of these unique criteria never yet found in artificial or synthetic rubber.

Textiles. The behavior and constitution of the crystalline threads of cellulose and silk, and the deduction of a vastly improved type of rayon.

Catalysts. The deduction of optimum constitution and particle size for high-pressure synthesis of methanol and other products.

Gelatine, biological structures, road materials, paints, nitrocellulose explosives, lacquers, and transparent wrappers are studied by X-ray methods. The cause and prevention of cracking of patent leather, liquids of all kinds, carbon, cement, adhesives, paper, the tiny objectionable stones in pears, electroplating, food products—all of these and many more materials are yielding their secrets of constitution and of their good or bad practical behaviors in every-day use to the searchings of X-rays.

Synchronous Selector Supervisory Equipment and Telemetering

By C. E. STEWART,[1] PHILADELPHIA, PA.

AMONG the recent developments of centralized control of electrical energy are the supervisory and telemetering equipments which automatically give the dispatcher of a system load a continuous picture of the power-circuit conditions, and provide him with means for controlling them. The effect is equivalent to the actual removal of the substation switchboard to the power dispatcher's office, however, with only the control keys, indicating lamps and meters in view and concentrated on but a small panel, so that a large number of substations may be supervised. This paper is devoted to a description of one of the latest types of automatic supervisory equipments, its application to electrical power supervision and its functioning with automatic telemetering equipment. The supervisory equipment is designated as the synchronous selector type and is accurate in its selective features, highly speedy in selection, provided with an inherent "check-back" feature for checking the selection before performing the operation. It performs selection, operation, and indication over a maximum of four telephone or No. 19 B. & S. line wires between the dispatcher's office and each outlying station, requires no duplicate line wires for a moderate-sized substation, registers any change in the position of one or more supervised units promptly at the dispatcher's office by both visual and audible means, establishes a control circuit for operating any supervised device simultaneously with the closing of the dispatcher's control key, registers the correct indication simultaneously in the dispatcher's office when the dispatcher operates a substation unit, notifies the dispatcher automatically when the system is not operating due to open or shorted line wires, loss of operating potential and other major troubles. The individual devices are of standard design mounted on panels of the usual switchboard design.

The system employs very simple electrical circuits and very few common devices which is an aid in operation, inspection, and maintenance. A system for supervising 46 units contains as the common equipment the following electrically operated devices: at the dispatcher's office 3 selector switches, 11 small relays, and an alarm bell; the substation circuits connect to 3 selector switches and 7 relays, five of these relays being used for their convenience only, and four of the selector switches being used to supervise that group of substation units between 23 and 46 and not essential to units 1 to 23, so that basically the system consists of 2 selector switches and 13 relays, all other devices being added in accordance with the control and indication circuit requirements, or to facilitate circuit inspection, adjustments, and application. Circuit failure is guarded against by a minimum number of series contacts, two contacts in parallel on the smaller types of relays, increased operating voltage, and use of protective resistors in the battery circuits to selectors and relays.

The standard panels, completely wired with numbered terminal blocks for all external circuits, are 24 in. wide by 90 in. high for control of 46 substation units, 16 in. wide for 23 units, 32 in. wide for 69 units, and for 92 substation units there are two 24-in. panels. The dispatcher's supervisory panel contains the selector switches and common relays, control-power switches, fuses, line-wire test jacks, keys and indicating lamps, alarm bell, and meters for telemetering. The indication panel has one two-position type of polarized relay for each substation unit. Suitable panels are provided for any number of units for the selective and indicating equipment at the substation, including control power switch, selector synchronizing relay, line-wire jacks with the selector relays and auxiliary relays.

The polarized control relays operated over the control-line wire and generally mounted on the substation panel associated with the controlled unit may be of the two-position or three-position type. The synchronous-selector equipment is operated from two 60-cell storage batteries, one in the dispatcher's office and one in the substation. A continuous drain of 0.1 amp. is required of the dispatcher battery while the substation battery must deliver 0.1 amp. plus 0.02 amp. times the number of substation units indicated. Both batteries must also supply $^1/_2$ amp. intermittently. An independent 24-volt circuit supplies the dispatcher's indicating lamps with 0.04 amp. per lamp. All line wires are protected at each station with a self-restoring arrestor.

The selector switches in the dispatcher's office and the substation consists of 5 contact banks, each consisting of 25 contacts and an associated contact wiper which is stepped from point to point by the operation of a notching magnet and spring. The synchronizing bank and the notching banks at each station operate in conjunction with each other and their respective selector synchronizing relays in order to step the wiper arm of each slector ahead in exact synchronism. Individual select keys in the dispatcher's office feed potential to each of the contacts on the synchronizing bank, and the selectors can be stopped by opening the associated select key. The control circuit is connected directly from a two-position control key in the dispatcher's office to a two-position polarized control relay in the substation. The contacts of the indication relay establish potential across either red- or green-capped indicating lamps, depending on the position of the supervised unit. The immediate "check back" feature consists of checking the polarity as placed on the synchronizing line wires by the substation selector against the polarity as determined by the dispatcher's selector. If the polarities are correct, the control circuit is established for the dispatcher. An amber-capped lamp associated with the keys and lamps of the selected unit indicates the correct operation of the position-check relay.

The dispatcher's panel pilot lamp lights whenever a change occurs in the associated substation. The individual white-capped lamps indicate an automatic operation of a supervised device or incompleted operation started by the dispatcher. The equipment cannot start unless selectors are in synchronism on the normal starting position, a reset key being provided at the dispatcher's office for placing the selectors in synchronism at the normal rest position. The dispatcher is notified in case of operating-potential failure, if either selector steps from the normal at-rest position, or when there are line-wire troubles. The control wire closes only when the selectors stop on a contact, and they step from point to point at the rate of from ten to twelve impulses per second, so that the ninetieth breaker position can be selected within about 9 sec. Indication is in-

Abstract of address delivered at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

stantaneous with the movement of the supervised unit. For manually operated stations, only about 11 sec. are required for the synchronous equipment to indicate the position of 275 units over four interconnecting line wires. From the dispatcher's office of the Cincinnati Street Railway, 18 railway substations are supervised.

The supervisory system provides also an easy means for selecting and obtaining intermittent meter readings over the 4 common line wires, the supervisory equipment being inoperative while the meter readings are being made; however, additional line wires are required for continuous or recorded meter readings. The telemetering equipment thus supplements the information given the dispatcher by the supervisory equipment, which may be used to inform him of division of load between generating stations, exchange of energy between power systems, load on machines, feeders, or transformer banks, and desirable voltage readings. A transformer and feeder station of the Bronx Gas and Electric Company, New York is provided with equipment for selectively reading a.c. amperes and a.c. voltage on 12 circuits by means of the rectified current-type of telemetering, the rectified-current type having no mechanical-motion parts except the indicator.

FSP-51-10

Trends in Development of Electricity-Supply Systems

By W. F. SIMS,[1] CHICAGO, ILL.

ALTHOUGH there is a growing use of automatic and remotely controlled equipment, the present trend seems to point toward simplification of this type of apparatus. On account of the complexities of the control wiring and equipment necessary, the initial cost was high, and an excessive amount of maintenance was required. The present trend is toward as simple and reliable a system as is possible.

The use of pulverized fuels has passed what might be called the hysterical stage and is now on a practical basis of consideration. This change in attitude toward the subject has in no way lessened its importance. The increase in the size of boilers has increased the difficulties of stoker firing, and this has stimulated the trend toward pulverized fuel. There has been some difference of opinion as to the relative merits of the bin and unit systems, with an apparent tendency toward the latter.

The improvements in combustion conditions have brought about a marked reduction in the size of furnaces. Water-cooled furnace walls are rapidly becoming standard practice, but it is not yet generallly agreed as to whether bare metal or a thin refractory covering should be used. The dust problem, which is yet unsolved, has become very troublesome, and it is important that definite progress be made in its solution. Automatic combustion-control systems are gaining in favor, particularly on large units where the initial expense can be justified.

In reference to higher steam pressures, although past developments in the 1200-pound class have been confined mainly to smaller installations, several installations of considerable size are going ahead. In these installations the steam temperatures are conservative.

For compound turbines in the 600-lb. class, reheating of steam seems to be more or less standard. Experience with live steam for reheating, however, has not yet established the fact that this is the most economical method. Although the mercury-vapor boiler installation at Hartford is being watched with a great deal of interest, the contemplation of no other such installation has yet been announced.

The subject of low-temperature coal distillation has attracted the attention of many engineers, and considerable research work is being done along this line. So far, it is only in the experimental stage. As the extent of interconnection and growth of individual systems increase, the trend is steadily toward larger units, which of course, is reflected into all the component parts which make up the generating station.

Definite progress has been made in the design of higher-voltage generators, and machines designed for 22 kv. have been built, and the possibility of even higher voltage is being given serious consideration.

The necessity for improvement in system stability in connection with hydroelectric plants feeding long transmission systems, has brought about the application of quick-response excitation equipment. Some application has been made, and a wider use may be expected, on steam turbo-generators connected to long transmission lines. There is also a field for its use on synchronous condensers used in connection with transmission systems. On the other hand, closely connected systems supplied from steam turbines, and with underground transmission such as is the case in most metropolitan areas, being much more stable, are not greatly concerned with this problem. As this method of stiffening the system under fault conditions is much less expensive than by changing generator characteristics to obtain the same result, it is likely that this feature will come into more general use. The use of the pilot exciter for exciting the main-exciter field, which has been developed in connection with quick-response excitation, in many installations also permits the elimination of the main-generator field rheostat.

More accurate frequency regulation has become a vital factor on interconnected systems, and even with hand regulation fairly uniform frequency is now being obtained. Considerable attention is being given to automatic frequency regulators, and several large companies have, on their own systems, made up regulating devices operated from the frequency recorder. It is interesting to note that although these various devices were worked out independently in different parts of the country, the fundamentals and some of the details are quite similar. Some of the manufacturers have brought out factory-made devices of this kind, and the attention being given to this class of equipment gives promise of much further development and application.

In the field of switching equipment, attention is being given to the further development and use of the truck type and of the metal-clad switch gear. Both types lend themselves to a maximum of factory assembly, and a minimum of field labor.

For some time manufacturers of circuit breakers have been investigating the possibilities of developing circuit interrupting devices that will open power circuits without the use of oil. Although none of these devices has yet been placed on the market, factory, and field tests show very encouraging results. A series of papers read before the midwinter convention of the American Institute of Electrical Engineers discussed the theory, design, and test performance of one such device. Although it is too early to predict the outcome, and there is some question as to the voltage limitations which may be reached, it is very possible that this form of current-interrupting equipment will come into use on power systems.

Under conditions where the attendance is a large factor in the cost of operation, there is a growing use of automatic and remotely controlled installations, which have demonstrated a high degree of reliability, and it is probable that a much greater use of them may be expected.

In synchronous-converter substations in densely built-up areas, and particularly where it is necessary to install the equipment in the basement or lower floors of commercial buildings, the problems of ventilation and elimination of noise often become quite serious. The use of enclosed converters offers many advantages under these conditions, one of which is the reduction of temperature in the general substation space. Much more positive ventilation can be secured as well as the practical elimination of noise from the machines. This arrangement also permits the use of air recirculation and air coolers.

In railway substations there is a growing use of mercury-arc rectifiers instead of synchronous converters. Although their

[1] Field Engineer, Generating Stations, Commonwealth Edison Co., Chicago, Ill.

Abstract of a paper presented at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

first cost is at least as great as that of converters, their higher overall efficiency, and the advantage of static over rotating equipment, together with the practical elimination of the ventilation problem, and the great reduction of noise, makes their use decidedly advantageous. There is a demand for rectifiers of larger size, and it is expected that developments now in progress will be successful. If the size of rectifiers for potentials around 250 volts can be increased, and if the manufacturers are able to improve materially rectifier efficiency and regulation on the lower voltages, it is possible that some further installations may be made on direct-current network systems.

The development and application of the high-speed air circuit breaker marks the most important improvement in railway substation practice in recent years. Its ability to disconnect d-c. short circuits almost instantaneously eliminates the reflection of their effects back into the power system, and reduces greatly the number and severity of commutator flashovers. A much more extended use of this type of breaker is probable.

The increase in the development and use of household appliances, including refrigerators, oil burners, etc., has had a definite bearing on distribution conditions, making reliability of service to residence customers much more vital in the past. Regardless of the type of distribution system used, this situation emphasizes the need for reducing customer outages and generally improving service. Continued efforts in this direction may be expected.

The interconnection of systems is continuing, and it is reasonable to expect further developments of those already in operation, and the bringing together of many other systems now operating independently. There are still many places where the savings to be effected by the long-hour load of the more efficient plants, the reduction and better use of system reserve, and the improvement in reliability and quality of service are yet to be realized.

The problems of operating large interconnected systems are complicated by the lack of relay equipment that is adequate to meet all conditions. This situation is being studied by utility engineers and relay specialists in the factories, and continued improvement in relay methods and equipment is to be expected.

In general, transmission voltages are reasonably well standardized at 66 kv., and for the higher voltages from 110 to 140 kv., with 132 kv. as the most generally accepted figure. Recent developments, however, indicate that where the distances and amounts of power to be transmitted offer the necessary justification, there will be an increasing use of 220 kv. There is also a trend toward the use of higher voltage on short heavy lines because of better regulation and less liability of lightning interference.

The use of synchronous condensers for power-factor correction of transmission lines is increasing. The conditions under which their installation may be expected are where the length of the line is such that the value of the increased line capacity thus obtained, together with the capitalized value of the saving in line losses will offset the cost of the condenser installation. There are also systems where their installation may be justified by the improvement that their installation will make in regulation.

Notable improvements have been made in the design and construction of such machines. They are now being built for higher speeds, with a corresponding decrease in weight and floor space, and a considerable reduction has been made in operating losses. There have been several condensers built for outdoor operation, at least one of which is equipped with hydrogen cooling.

The active interest shown by transmission engineers in the study and discussion of the value and proper application of ground wires, arcing rings, and other protective measures, leads to the hope that the present differences of opinion on these subjects will be reconciled within a reasonable time. Field and laboratory tests now in progress should aid in an early settlement of these much debated questions.

Field investigations are now being made by the manufacturers on the transmission lines of some of the operating companies, looking toward data on the characteristics and wave shapes of lightning surges. Automatic cathode-ray oscillographs and other similar devices have been connected to the lines, and the use of the data which it is expected to secure should result in improvements is lightning-arrester design, and a better knowledge of how they should be applied.

Developments in high-voltage underground cable, and the successful installations at 132 kv. in both New York and Chicago, show the feasibility of its use. The field of application of such cable is primarily in extending from overhead lines to power houses in or adjacent to congested localities.

The large capacity of some of the high-voltage transformers manufactured during the past year, indicates a trend toward a greater use of larger units, and there is also a definite indication of a more widespread use of load-ratio control and other similar regulating equipment. Parallel with the development of the two-winding generator has come the split-winding transformer with similar reasons for its use and application.

As was the case several years ago on the lower-voltage systems, the need for reactors on high-voltage systems is beginning to become apparent, and the successful production of equipment shows that it can be procured when required. The necessity for a better knowledge of system conditions during disturbances has led to the installation of automatic-recording devices by several companies. The information already secured by this means has proved very valuable, and has resulted in a number of improvements in system design and operation.

Use of supervisory control has been extended, and in some instances includes the control from a central point of a system of hydroelectric stations and substations. The equipment developed for this purpose has proved to be extremely reliable, and its further application can be expected. The increased use of electric power in metallurgical and other industrial purposes, and also the progress of rural electrification are presenting new problems in power supply, some of which are not yet satisfactorily solved.

The size of the industry has now reached a point where on many systems the annual increase in load even of only a nominal percentage, in actual kilowatts is such that to meet the demand a very large increase in the capital accounts is required on all parts of the system. The magnitude of these additions is such that many companies have found it necessary to make organized studies of probable future development several years in advance, in order that probable capital required may be budgeted far enough ahead to permit of proper financing. This also permits the construction program to be so laid out that the new equipment may be provided and utilized in the most effective manner.

The notable developments in the industry which have taken place in the past, and which may be expected in the future, have been contributed to by men in every branch of the power industry, and also by the engineers of the various manufacturing organizations who are supplying the equipment required to build up the systems. The results obtained are an evidence of coordination of effort and cooperative action, of which the industry may well be proud.

FSP-51-11

Refrigeration and Ventilation as Aids to National Efficiency

By S. C. BLOOM,[1] CHICAGO, ILL.

This paper describes developments in air cooling and air circulation that are being incorporated in modern office buildings. The amount of refrigeration required is large and current practice is to recirculate and recool 50 to 75 per cent of the air used. The volume of cooled air introduced is sufficient, usually, to change the air of a building 5 to 8 times per hour. The period during which cooling is required is but a small part of the year and current practice is to provide refrigerating equipment of capacity sufficient to handle the peak load. The power demand resulting is high and intermittent, and much expensive apparatus must remain idle a preponderant part of the time.

REFRIGERATION plays an important part in our national life, in the way of transportation, storage, and preservation of perishable food stuffs, and in its contribution to the comfort and health in the home. Of our great dependence upon this useful agent there cannot remain the slightest question; one need only to visualize the situation if it were withdrawn suddenly.

Similarly, ventilation in schools, office buildings, industrial plants, and the like is recognized as a vital necessity in the maintenance of decent and healthful conditions for those who must occupy them. In the past few years public attention has been focused upon the combination of refrigeration and ventilation as an aid to comfort in hot weather, as exemplified in an ever-increasing number of theaters, which have adopted cooling systems as a box-office attraction, with amazingly successful results.

This has, by no means, been confined to the metropolitan centers, with the result that the public has had a taste of this luxury, and there has been a spontaneous interest in the extension of its use to other fields. Thus we find department stores, restaurants, and hotels incorporating cooling apparatus into their ventilating systems to increase business by the provision of a comfortable environment for the patrons of their establishments.

In industry there are many manufacturing processes which cannot be carried on during the summer, when outdoor temperature and humidity exceed certain values. In such instances, the maintenance of production schedules or quality of the output has been successfully accomplished by the application of cooling systems, thus doing away with the expensive practice of seasonal shutdowns and throwing out of employment large numbers of people.

As a matter of fact, the industrial usage of air cooling was earliest, but knowledge of its success and possibilities spread very slowly, since many of the applications constituted trade secrets which were quite properly protected as long as they could be.

The direction which the development of the air-cooling field has taken is only natural, since it must be borne in mind that the use of cooling rarely springs from benevolent or philanthropic motives; it must pay dividends. In the applications previously referred to, it has been relatively simple to establish the worth of the investment.

There is a field of tremendous potential value yet to be exploited, where the investment yield is not so easily evaluated, yet none the less real. This lies in the cooling of office buildings, wherein a vast number of our people pursue their livelihood. Among them are the major portion of the executives directing the business of the nation; men whose minds must be concentrated upon the many and varied problems with which they are confronted.

One cannot be at his best when conscious of discomfort. We do not permit ourselves to be tortured by the rigors of cold weather, hence heating is considered an indispensable requirement of buildings. There is no more reason why we should allow ourselves to be uncomfortable in summer. That hot weather is accompanied by an extensive let-down in productive effort is apparent to every one. Thought of how to escape the heat is uppermost in mind, as is evidenced by the action of millions seeking the seashore, the mountains, the lakes, anywhere to get relief. The disturbance of business which this situation occasions is widespread and severe, reflecting itself in a reduction of national efficiency, the cost of which is incalculable.

We have become accustomed to accepting the situation as inevitable. Now, with the tools at hand to correct it, the confident prediction may be made that they will be utilized to best advantage. There have been a few outstanding examples of cooled office buildings in this country, operating for many years which afford a background of experience warranting the prediction just offered. It is the unanimous opinion of the managements that they could not afford to be without them.

Contrast the picture of the hot office with open windows admitting the dust and noises, the perspiring occupants and the disinclination to work, with that of one wherein the air is comfortably cool, dry and clean, where the windows may be closed to exclude noise and distraction. But little imagination is required to visualize the superior efficiency which will be obtained in the comfortable office.

Occupants will not only be happy to remain in such a place, but will feel like working while there. In one large office building where cooling has been used for a number of years, the refrigerating plant went out of commission in the middle of summer and was down for about two weeks. Although the ventilating system was operated in the interval, it was necessary to open windows which had not been opened for years in order to relieve the situation.

During this period the number of absentees went up decidedly and the office manager estimated that the efficiency of the office fell off at least 50 per cent. With the restoration of cooling its importance was appreciated as never before, a very common experience, when something essential to our comfort, health, or happiness is taken away temporarily.

At present there are several large office buildings planned and some under construction which will be cooled throughout, and they are but the forerunners of a practice which will become general. The cooling plant will take rank with the heating system as an essential item of equipment.

A cooling system, as applied under prevailing practice draws fresh air from outside into an air cooler where it comes into direct

[1] Consulting Engineer, Chicago, Ill.

Presented at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

contact with a veritable storm of cold water spray. The cold water simultaneously purifies the air, cools it, and condenses some of its moisture, thereby lowering the humidity. The cooled air is then forced by a fan or blower through a system of air ducts leading to the various rooms which are to be ventilated and cooled. There it absorbs the heat transmitted through the walls and windows, also the heat given off from the occupants and from lights and its temperature rises, with a corresponding drop in relative humidity.

The temperature of the incoming air, the amount of heat to be absorbed and the ultimate room temperature and humidity desired, govern the quantity or volume of air required, so that it is perfectly feasible to design a system for maintaining any condition wanted. The water which is sprayed in the air cooler is cooled and recooled, with refrigerating machinery, to the temperature required. There are some localities which are blessed with an abundant underground water supply of suitable temperature, which is easily available through the use of well pumping equipment. The upper limit of temperature at which well water is serviceable in this connection is about 58 deg. fahr.

With the contrariness of nature, we find that ground-water temperatures decrease the farther north we go, and at the same time the need for air cooling lessen or at least, the period during which cooling is needed is shorter. The amount of refrigeration required for air cooling is large. For example, to cool air at the rate of 1000 cu. ft. per min. requires the equivalent effect of melting ice at the rate of 2 to 3 tons per 24 hours depending upon the relative proportions of air taken from outside and that returned from the building for recooling.

Current practice is to recirculate from the building and recool 50 to 75 per cent of the air supplied, so that refrigeration at the rate of $2^1/_2$ tons per day per 1000 cu. ft. per minute of air supply is fairly representative of the amount provided. The volume of air introduced is sufficient usually completely to change the air of a building 5 to 8 times per hour, so that at a glance it is seen that the refrigeration requirement runs into big figures on a large building. There are some instances in which refrigerating machinery has been provided having a capacity in excess of 1000 tons equivalent ice-melting capacity for 24 hours.

There is at present a diversity of ideas as to the extent to which cooling should be done in order to maintain satisfactory conditions, and the tendency is to work toward higher room temperature and lower humidity. When cooling was first advocated, the prospective users almost invariably wanted a condition of weather 70 deg. fahr. and 50 per cent relative humidity indoors, with hottest summer outside. A very few such installations were made and experience demonstrated quickly that such a contrast was unbearable.

Today a condition of 80 deg. fahr., with a relative humidity of 55 per cent is considered quite satisfactory, when it is 95 deg. fahr. outdoors. The combination of experience and research promises to establish a standard which will not only assure a suitable degree of comfort, but which will take into consideration the factor of expense for producing such a condition, with a view to its reduction.

The period during which cooling is required is a relatively small part of the year and current practice is to provide refrigerating equipment of capacity to handle the peak load, with the result that power demand is high and intermittent, and much expensive apparatus must remain idle a preponderant portion of the time. These characteristics add greatly to the overall expense for cooling.

Development of means whereby the operation of the refrigerating machinery could be made more nearly continuous during the cooling seasons, even though the ventilating plant is inoperative when the building is unoccupied, would go far toward solving the expense problem and make a much more desirable power load. A few attempts at a solution along this line have been made, but without conspicuous success to date, although the possibilities in this direction have by no means been exhausted.

Multi-story office buildings present some interesting problems in the application of cooling, because of the necessity for conserving usable or rentable area, and of obtaining proper distribution of cooled air to the various stories. As stated previously, the current practice is to recirculate and recool a very substantial portion of the air. This requires valuable space, for the running of return air ducts in addition to those for the supply. Recirculation of air is done primarily to reduce the amount of refrigeration required, to temper the air supply and to obtain desirable humidity conditions within the building. In addition it is an expedient whereby existing standards as to the volume of air supplied to ventilated spaces are apparently complied with.

It is perfectly evident that if air recirculated from a building is recooled, it will require less refrigeration than if the same volume of air were taken from outdoors and cooled to the same temperature. Similarly, if a portion of the recirculated air is mixed with the remainder of the air which has been cooled, the resultant mixture will have a higher temperature and lower relative humidity than if all the air had been cooled. This device has been resorted to in order to avoid difficulties from drafts attendant upon the introduction of relatively large volumes of air at temperatures too far below the required room temperatures. It also facilitates obtaining satisfactory relative humidity at room temperatures which have been found desirable.

Existing ventilation standards differ widely throughout the country and many of them were formulated prior to the advent of air purification, cooling, proper usage of ozone, etc., as auxiliaries to ventilation. Strict adherence to them would preclude the use of cooling in many localities because of the excessive cost for refrigeration. Under these circumstances the air-conditioning engineer has boldly utilized the method of recirculating air, which in effect amounts to a corresponding reduction in volume of outdoor air taken into the system. To his credit it should be recorded that he has demonstrated in a practical way that quality of ventilation has not been diminished by the practice of recirculation, or to put it another way, that satisfactory ventilation may be had with greatly reduced volume of outdoor air.

The significance of this demonstration is very great in connection with the future of office building cooling and ventilation, for the reason that recirculation of air can be abandoned completely, and ventilation accomplished by the use of a relatively small quantity of outdoor air, purified and cooled to a low temperature. No special provision for its escape from the building would have to be provided, and thus a slight internal air pressure would prevail. The air would escape through cracks around the windows and elsewhere, and thus reduce or prevent inleakage of outdoor air, which under normal conditions greatly increases the air volume and refrigeration required for cooling. It will also be evident that the exclusion of inleakage will result in a greater air purity within the building.

The reduced volume of air supply, the omission of recirculation and of special provision for the exhaust or escape of air, greatly reduces the space requirement for air ducts and for the ventilating apparatus. At the same time there is a very desirable simplification of the system. Still further opportunity for lessening the space requirement lies in the direction of increasing air velocity in the ducts or conduits 5 to 6 times that used in conventional ventilating systems, and of operating blowers at pressures ranging upward to 1 lb. per sq. in. instead of the very low pressure customary. The power required to handle the greatly reduced air volume at the higher pressures will compare favorably with that needed in systems of current designs.

The use of higher air pressure will aid materially in the equal distribution of air throughout a high building, where many stories are interconnected by a common piping system, through offsetting the chimney effect prevailing in such a building. Furthermore, the maintenance of sufficient pressure at the branches will facilitate meeting the effects of windage which frequently disturbs distribution.

The form of conduit required to handle the air at the pressure suggested would perhaps require a change from the ordinary galvanized ducts which are not sufficiently tight. Light tubing or galvanized sheet-iron pipe of the type made to withstand low pressures would prove serviceable. The use of cold air would necessitate some insulation, but it would not have to be very heavy for the reasons that the prevention of condensation on the exterior is its primary object, and the low humidity of the air within the building would reduce the tendency for condensation to form.

Use of small quantities of cold air results in a low relative humidity, which is a desirable objective, for the common complaint in summer is that "it isn't the heat, but the humidity," which is the principal cause of discomfort. The lower the relative humidity, the higher the temperature can be for an equal degree of comfort. The higher the temperature indoors the less heat is transmitted through the walls and windows of a structure, thus reducing the amount of cold air and refrigeration required.

The tendency to carry room temperatures too low should be discouraged; it is expensive, unnecessary and even undesirable. Excessive cooling in summer is just as objectionable as overheating in winter. The provision of a reasonable contrast between indoor and outdoor conditions should be the objective. Avoidance of excessive contrasts is essential in order that readjustments of the body-temperature controls may not be too great, for it must be borne in mind that the passage of people from indoor to outdoor environment is sudden, and the effect is temporarily magnified. Furthermore, lighter clothing is worn in summer and street dress and indoor dress are the same, thus the body is more sensitive to changes in conditions.

So long as the answer to what is sufficient remains in the realm of opinion, there will be a diversity of viewpoints, however, there is some research work bearing upon this matter which has been underway for some time, and the results coupled with experience gained in existing installations should serve as a valuable guide in the determination of correct practice.

The prospect of providing for the comfort, health, happiness, and efficiency of people in summer, who are confined indoors by virtue of the necessity of gaining a livelihood, is most alluring. There are many well-qualified, forward-looking engineers who are concentrating their talents upon the problem of how to make this great boon to heat-ridden humanity available; men who are unprejudiced, who are not slaves to convention and who are boldly setting out on new and uncharted paths, confident of arrival at the goal of their endeavors. The spontaneity of the demand for cooling is most surprising and it appears to offer a most fruitful field for development. As an aid to national efficiency, it is difficult to conceive of anything which offers greater promise.

FSP-51-12

Application of Refrigeration to the Preservation of Foods

By A. J. AUTHENRIETH,[1] CHICAGO, ILL.

This paper tells how the application of refrigeration to perishables has brought about a very marked betterment in the standards of living throughout the country. It has placed the products of a nation of diversified soils and climates in the home of every one. The health of the whole people has been safeguarded in increasing measure as more and better products are being made available. The applications of refrigeration to perishables have made possible the agricultural development of sections of the country which would otherwise lay as wasted useless land.

REFRIGERATION in its application to perishable foods divides itself into three major departments. These are transportation, storage, and small commercial and home divisions. Refrigeration in transportation is mainly railroad car icing and steamship refrigeration. A number of different methods of cooling freight cars have been devised but none of these methods are commercially important at the present time.

There are a number of perishable food products which are peculiarly adapted to production in certain locations or climatic conditions. Among these are citrus fruits, hops, and figs. Other fruits and vegetables can be grown in nearly every locality in this country during suitable seasons but because of adaptability to certain combinations of climate and soil these in mass production have been confined to certain areas. These include apples, peaches, celery, grapes, pears, onions, and similar products. This localized production is carried on such a scale that no nearby market could absorb any appreciable quantity of product. For this reason refrigerated transportation has been adopted to carry these commodities to distant markets or to their points of distribution.

Refrigerated transportation combined with storage has had a part in the economic development of our country which is not even realized by a number of the men in the refrigeration industry, much less by the general public. None of the winter-garden areas and none of the western mass-production centers could have had more than a small percentage of their development without the aid of refrigeration in distributing and marketing their products. Climate and soil would have been valueless, had there been no way to transport their products to market.

Present Development in Transportation

The products of the packing industry form a large field for the use of refrigeration in transportation. From the center of this industry in Chicago shipments go to all parts of the country. Centralized packing has grown up in the face of great local competition and has now reached such a scale that 300,000 refrigerated carloads of packing-house products are shipped every year. These move to branch houses and wholesale storage houses in the larger towns. Smaller towns have been enabled by refrigerator-car shipments to secure fresh meat direct from the packer in cars which make periodical stops to deliver meat to the retailer. In this way markets have been widened to the greatest possible degree while people in very small towns have been enabled to supply their tables in the same manner as the large city dweller.

Refrigerated ships ply between this and every country which produces perishable products. From the ports of entry these products must be transported under refrigeration to their markets throughout the country. Bananas offer a good example of this type. A great portion of the bananas used in this country have in the past entered through the South and East ports. The new Western banana terminal of the United Fruit Company at San Francisco gives evidence of the present importance of this foreign product. Cargoes as high as 47,000 bunches are unloaded at this terminal for shipment to various points in the West. Present importance of this one commodity is shown by the figure of 64,000,000 bunches, which is given as the consumption during the past year. The refrigerator transportation of this fruit alone is quite a large item. Other tropical fruits are brought by refrigerated ships from Hawaii and the West Indies and we found some time ago that citrus fruit brought all the way from Italy could flood our market.

Approximately 1,550,000 cars of perishable food were transported in the United States during 1927. Of this amount 577,000 moved under ventilation while the remainder 973,000 were iced. The refrigeration of these cars consumed 12,500,000 tons of ice. In placing Imperial Valley lettuce on the table here in the Palmer House, the time in transit from San Antonio, Texas is the same as that from Tampa, Florida. The ice used per car on a given trip varies with the temperature maintained in the car. The latter depends upon the commodities being transported, some of which require the packing of ice in the load to keep them fresh. In coming from the Rio Grande Valley to Chicago in the summer, cars use 8 to 16 tons of ice, depending upon the commodity being carried.

Cold Storage

Refrigerated storage forms the next phase of our study of perishable food preservation. The central idea of all storage is to provide a reservoir to keep perishable products from the season of production, when there may be an oversupply, to the non-productive season or a season in which the demand exceeds the ability of the country to produce. Of course, there are certain commodities such as meats which are chilled and stored as a portion of their preparation for transportation and sale. This latter is more or less an activity of the packing-house storage, while the bulk of the business of the general cold-storage houses is the intro-seasonal preservation of perishables.

In the early days of refrigerated storage a lack of knowledge on storage methods in some cases brought about a reduction in the quality of the stored food. The public became conscious of this fact and developed a partial dislike for "cold storage" products. The cold-storage operator then in some cases tried to circumvent what he conceived to be an unfair prejudice by selling his products as freshly produced foods. This situation which based the sale of cold-storage products on the practice of deception was unfortunate and could not be maintained long.

Scientific study developed more effective methods in cold-storage practice. Producers of foods gave more attention to well-timed harvesting and proper lading and refrigeration in transit. These had their effect, cold-storage products were

Abstract of paper presented at Midwest Power Engineering Conference, Chicago, Ill., Feb. 12 to 15, 1929.

Note: Statements and opinions advance in papers are to be understood as individual expressions of their authors, and not those of the Society.

essentially as good as fresh products and a conversion of the public from its prejudice was begun. Cold-storage eggs were sold unblushingly as cold-storage eggs and the economic advantages of their use was stressed by the storekeepers. At the present time, the public is losing its disproval of the use of cold-storage products. This situation is very much more desirable from the viewpoint of the producer, warehouseman and consumer.

The refrigerated warehouse is now one of the most necessary units of the modern city. Without it we could not live in our accustomed comfort. Larger and larger storage houses are needed, and more and more of them are being built. Here are a few from recent press reports. The Pennsylvania Railroad completed a 2,000,000-cu. ft. storage and terminal at Philadelphia. A terminal and refrigerated storage of 4,600,000 cu. ft. capacity has been completed recently in Houston, Texas. A 1,500,000-cu. ft. terminal with cold storage is to be built at Walkerville, Ontario, Canada. The Chamber of Commerce of San Francisco has petitioned for the construction of a 2,000,000-cu. ft. harbor terminal and cold-storage house.

Cold Storage Available in All Parts of United States

Figures which include the latest installations are not now available, but the figures taken from the last biennial census (October, 1927) place the total cold-storage space in the United States in both private and public plants at 731,377,000 cu. ft. This indicates an expansion in the past 27 years of more than 400 per cent. Present building operations show no slackening in this expansion at the present time. It is illogical to assume that the saturation point is being approached. Relatively few people take marked advantage of the extension of the fresh-fruit and vegetable season with refrigerated storage. Then, too, the preservation of the highest quality of perishable foods is receiving increased interest and the application of refrigeration to a wider range of commodities can be expected during the next few years.

Refrigerated ships are enabling us to seek the markets of the world with a number of our products. American apples are finding favor in a number of countries. We see in the press notices that the largest shipment of Virginia apples ever made at one time, 40,000 bbl., went out recently from New York for Buenos Aires on a new refrigerated steamship. A recent Bureau of Commerce report carries the following "Barreled and boxed apples are arriving in the British markets in splendid condition, the stock having a good color and bright appearance." This export trade helps all along the line because it makes use of refrigeration in railroad transportation as well as in terminal storage.

Cold Storage as a Power Consumer

Looking at the power consumption side of the cold-storage business we see a gross consumption in that unit of the refrigeration application cycle is not inconsiderable. We must realize also that this is one of the integral parts of the system from producer to consumer. On the basis of 731,377,000 cu. ft. of cold-storage space in the United States and at a nominal rate of 60 kw-hr. consumed per 1000 cu. ft. per month, the power for cold storage amounts to 526,591,440 kw-hr. per year. It is not possible to determine what portion of this is electrified at the present time; but, if the same percentage obtains as in ice manufacturing it is 59 per cent and the year electrical consumption is 310,688,600 kw-hr.

The total production of ice manufactured and harvested in the United States during 1928 approximated 72,000,000 tons. Of this amount, 11,000,000 tons were harvested from lakes and streams and 61,000,000 tons were manufactured. When, as has been shown, 12,500,000 tons were used in icing refrigerator cars, the balance of 59,500,000 tons for domestic and commercial consumption seems small. It is only 1020 lb. per capita, yet per capita figures are usually small where a product not in universal demand is being considered. Ice is such a product. There are 5,000,000 less refrigerators in the country than wired homes. That is to say that there are 15,000,000 homes without refrigerators although a number of these are not available to ice and electric service. These statistics bring out the fact that refrigeration has touched little more than 50 per cent of its domestic market. The situation is one of challenging possibilities to the power industry as well as to the ice and refrigeration industry. In spite of past growth we yet have a large field for expansion before us.

The total number of ice plants in this country is somewhat in excess of 7000. Of this number 32 per cent are steam driven, while 59 per cent use electric drive and 9 per cent gas and oil drive. Assuming that the same percentage of the total production came from these plants, then 19,500,000 tons of ice were produced in steam-driven plants, 36,000,000 in electric-driven plants and 5,500,000 in gas- and oil-driven plants.

Using an average figure of 62 kw-hr. consumed per ton of ice made, the total of electric power used by ice plants last year was 2,232,000,000 kw-hr. This is a consumption which was exceeded by few industries in the United States and the future holds such a promise. Electrification is going forward rapidly in a number of locations. A new electric process of demineralizing water now makes it possible to electrify plants which were heretofore considered only from an angle of distilled water operation.

The ice industry, therefore, is one which uses more than 3 per cent of the total output of the electric-light and power industry. Added to this fact is the desirability of this ice-plant load which comes to its peak at a time far removed from the annual peak of the central-station load. The ice plant is also well suited to the use of synchronous motors, an aid in power factor correction.

Small Commercial Installations

There is another phase of this domestic and small commercial refrigeration field. This is in the field of the so-called electric refrigerator. The total of these units in homes and small stores is placed at 900,000 and the annual consumption at 700 kw-hr. per unit. These machines bring an increased load of 630,000,000 kw-hr. per year, a load which is very steady and reaches its peak demand during the summer months, when the demand on the central station is at its lightest point. The sale of mechanical refrigerators continues and this very desirable power load will increase in parallel with the sales volume.

Dairy and ice-cream plants have very extensive refrigeration possibilities and at the present time aggregate more than 80,000 tons of refrigeration. A portion of this is for use in manufacturing processes, but at the time the refrigeration preparation preserves the product in later handling. The refrigeration installations in meat markets and produce houses play a very important part in the national life. The influence of these installations has not made itself felt in the popular consciousness because a number of them have been in operation for twenty

YEARLY POWER CONSUMPTION IN APPLICATIONS OF REFRIGERATION IN THE UNITED STATES

	Kilowatt-hours
Cold storage	310,688,000
Ice making	2,232,000,000
Small electric refrigeration	630,000,000
Moderate size commercial installations	584,575,200
Total	3,757,263,200

years or more, yet it requires little study to see the effect they have upon our every-day life. From the point of power consumption these cooler and storage installations also have a real significance. Of all these there are 17,993 installations in the United States aggregating 159,720 tons refrigeration. On a 33⅓ per cent load factor these consume 584,575,200 kw-hr. per year.

On the score of power development we see that an industry has grown up which proves to be one of the best, if not the very best customer of the electric power industry. It consumes a great volume while it makes no exactions of extraordinary service. The accompanying tabulation is made up of the different figures arrived at in our discussion of the various units of the industry.

Research as Applied to Heating and Ventilation

By SAMUEL R. LEWIS,[1] CHICAGO, ILL.

This paper gives the results that are being accomplished, through various research programs, that are being conducted, in the field of heating and ventilation, by the research laboratory of the American Society of Heating and Ventilating Engineers. Cooperative arrangements are in effect with many universities, colleges, and departments interested in this research work and these enable the work to be carried on, at a cost, very much less than would be necessary otherwise.

RESEARCH as applied to heating and ventilation is worthy of attention and has unusual importance because it so profoundly affects the health and the comfort of the whole race, in contradistinction to those researches which constantly are under way in the laboratories of great manufacturers and which have usually as their object an ultimate financial reward. We can trust the manufacturers to study improved methods and can expect inventors constantly to search for and to experiment with improved processes and machines which will bring back dollars. The free-lance engineers of the country, however, know of a great many problems the solutions of which will benefit the whole race without immediate apparent monetary reward to any particular person or group of interested persons. These individual engineers do not have the means alone to pursue research.

The Research Laboratory of the American Society of Heating and Ventilating Engineers was organized for the purpose of securing contact between public-spirited individuals in order that research for the good of all, without any selfish angle whatever, might be conducted. The Laboratory entered into a contract with the Bureau of Mines under which the Laboratory was given space in the Bureau of Mines experiment station in Pittsburgh, for offices and for experimental apparatus, free of charge. A great deal of assistance and support is constantly being contributed by the Bureau of Mines in this friendly cooperation, in addition to the specific housing.

The Laboratory as first established was supported by gifts from members of the Society and from its friends. This method of financing being somewhat difficult when it came to establishing a budget, the constitution of the Society was eventually amended so that the dues paid by the members were raised 66 2/3 per cent, two-fifths of all receipts for dues from members thereafter being devoted to the Research Laboratory.

As is the case in most research situations, the need for work to be done soon expanded beyond the income, and in 1928 the budget of the Laboratory was double the income from member dues. The additional money is contributed by friends, who make such contributions without any restrictions as to the direction in which the funds shall be invested, and who contribute comparatively small sums each, year after year, rather than large sums such as might have been forthcoming from intensive money-raising campaigns. It is an inspiring situation that there is never any particular difficulty in raising the necessary money to finance the laboratory, and that in many instances, we are told by these friends—"If you find yourselves running short, let us know and we will send some more."

The activities of the Laboratory are directed particularly toward research in fields not likely to be covered by immediate commercial results, and which therefore tend to lag behind the developments and inventions emanating from the researches of the larger manufacturers. Thus our laboratory has studied intensively such things among many, as air infiltration through walls, heat conductivity of structural materials, effect of paint on radiating surfaces, carrying capacity of pipes, and the physiological and the psychological influence of different ventilating and temperature conditions on the human body.

There was so much work to be done by the Laboratory that the facilities of the Bureau of Mines at Pittsburgh available for our service soon were fully occupied. An opportunity came early in 1927 for making a cooperative arrangement with the University of Wisconsin, whereby research would be carried on at Madison under our general technical direction and approval, and under a joint expense account. This idea of cooperative research has proved very satisfactory to all concerned. It enables the University to make close contact, without cost, with the leaders in engineering thought in other Universities and in industry. It gives a practical aspect to the often otherwise routine work of the students. It trains research workers It lends authoritative prestige to the output.

This cooperation enables the American Society of Heating and Ventilating Engineers to carry on research at very much less cost than otherwise could be attained. It gives access to laboratories which have ready at hand most of the equipment needed. It brings educators of national reputation to collaborate with our own Director and technical advisory committees.

The contract developed and put into effect at Madison proved so satisfactory that the University cooperation idea has been extended, until today we have similar cooperative agreements with the University of Wisconsin, University of Minnesota, University of Kentucky, Carnegie Institute of Technology, United States Weather Bureau, health departments of thirteen representative cities, Purdue University, Texas Agricultural and Mechanical College, and Harvard University. Further extensions of the arrangement are imminent, and are delayed by our financial budget, rather than by any lack of good will or desire on the part of the cooperating agencies.

We have encouraged the two northern universities to study especially, the construction of buildings, so that our knowledge of the infiltration of air through walls and around windows and doors and our knowledge of the conductivity of materials used in building construction shall be increased. There are already in our literature exceedingly valuable papers from the University of Wisconsin on air infiltration, and we will soon publish the results of a years work on the leakage through various kinds of walls. We apprehend that these results will express among other things, to a startling extent, the effect of quality of workmanship in masonry walls.

We have devised heavy structural steel frames, at the Madison laboratory, in which any desired number of sample walls each about 8 ft. square and of any desired thickness can be built in the open, and allowed to dry out; then can be moved into the testing apparatus and have the leakage rate determined quickly. Prior to this arrangement, in other laboratories when the walls were built inside the testing maching it sometimes took six months or more for a wall to dry out enough to reach a stable condition as to air infiltration.

At the University of Minnesota we have what is probably the most authoritative facilities, that there are anywhere in the

Presented at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

world, for testing the conductivity of materials. Both the hot-plate and the hot-box electrical methods are in use. This work, of course, has to do most intimately with the amount of heat-generating and transmitting apparatus the heating engineer shall provide for the building. In the development of the use of the comparatively recent building-insulation materials, so potent in their effect on operating costs with gas and oil fuels, our laboratory is giving an important service.

The tendency has been for the inventors and manufacturers of insulating materials to be rather more optimistic than otherwise. A given wall construction, for instance, may show a conductivity rate of some number of heat units per degree temperature difference between the two sides, and the manufacturer may so advertise in the best of faith. He may know that with an air temperature of 100 deg. near the ceiling of a normal uninsulated 70-deg.-breathing-line room, he has an attic-air temperature of 40 deg. He may not and usually does not know that after the insulation shall have been applied to that ceiling the air near the ceiling under the insulation may be still warmer than it was before, since it now has met with resistance to outgo; while the attic, no longer receiving a great flow of heat from below, due to the insulation, may drop from the former 40 deg. to zero or below, thus giving a considerably greater temperature difference than that on which the optimist based his calculations, and showing regretably, a much smaller saving due to insulation than that which he at first estimated.

There has been a vast increase in the number of oil- and gas-heated houses. The heaviest demand for gas boilers today is for the small homes having from five to six rooms, and a surprising number of these small installations are being made. Gas gradually is being sold at a lower price while other fuels are rising in price, and this militates in favor of homes insulated against rapid heat flow. The explanation of the reduction in price of gas seems to be that the gas companies have through research, discovered that their overall load factor can be improved vastly by acquiring a heating load.

Experience has demonstrated that it is easy to gain a return in cost of fuel saved, of from 10 per cent to 35 per cent, on money invested in house insulation. The cost of the heating apparatus can be reduced around 18 per cent by a reasonable and justifiable investment in better building construction. Research by the Gas Association, with which we maintain, through our own laboratory, very friendly and beneficial contacts, has shown that the domestic gas load for cooking, water heating, etc., follows the weather conditions, increasing noticeably as the weather gets colder and decreasing as it gets warmer. It is very clear that both domestic and heating demand for gas occur simultaneously, and that in intensity they are a function of the outside temperature.

At the University of Minnesota, we have shown that the efficiency of an air space in the wall of a building is increased rapidly as the thickness of the air space is increased, up to about $^3/_4$ in., after which the heat-resisting efficiency of the air space increases very slowly as the space is widened. This is with reference to small air spaces, in which interior convection air currents do not interpose their potent influence. It is well known, of course, that large air spaces in walls, especially if they have considerable height, allow interior air currents, up the warm side and down the cold side, which are not conducive to effective retention of heat within the building.

We are endeavoring to develop a code for the uniform testing of air-cleaning devices. The difficulty which has handicapped us in the past is that the measurement of the effectiveness of any air cleaner depends on some standard form of dust determinator. Years of study in many leading nations of the world have been given to the development of a dust-measuring machine, but we have today no universal acceptance of any particular type of measuring machine or method, and therefore we have no relative standards of efficiency of cleaning devices.

We have been studying a Hill machine, which is of the type which draws a sample of dusty air through an orifice, impinging the dust on a sticky, ruled object glass, where the particles can be counted under a microscope. We have devised a special apparatus in which several orifices and object glasses are arranged in series and have proved that with this machine from 80 to 85 per cent of the dust in a given sample sticks to the first object glass. We have discovered also the most effective distance from orifice to object glass and can foresee that any standard method of laboratory dust filter testing by this method must provide for a specific air velocity through the orifice of the dust determinator.

The smoke problem in cities gets worse year by year, as far as we can learn. It is more troublesome in some cities than in others. Some cities have a higher death rate from those diseases which we think have to do with air conditions than do other cities. In cooperation with the Weather Bureau, our laboratory is going into this matter with considerable elaboration. We know that results may be attained by this study which will be of undreamed value.

For instance, each Weather Bureau keeps a record of the hours of sunshine each day. The automatic sunshine-recording machine, however, must be favored with a twilight correction factor, being an allowance for the varying interval between true sunrise and true sunset, and the time when the sun is high enough above the horizon to penetrate the overhanging cloud of smoke and dust and so sensitize the instrument. We suspect very strongly that we have discovered that the "twilight correction" is a true measure to a degree, of the amount of suspended impurities in the air above cities. We hope soon to prove or to disprove this suspicion, and to check authoritatively over a period of years, the apparent truth that the "twilight correction" factor consistently is lengthening.

The Research laboratory has arranged with the Weather Bureau to have simultaneous daily observations made of the dust in the air, all with the same dust determinator in the following thirteen cities: Atlanta; Boston; Chicago; Cleveland; Denver; Detroit; Lincoln, Nebr.; Madison, Wis.; New York; Pittsburgh; St. Louis; Washington, D. C.; and Salt Lake City. We have arranged with the health departments of these thirteen cities to furnish us the statistics of the daily incidence and mortality of the infectious diseases in the standard international list of communicable diseases.

The results of all this cooperation will show for the first time the relative air cleanness of the cities, using identical measuring technique, and these data will be coordinated with temperature, humidity, wind velocity, sunshine, and twilight correction, as well as with health conditions. Illness may or may not be a function of dust. These determinations should help to settle the suspicion. The results should be of interest, at least, to the various smoke-prevention bureaus, if not to the various chambers of commerce. The technical advisory committee having the matter in charge, the various health officers, and the Government will all contribute to the authenticity of this study, and the results will, of course, be available in the publications of the Laboratory. When publicity to this research was first given, we were waited upon by one Chamber of Commerce which had gathered the impression that we were undertaking research to prove what city was the most healthy one in which to live. We have also been visited by laundry men and soap manufacturers.

At Harvard University, with the School of Public Health, we are carrying on cooperative research on Heating and Ventilation in its relation to Health and Comfort. Exceptional laboratory

facilities are available there, especially as evidenced in imported apparatus, for the most delicate psychological as well as physical observations.

At Purdue University, a radiator-testing laboratory has been built, to fulfil the most modern conception of what such a plant should comprise and work is under way intensively. There is a strong demand for data to check radiator ratings published by, sometimes, over-optimistic manufacturers and we hope to make Purdue, with our cooperation, an authoritative court of last resort on the subject. There are so many recent improvements in radiators, concealed and exposed, direct and indirect, copper and brass, that the test codes of former days may be obsolete.

At the University of Kentucky, we aided in the construction and inauguration of one of the most complete boiler testing laboratories in existence. Facilities are provided there for the rapid and authoritative testing of any kind of heating boiler, with up-to-the-minute instruments. An exceedingly interesting feature of this laboratory is the arrangement whereby every possible happening and variation during a test is recorded automatically, thus checking and fortifying the human element. Even the opening of a fire or draft door is recorded as to duration and time of incidence, by a machine.

At Carnegie Institute of Technology, Pittsburgh, cooperative research is conducted on the flow of steam and condensation water in pipes. This is fascinating work, profound in the possible economic results. These are published in the Guide, the annual handbook of the American Society of Heating and Ventilating Engineers, and the information gleaned has resulted in many corrections in pipe tables, the authenticity of which was clouded in hoary tradition. In general, it has proved possible to reduce the sizes of pipes for given duties, with tremendous savings in cost to building owners. This work will continue indefinitely.

At the Texas Agricultural and Mechanical College, Austin, Texas, similar work is being conducted directly under Professor Giesecke, a national authority on hot water heating pipe sizes and arrangements. New tables already are available in the Guide. Importance must be stressed on the reaming off of the pipe-cutter burrs in all piping and nipples, as these restrictions in area reduce pipe capacities greatly.

At Pittsburgh, in the Bureau of Mines, we have two psychrometric chambers, where controlled atmospheric conditions are available. We are equipped with the necessary instruments and facilities to study the effect on human beings of the varied atmospheric conditions encountered in industry, as in steel mills and in theaters or places of assembly. Our study in the psychrometric room covering heat production in and dissipation from the human body has extended over many years work. It has involved a study of the rate of metabolism and required the development of apparatus for measuring the heat outgo from the lungs as well as that from the skin.

The study which we are making in this connection is of profound value in all man-cooling projects. Many reports have been published covering the results of this research. We did not discover that there is a certain temperature and moisture condition above or below which the metabolism rate increases, but it is in any event an interesting thing to know. When the surrounding air is too cool, the heat production in the body speeds up to compensate. When the surrounding air is too warm, the heat production in the body speeds up to enable the body to get cool because of greater heat given off as by evaporation of perspiration. We are now publishing data dealing with the bodily heat-controlling mechanism, the results of a year's observation in these test rooms.

The results of this research, on which perhaps more time and resources have been spent than on any other of our studies, are classical, involving participation in the well known "Comfort Zone" chart of the American Society of Heating and Ventilating Engineers and covering fundamentals which are of almost inestimable value in all projects involving the promotion, by air conditioning, of human comfort and well being.

The results of the Research Laboratory appear in the monthly reports of the American Society of Heating and Ventilating Engineers and are the basis for most of the technical information given in the Guide of the society, an annual publication. This Guide is a combination text book and directory and contains the latest engineering data available. It is contributed to by all of the members of the society without compensation and is revised every year.

FSP-51-14

Commercial Problems in Steam-Turbine Design

By R. C. ALLEN,[1] PHILADELPHIA, PA.

This paper discusses developments in steam-turbine design. Concentration of power, in modern turbines, has led to an increase of operating stresses of turbines parts. The tendency now is toward higher blade speeds and reduced size and cost of machines. Manganese copper is used for blades of low stress and of small size; for the larger and more important blades, stainless steel is used. It can be forged and machined without difficulty.

IN THE CONSTRUCTION of large machinery, steam-turbine equipment, for example, the element of time is a dominating factor. We must invent, design, construct, install and place in service machines up to 6000 kw. in three months' time. This rapid procedure in the building of turbine equipment is not confined to simple types of units that are altered slightly to meet specific operating conditions. On the contrary, many extremely complicated industrial turbine combinations are required on a short delivery basis.

In the central station field, the turbine builder is called upon to design and construct units of the largest size in less than one year's time. Single-cylinder machines of the largest size have been designed, built, installed, and placed in service within ten months' time. With multiple-cylinder machines, there has been a corresponding record of achievement.

The nature of the large steam-turbine business makes it impossible to standardize designs, even in the turbine blades, at least not to any appreciable degree. Experiments are carried out with miniature turbines and the results applied, when predicting the performance of the full-sized units. The real test of engineering comes when the finished product is placed in service.

Turbines of today require larger and much more expensive blades than formerly as they are subjected to heavy stresses. For reasons of strength alone we would like to make them tapered rods or tubes. To secure a reasonable thermal efficiency the blade sections must be crescent shaped, with the horns of the crescents as the extreme fibers from the neutral axes of their least moments of inertia, when the blades are considered with regard to bending stresses. The inlet and outlet edges of blades must be reasonably thin to secure the desired efficiency. Formerly, the inlet and outlet edges were left ragged after the machining operations, so that fatigue failures were not uncommon. It required an unbelievably long time for the turbine builders to discover that the rounding of the inlet and outlet edges would give a substantial improvement in the fatigue-resisting properties of the finished blades. The fatigue resistance of turbine blades has been increased at least three times, by the introduction of the simple process of rounding the edges. The rounding of the upper edges of blade-packing pieces and the rounding of the edges of lashing-wire holes are other examples of the value of little details in blade design.

The study of blading materials has occupied the attention of metallurgists for many years. One important property brought to light has been the matter of solder cracking. If a $^3/_8$-in. rod of 30 per cent nickel steel is fluxed and coated with silver solder, it may be snapped off short with but little effort while at the soldering temperature. This is due to an attack by the molten solder upon the intercrystalline cement. Stress is required to bring the action into play. This obscure effect caused many troubles before it was discovered.

Long turbine blading requires a reinforcement in the form of shroud bands, or lashing wires, to keep down the bending stresses, whether they be caused by direct steam loads or by blade vibration. It is believed that silver soldering is the most-durable method of preventing relative motion between the blades and their lashing wires. It is therefore essential that blades and lashings be of material that can be silver soldered easily.

In the practice of the Westinghouse Company, manganese copper is used for blades of low stress and small size in turbines of the industrial class. For the longer and more important blades stainless steel is used. Stainless steel is a general term covering a large class of materials, most of which are not suitable for blading practice. The present standard material has a chromium content of $11^1/_2$ to 13 per cent and a carbon content of 0.07 to 0.12 per cent. It can be forged and machined without serious difficulty. It is believed to be the safest material now available for use in the extreme low-pressure zones. It is not a perfect material, as there may still be some erosion at high blade speeds. On the other hand, this steel is available in quantity and with sufficient uniformity so that the production of reliable blades is further assured. The physical properties are retained satisfactorily under high-temperature conditions.

There are many stainless steels that are less corrosive than the material now in common use, and while some of these are less susceptible to the erosion found in the last rows of large machines, there are definite objections to the use of these materials for blading; if not that of solder cracking, there is the question of low elastic properties. Some of these materials are extremely hard to fabricate.

Starting in about 1918, several large three-cylinder turbines of around 60,000-kw. capacity were designed and constructed by the Westinghouse Company. Among these units were two 60,000-kw. machines installed at the Colfax plant of the Duquesne Light Company. The turbine parts of one of these units weighed 1,652,000 lb. The low-pressure blades were 18 in. high with a tip speed of 607 ft. per sec. The rotative speeds were 1800 and 1200 r.p.m. for the high- and low-pressure elements, respectively.

In November of last year a 60,000-kw. 1800-r.p.m. Westinghouse single-cylinder turbine was placed in service at the Lakeside plant in Milwaukee. The turbine parts of this new machine weigh 635,000 lb., over a million pounds less than the corresponding parts of the older Colfax turbines of the same capacity. The generator parts of the new Milwaukee unit provide a further reduction of 350,000 lb. below the weight of previous designs. The low-pressure blades are 34 in. high with a tip speed of 1147 ft. per sec. The turbine at Lakeside occupies about one-third of the floor space required for the older Colfax machine, while, on the other hand, the engine efficiency of the new turbine is higher. The reason for the greatly reduced proportions of the new frame is found in the high blade speed and the great length of the last row of low-pressure blades.

[1] Manager of Large Turbine Engineering, Westinghouse Electric & Manufacturing Co., Philadelphia, Pa.

Abstract of paper presented at the Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

It must not be assumed that the new machine at Lakeside cost the turbine manufacturer the same average amount per pound as the older turbine at Colfax. Details of construction are more expensive in the smaller and higher-speed unit when considered on the pound basis. In the 60,000-kw. Colfax turbine, the spindle parts were designed so that they could be made from steel castings. In the Lakeside turbine the spindle parts are machined from steel forgings, while the coupling end is forged of $3^1/_2$ per cent nickel steel. In the Lakeside turbine, an improved form of blade fastening has been developed that permits a substantial shortening of the spindle, although adding greatly to the cost. Central-station people appear to be intensely interested in the largest sizes of single-cylinder turbines. It is believed that for steam pressures not exceeding 650 lb., the multiple-cylinder units will become increasingly hard to justify.

The great concentration of power in modern turbines has called for increases rather than reductions in the operating stresses of the turbine parts. Years ago a designer usually expressed pride in a machine design in which there were lower operating stresses than found in similar equipment of earlier types. Today the reverse condition exists, in that the engineer must work all material to the maximum possible stress consistent with good reliability. In many instances we have been asked, during the negotiation stages of large jobs, if the stresses in certain rows of blades were greater than those existing in previous designs. In some cases we were forced to reply in the affirmative, thereby creating doubts in the minds of the prospective purchases as to the sufficiency of the new designs. The author would like to bring out one important point in connection with the determination of operating stresses: namely, that most of the developments in the past few years have been made in the direction of discovering and eliminating high local stresses. In other words, in our modern designs we can operate with higher average stresses because our factor of ignorance is less and it has been made so by continued study and research on the problem of local stresses. It should also be borne in mind that little is known of the true stress distribution in a bar in simple tension. We still have factors of ignorance in machine construction that will be reduced gradually, permitting in the future still higher average stresses and securing at the same time an improved reliability.

The tendency toward higher blade speeds in modern turbine design has been the most important influence that has led to reductions in size and cost, and that has permitted the construction of the huge machines that have been placed in service the past year. How far we can go in further increasing blade speeds, we do not know. We have not yet reached the practical limits with the materials now available. The Westinghouse Company has in service, or on order, five turbines of the single-cylinder 1800-r.p.m. frame, designed for a normal rating of 65,000 kw. The General Electric Company has sold a single-cylinder machine for Cahokia with a 75,000-kw. rating. If the industry can use still larger single-cylinder machines, they can be constructed with good assurance as regards operating reliability and efficiency. Large multiple-cylinder turbines of 100,000 kw. capacity and greater, are, in most cases, tailor made to suit particular needs. The general trend of turbine design is naturally in the direction of reliability and simplicity. The Westinghouse Company has introduced the oil governor as a speed-controlling mechanism. The oil governor has been adopted because of the greater reliability that is to be secured through the elimination of the many wearing parts of the older flyball governor mechanisms.

In the general arrangement of Westinghouse turbines on their foundations, an attempt was made formerly to standardize the placing of steam chests, throttle valves, and other important parts. We tried to use standard assemblies of oil piping and similar auxiliary details. This was found to be impossible to carry out with the larger central-station turbines of recent designs because of the many types of foundations on which the equipment must be installed. It is therefore necessary for the members of our designing staff to cooperate with the engineers of the power-plant constructor and to work out with them the best arrangement of steam chests, oil tanks, oil piping, and other similar equipment.

It may seem anomalous that the reliability of central-station turbines is increasing in spite of the higher blade speeds, longer blades, and higher operating stresses. This is bound to follow from practical experience, as well as from advanced research. It is believed the future holds further possibilities in the way of greater concentrations of power and higher efficiencies, and that we shall at the same time be able to accomplish these things with increased reliability and with reduced labor on the part of our most loyal friends, the turbine operators.

Centrifugal-Pump Economics

By A. F. SCHERZER,[1] ANN ARBOR, MICH.

In this paper the author presents some developments in the theory of the centrifugal pump with which he has been connected and shows their application to pump practice. In reviewing the technical and theoretical aspects of the problem, he refers to the fact that the performance of the centrifugal pump is shown best graphically by the quantity-head curve. In the extensive centrifugal-pump literature existing there are to be found a number of theoretical analyses of the action of such pumps, all of which are based on somewhat similar assumptions. In each case the striking fact is the wide difference between the so-called theoretical curve and the one actually obtained by a test. To bring about any sort of an agreement it is necessary to assume in some cases large and disproportionate losses. To show this difference the author presents a chart showing the theoretical quantity-head curve and the actual curve obtained by a test of the pump. Around the point of zero discharge there was a discrepancy of about 100 per cent between so-called theory and practice. At or near the shut-off point the head actually obtained from the pump was nearly twice as much. A careful study of these matters resulted in the discovery of a surprising error in the derivation of the fundamental theory for the centrifugal pump.

Another interesting point brought out in the paper is that the use and the benefits claimed for guide vanes are founded on a misconception of theory. The same is true of the so-called volute or spiral casing into which the runner discharges the water.

The author states that the real function of the pump case is that of compelling the water to revolve in a more or less circular path. Thus the natural form of a case should not be volute or spiral, but rather a plain concentric circular case of constant cross-sectional area. Tests of a circular case pump and a good design of the volute type showed a remarkable increase in head development by the former. At its point of maximum efficiency the circular case pump developed an excess head of 50 per cent over a similar volute design.

PERFORMANCE of a centrifugal pump is shown best graphically, by the curve representing the relation between the quantity discharged and the height to which it is lifted, the speed of rotation being constant. This is known as the quantity head curve, or sometimes the pump characteristic. Such a curve is shown in Fig. 1. The shape of this curve is fixed by the design and proportions of the pump, and it can be determined exactly only by a test. It is not a question of impeller design or shell design, but rather the combination of the two. The same impeller in different shells will not give the same curve.

In our rather extensive centrifugal-pump literature, there will be found a number of theoretical analyses of the action of such pumps. Most of these are based on somewhat similar assumptions, and what is true of one is with some exceptions, common to all of them.

The striking fact in each case is the wide difference between the so-called theoretical curve and the one actually obtained by a test. In order to bring any sort of agreement, it is necessary to assume, in some cases, large and disproportionate losses. In view of the high efficiency of well-designed pumps, it seems impossible to account for the existing difference on any such theory of losses. When this problem first came to the author's attention fifteen years ago, he dismissed from his mind any idea that the commonly accepted theory of the centrifugal pump could be in any way open to question. As time went on, however, his confidence in it weakened gradually and the belief amounted almost to certainty, that some error had been made somewhere in its derivation. What this error could be, was the real question. The derivations found in texts were, in general, very simple and direct in their reasoning, and for some time no fault could be found with them. Without going into the details of existing pump theory, it will be sufficient to state, that the so-called

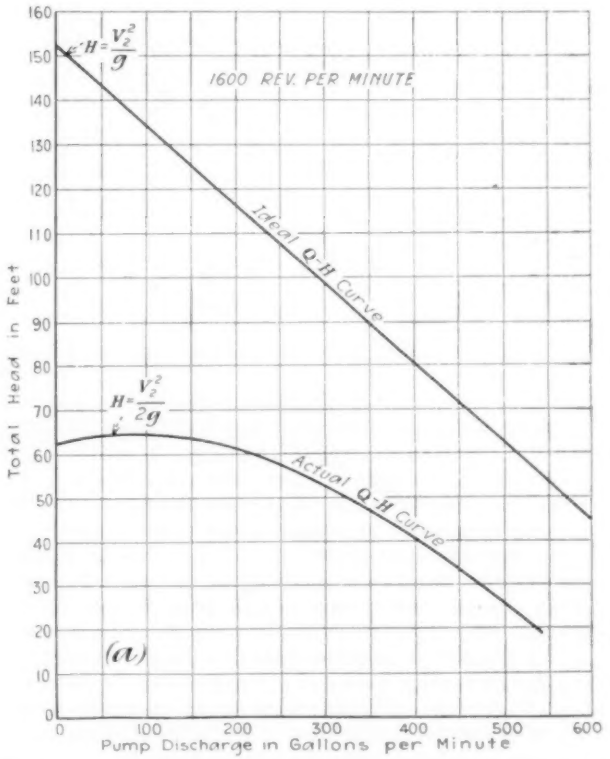

FIG. 1 COMPARISON OF ACTUAL AND THEORETICAL QUANTITY HEAD CURVES

theoretical relation between the quantity and head can be expressed by the relation:

$$H = \frac{V_2}{g} + \frac{V_2 \cos B_2 Q}{g A_2}$$

where H is the theoretical head developed, V_2 the peripheral speed of the impeller at its outer diameter, B_2 the vane angle as shown in Fig. 2, g the constant of gravity, and A_2 the area of the water passages in the impeller perpendicular to the relative velocity W_2. This equation leads to the straight-line relation between Q and H shown in Fig. 1 and marked ideal Q-H curve." Below this is shown the actual Q-H curve as obtained by a test. As can be seen around the point of zero discharge, there is a discrepancy of about 100 per cent between socalled theory and practice. At or near the shut-off point the head actually obtained from the pump is approximately $V_2^2/2g$, while the head called for by present theories is about V_2^2/g, or nearly twice as much. This

Presented at the Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

difference is explained and accounted for in various ways, by different authorities, none of which appear to the author as either probable or convincing and further do not meet certain requirements of fact. A great deal may be found in current pump literature on this subject. A careful study of these matters resulted in the discovery of a rather surprising error in the derivation of the fundamental theory for the centrifugal pump, which will be explained in some detail.

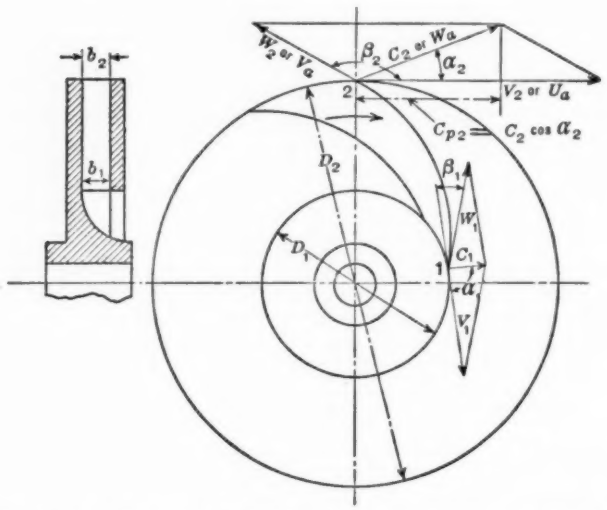

FIG. 2 PUMP DIAGRAMS AT ENTRANCE AND DISCHARGE OF IMPELLER

The usual explanation of this discrepancy indicates a serious misconception, not only of the action of the centrifugal pump, but of one of the fundamental laws of hydraulics. The error is due to a misapplication of the well-known Bernoulli theorem.

When water flows in a pipe, it is customary to say that the total head is obtained by measuring the pressure head by a piezometer at right angles to the flow, and adding the velocity head. This is a correct application of the theorem. The pressure and velocity exist as separate and distinct factors. However, when water is set in rotation, in a cylindrical vessel by the action of a paddle or impeller, there is a pressure created, by centrifugal force which is equal to $V_2^2/2g$ and which is part of the velocity itself. The total head may be regarded as either, but not both. The pressure exists merely because of the velocity in the circular path, but certainly not in addition to it.

It would be as logical to say that the "hammer," swung around by the athlete, has a total energy equal to the sum of the kinetic energy of the ball and the tension in the wire. Clearly the tension is not energy, but merely a force existing because of the tendency of the ball to fly off at a tangent. The energy is entirely kinetic. The act of letting go of the wire (destroying the tension) does not change any of the original energy, and the hammer flies off at a tangent with a velocity V which is the same as its former peripheral velocity. Therefore the total energy is $V_2^2/2g$.

It is clear that the pump gives a head of only $V_2^2/2g$ at "shut off," instead of V_2^2/g as required by all present theories, for the very simple reason that the energy imparted is only $V_2^2/2g$, and naturally the water can have no more energy than it is given by the impeller.

One of the reasons that might be advanced as to the cause of this error is the widespread failure to distinguish properly between pressure and energy. Pressure may measure potential energy and may serve to transmit energy, but it is not in itself energy any more than force is work.

Fig. 1 shows graphically the generally accepted theory of the centrifugal pump. Here the ideal quantity-head curve is shown beside the actual quantity-head curve for comparison. Similar curves may be found in numerous works of reference. There is an obvious inconsistency between the equations representing the head imparted to the water and their graphical representation as Fig. 1. For example, the ideal quantity-head curve is seen to pass through a point representing more than double the head actually developed at the point of zero discharge, an obvious impossibility, as the pressure is caused only by centrifugal force.

According to the present theory, the total head is considered to be composed of two items, pressure and velocity. A measurement of the pressure indicates an average value of about $V_2^2/2g$ at or near the point of zero discharge. Discharge diagrams of runners show that at small rates of flow the absolute velocity C_2 is nearly equal to V_2 and, hence, the energy represented by it is

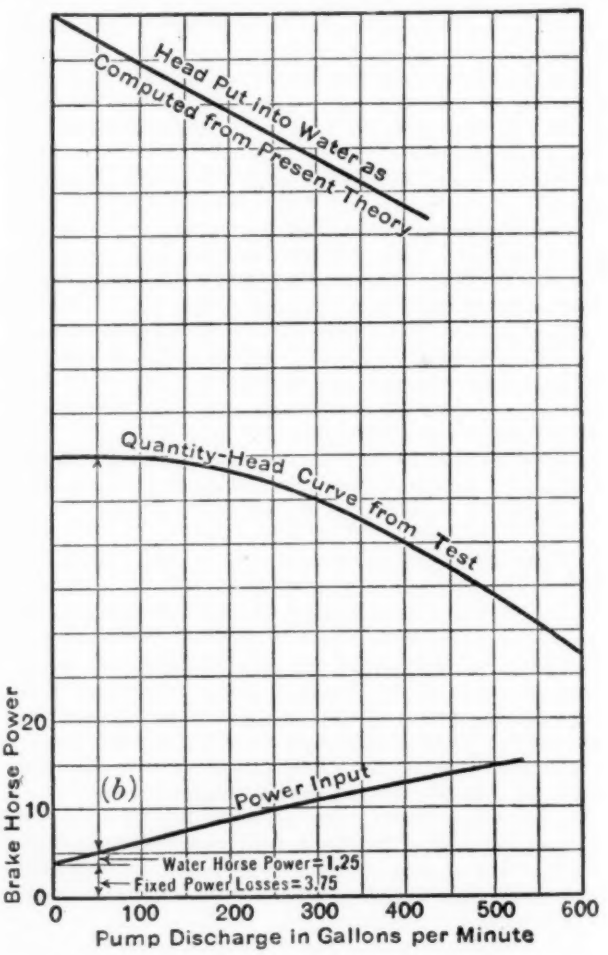

FIG. 3 DEMONSTRATION OF ERROR IN PRESENT PUMP THEORY BY A TEST

nearly $V^2/2g$. This would apparently mean that the total head is approximately $V_2^2/2g + C^2_2/2g$, or very nearly V_2^2/g. As a matter of actual experience, only a head of about one-half the ideal is developed by the pump. The difference is commonly said to be due to shock losses, and many elaborate formulas have been developed to account for it.

Fortunately, it is possible to settle this question beyond any doubt by a simple test in the laboratory. Referring to the characteristic curves obtained from a test of a centrifugal pump,

as in Fig. 3, it will be noticed that at the point of zero discharge the power required to drive the pump is the minimum (3.75 hp.). This power is consumed in doing the following things: (1) Overcoming the bearing friction; (2) overcoming the stuffing-box friction; (3) overcoming the disk friction of the impeller; and (4) pumping the internal leakage.

Since no water is being discharged by the pump, it follows that no useful work is done. If the discharge valve is opened and a little water allowed to flow, it will be noticed that the power required to drive the pump is increased. Assume that 50 gal. per min. is allowed to flow. The four losses mentioned will continue substantially as before, since there is nothing to change them at small rates of flow. To cause this flow requires an input of 5 hp.; the losses are 3.75 hp.; the difference, 1.25 hp., represents the amount of energy imparted to the water. Now, determine to what height 1.25 hp. would raise 50 gal. per min. A simple computation shows this to be 100 ft. Referring to Fig. 3, it will be seen that that is exactly the head developed by the pump.

According to the current pump theory, the head put into the water under the conditions of the test would be about 195 ft. If this were true the dynamometer would have to show this power input. As a matter of fact, it merely indicates the power required to lift the water to the head developed by the test and, at the same time, to overcome the various mechanical losses in the pump.

One of the questions debated for years by centrifugal-pump designers concerns the use of guide vanes. Some state that it is always possible to secure better efficiency by their use; others would never design a pump with guide vanes. Still a third class claims that it recognizes their advantages in some cases and uses them when by so doing the efficiency can be improved, thus giving the impression that they have some possible use.

In order to answer this question, consider what is supposed to be their function. It has been shown in the various theories that at discharge from the runner the water has a pressure head $V_2^2/2g$ as well as a velocity head $C_2^2/2g$. It is often stated that this velocity head $C_2^2/2g$ will be lost in shock, friction, etc., unless suitable provision is made for its recovery. The commonly accepted idea has been that at very small rates of flow this energy is about equally divided between pressure and velocity, and that the entire velocity head under these conditions was apt to be lost unless special provision was made in the form of guide vanes or diffuser vanes. Such vanes were designed so as to receive the absolute velocity of the water. By increasing the area of the water passages between them, the velocity was expected to be converted most efficiently into pressure.

Evidently, from the previous discussion, the use and benefits of guide vanes are founded on a misconception of the theory. In a centrifugal pump it is absolutely wrong to assume that the total energy is represented by the pressure in the casing plus the kinetic energy of the absolute velocity of discharge.

As the water is confined to a circular path, its kinetic energy is necessarily converted into pressure without any assistance from the guide vanes. In fact, they often serve to obstruct the natural flow of water, which entirely defeats their purpose and renders them useless. From the point of view of practice, equal or better efficiency can be obtained with a properly designed volute.

What has just been said with regard to the use of guide vanes may also be extended to include the so-called volute or spiral casing into which the runner discharges the water. The advantage of the volute casing is supposed to lie chiefly in permitting the efficient conversion of velocity into pressure through the recovery of a part of the energy represented by the absolute velocity of discharge from the runner.

While it is true that velocity is converted into pressure in the casing, yet it is not at all in the manner, or for the reasons usually given. If a body of water is set in rotation so that the peripheral speed of the outermost particle is V_2, then a pressure will be developed equal to $V_2^2/2g$, a case of perfect conversion of velocity into pressure. This is exactly what is taking place in the centrifugal pump.

Apparently, the only function of the casing is to restrain the water and compel it to move in a circular path. The development of pressure then follows naturally. The pressure obviously exists only because of the velocity, and one may be said to be equivalent to or measure the other. The very existence of pressure here indicates clearly that the velocity has been converted into pressure. It is difficult to see how it can be done a second time, yet this is exactly what is supposed to be accomplished by the guide vanes and spiral casings. This shows how hopeless it is to expect any gain from the use of guide vanes and spiral

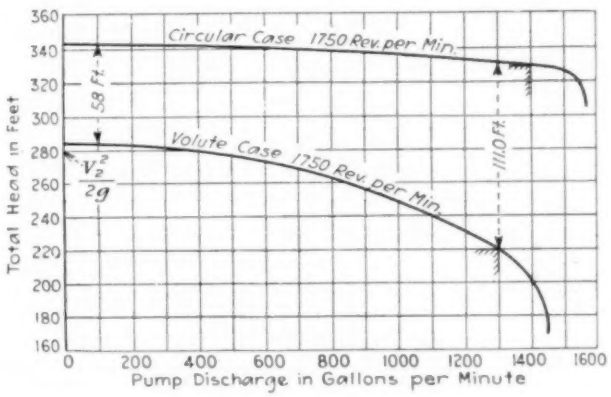

FIG. 4 COMPARISON OF A CIRCULAR-CASE PUMP AND A VOLUTE-CASE PUMP OF THE SAME DIAMETER, SHOWING EXCESS HEAD DEVELOPED BY CIRCULAR-CASE PUMP

casings, since their advantage is based on conditions, which can easily be proved never to have existed.

Up to this point we have been concerned chiefly with the technical and theoretical aspects of the problem. It is now proposed to show to what extent the conclusions which may be logically drawn from the foregoing discussion of the centrifugal pump theory may be applied toward improving performance.

The fallacy in the use of guide vanes and volutes or spiral casings has already been explained. The real functions of the pump case is seen to be, therefore, that of compelling the water to revolve in a more or less circular path, whereby the pressure is developed in much the same way that a stone whirled at the end of a string develops tension in it. From this it would appear that the natural form of case is not the well-known volute or spiral case, but rather a plain concentric circular case of constant cross-sectional area. This was such a radical departure from present accepted theories and practice that a pump was designed to test out the value of the new ideas.

The results of even the first design were quite remarkable and indicated in general two distinct points of advantage:

a Higher heads for a given peripheral speed
b Lower rotation losses for a given wheel diameter.

These two taken together made possible an increase of several points in the efficiency above that usually obtained in similar commercial designs.

Fig. 4 shows the very remarkable increase in head developed by a circular-case pump as compared with a very good design of the volute type. Each pump has its maximum efficiency at about the same capacity, so that they are fairly comparable. It is seen here, that the circular-case pump develops at its point of maxi-

mum efficiency an excess head of 111 ft. (50 per cent) over a similar volute design. The fact should be kept in mind, that both these impellers were of exactly the same diameter and both rotate at 1750 r.p.m. The circular-case design is clearly superior to the volute type in the matter of conversion of velocity into pressure within the case. This is accomplished by permitting a vortex of greater diameter than is possible in a volute pump.

Fig. 5 shows a similar comparison on another pump. Here a 17-in. impeller in the circular-case type is seen to produce at points of best efficiency about 60 ft. more head than a $17^1/_2$-in. impeller in a volute pump. If these two were compared on the basis of both $17^1/_2$-in. impellers the excess of the circular case over the volute design would be 77 ft. or 35 per cent.

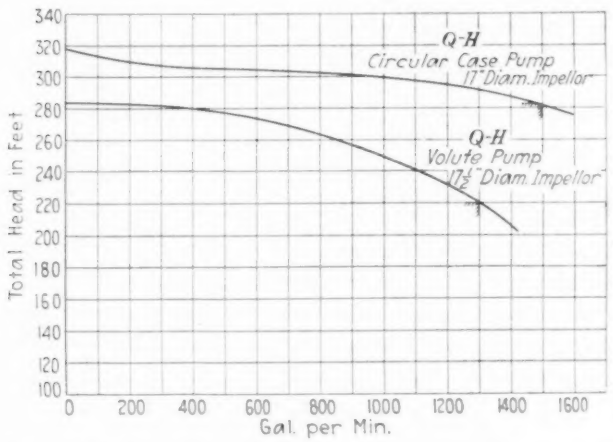

FIG. 5 COMPARISON OF HEAD DEVELOPED BY A CIRCULAR-CASE AND A VOLUTE-CASE PUMP AT 1750 REVOLUTIONS PER MINUTE

It is of special interest to note that the circular, concentric case is by no means new as the earliest pumps of this type were so constructed. Later on the circular case was replaced by the volute which was regarded as better hydraulically. It is now possible to demonstrate both theoretically and practically, that better results may be obtained with the circular case design, other things being equal.

The well-known failure of the various theories commonly accepted at present to agree with facts determined by tests, led to a very close study of both theoretical and practical phases of the problem. This has resulted in the development of an entirely new theory for the centrifugal pump. The author believes it to be theoretically sound, and its continued application to actual practice has resulted in exceptionally good agreement. The simplicity of the new theory should appeal both to those unfamiliar with present theories who desire to get some workable ideas as to pump performance, as well as those experienced in such work but hampered by the intricate and laborious calculations which now seem necessary.

The elementary action of a centrifugal pump will now be considered. First, imagine the pump revolving with the discharge valve closed. The water contained in the impeller revolves with it and through the action of centrifugal force has a tendency to move out into the case. As the case is filled with water, there is no place for it to go. Its desire to get out of the impeller is communicated, to the water outside in the case in the form of a static pressure. Thus the flow from the impeller is prevented by the equal and opposite back pressure of the water in the case, and no water is discharged. The pump is now said to be operating at shut-off, and the pressure head developed to approximately $V_2^2/2g$. Now the water in the case between the impeller and walls, also the water in the radial space beyond the impeller, is set in rotation by the dragging action of the revolving impeller. The angular velocity of this mass is less that that of the impeller, but due to its larger radius, in some cases, a pressure greater than $V_2^2/2g$ may be produced. The circular case is particularly favorable to this action. It is shown in Fig. 5 that a head 65 ft. in excess of $V_2^2/2g$ was developed by the circular case pump and only 7 ft. excess by the volute design.

Now assume the discharge valve to be opened a little. Water will flow through it. The back pressure in the case will be reduced and water will flow from the impeller into the case, due to the pressure difference existing. The water thrown off from the impeller has a large tangential component and mingles with the water revolving in the case. Some assistance may be received therefore from this source and a further increase in head may be obtained. This effect is especially noted in pumps having so-called rising characteristics.

The whole action might be compared in a rough way to water in a tub or barrel set in rotation by a revolving paddle, assisted at the same time by a jet of water directed more or less tangentially into it.

Consider a pump running at a certain speed, but with its discharge valve closed. The water in the impeller and the casing is set in rotation, creating a pressure in the pump, but flow from the runner is prevented owing to the pressure of the water in the casing. Now, assume that the discharge valve is opened a trifle to permit a slight amount of flow. The pressure in the casing falls, and the pressure opposing the flow from the impeller decreases, but the centrifugal force tending to throw the water out of the impeller remains the same, since the speed of the pump is constant. Consequently, water will flow in from the impeller into the casing, the quantity depending on the difference in pressure as well as on the area of the water passages. As soon as the water begins to move relative to the impeller, friction comes into play opposing the flow. The pump will adjust itself to these conditions so that the resultant of the pressure in the casing, the drop in pressure due to the flow, and the frictional losses in the impeller will equal the total pressure due to centrifugal force. From now on the pump will operate continuously at this discharge.

On further opening the discharge valve, similar readjustments continue until the entire pressure due to centrifugal force has been consumed in forcing the water through the runner, or else a point is reached where the atmospheric pressure is no longer able to force any greater quantity of water into the suction of the impeller. Thus, the flow from the runner is governed simply by the difference between the pressure due to centrifugal force and the pressure in the casing. Once this is understood clearly the problem is merely that of the flow through a very special form of orifice due to this pressure difference.

After the water has left the runner and has passed out into the casing, it must flow through the so-called throat of the pump before passing the discharge flange. This throat is merely the point of maximum cross-section of the volute. All the water discharged from the runner passes through this, a third orifice. Hence the entire problem of the centrifugal pump is that of flow through three orifices in series. The first is at the suction entrance to the impeller, and this determines the maximum capacity of the pump. The second is at the discharge from the runner, and the third is at the throat of the pump. Each of these orifices or points of restriction has its own characteristics and their combined effect determine the pump characteristic.

Consider that the pump is running at a constant speed. The pressure developed by centrifugal force, tending to force the water out of the impeller, is constant and is quite independent of the flow or the amount of it. Centrifugal force is equal to MV^2/R evidently, neither V nor R is changed greatly by the flow of

water and the mass M need not be considered in determining the energy input per pound of water. In other words, if there were no loss of pressure in the impeller and casing, the pump would deliver any quantity of water within the limit of the suction capacity at a constant pressure of approximately $V_2^2/2g$. A drop in pressure at the discharge flange is necessary if any water is to flow from the impeller.

The quantity that will flow depends on the area of the water passages; and its velocity, on the pressure difference established. The velocity is therefore quite independent of the quantity being discharged. The quantity is the product of the velocity and the area of the water passages measured perpendicularly to it.

The amount that the pressure at any point falls below the horizontal-line-tangent to the quantity-head curve at "shut-off" is very nearly that required to force this quantity of water through the pump. The total drop in pressure is (1) that required to cause the given quantity of water to flow, and (2) that required to overcome the hydraulic losses. These are fundamentally different in their nature and yet produce similar effects on the pump characteristic.

There is a rather close relation between the centrifugal pump and the electric generator. The drop in pressure required to produce flow is an example of a loss in pressure without any loss in power. A similar instance occurs in the field of electricity. An electric generator would deliver a constant voltage at its terminals, were it not for two principal losses. These are the drops in pressure due to armature reaction and to internal resistance. The drop in pressure due to armature reaction causes no loss of energy, whereas that due to resistance wastes energy in the form of heat. A loss of pressure that does not involve

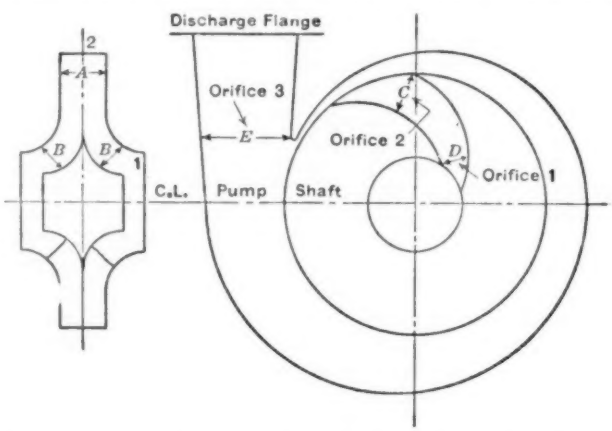

Fig. 6 Shell and Runner Showing Location of the Three Orifices

a loss of power is called a pressure drop, while a loss of power is called a pressure loss. These same terms might apply to the pump theory. In fact, many close analogies exist between the centrifugal pump and a separately excited shunt generator.

In the pump, the drop in pressure without loss of power merely means that a greater pressure drop is required to discharge a given quantity of water through a small orifice than for one of larger area; or that for a given pressure drop, more water will flow through a large orifice than a small one. This does not mean that the large orifice is necessarily more efficient than the smaller one for both may have a coefficient of nearly 100 per cent.

When water flows through the runner it has to overcome the frictional losses. These produce a drop in pressure, which is also a loss of power. Since the length of the path of the water in the impeller is short and the water ways are smooth, this loss of power due to friction is not large.

To make the new theory clear and indicate its application to practice, a characteristic curve, showing the relation between the head, and capacity at constant speed, has been worked out for a typical pump. The machine is of usual design and construction and of well-known make. Fig. 6 showing typical views, serves to illustrate the three points of control or orifices. The first is at the entrance to the impeller-vane passages, and its area is equal to the product of the dimensions, B and D, and the total number of vane passages. The second is at the discharge from the impeller-vane passages; its area is the product of the dimensions, A and C, and the total number of vane passages. The

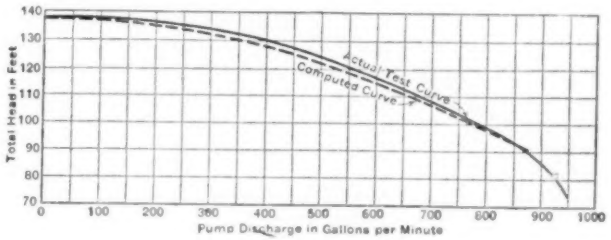

Fig. 7 Comparisons of the Quantity-Head Curves as Computed by the New Theory With That Obtained From a Test at 1750 Revolutions Per Minute

third is at the throat of the pump; its area is usually that of a circle of diameter, E (Fig. 6).

The following analysis of the quantity-head curve of a 4-in. double-suction pump will make the new theory clear. The areas given were determined from the pump design.

Area of orifice No. 1 equals $B \times D \times$ number of vanes = 0.0553 sq. ft.
Area of orifice No. 2 equals $A \times C \times$ number of vanes = 0.0625 sq. ft.
Area of orifice No. 3 equals $\pi E^2/4$ = 0.0694 sq. ft.

The velocity of flow through the orifice is equal to quantity ÷ area, hence the velocity through orifice No. 1 is $C = Q/0.0583$, through orifice No. 2 is $C_2 = Q/0.0625$, and through No. 3 is $C_3 = Q/0.0694$. The drop in head required to produce these velocities C_1, C_2, and C_3 can be compiled from the relation $H = C/2g$. Assuming Q = 200 gal. per min. $H_1 = 1.010$, $H_2 = 0.765$, and $H_3 = 0.645$. The total drop in pressure required to get 200 gal. per min. through the pump is the sum of the above three or 2.410.

Now assume Q = 400 gal. per min. and proceeding in the same way the total drop in pressure is 9.84.

For 600 gal. per min. the total drop is 22.0 ft.
For 800 gal. per min. the total drop is 39.0 ft.

The head developed at shut off was found by test to be 137 ft. The actual heads developed by the pump are therefore obtained by subtracting the total drop for various rates of flow from the head developed at shut off. Hence:

The head at 200 gal. per min. = 137.0 — 2.41 = 134.6 ft.
The head at 400 gal. per min. = 137.0 — 9.81 = 127.2 ft.
The head at 600 gal. per min. = 137.0 —22.0 = 115.0 ft.
The head at 800 gal. per min. = 137.0 —39.0 = 98.0 ft.

Fig. 7 shows graphically the agreement between the new theory and an actual test on this pump.

It will be noticed that in computing the drop in pressure to flow through orifices No. 1, No. 2, and No. 3 that no coefficient was used and also no account was taken of any possible gain in velocity head or of frictional losses. This was intentional. It

is evident that some coefficient must be used for each orifice also that some of the velocity produced at one orifice is available at the next.

The problem is so complex that any attempt to determine the coefficient or the regain of velocity head for each orifice separately would no doubt be beyond our present ability. It was therefore decided to neglect each as one tends to offset the other and then apply a blanket factor at the end to bring about agreement. It was surprising to note that even from the first, no great modification was needed and the results agreed pretty well as first calculated. This can mean only that neglect of one about cancels the other which is pure coincidence. It may be later on when further and more comprehensive data is available some factor may be used to advantage. If so it should be determined experimentally. Owing to lack of time the new theory[2] has been condensed to its essentials and some of the finer points have been omitted.

[2] The complete theory may be found in the Proceedings of the American Society of Civil Engineers, October, 1927, as well as in the author's closure Proc. A.S.C.E., January, 1929.

FSP-51-16

Coordination of Industrial-Plant and Central-Station Power

By P. J. GAUDY,[1] CHICAGO, ILL.

In this paper, the author discusses the generation of power for use of industrial plants. In general, he finds that central stations are able to deliver power as required by industrials, cheaper than the latter can produce it themselves. An industrial can generate electric energy for power purposes profitably only when the utility does not maintain proper service or charge a reasonable rate or when the industrial has energy available in some form, for conversion to power, which is a by-product, or natural result, of its major manufacturing process.

COORDINATION of industrial plant and central station power is, primarily, one of policy. It is unfortunate, in the past, that in many cases, policy has been a restricting element in a proper solution of this coordination, even when the economic situation is perfectly sound. The public-utility sales organization unquestionably demonstrates that it is earnest in its desire to cooperate with and serve the customers who supply the patronage which has allowed the utilities the prosperity which they have enjoyed. However, the sales effort and customer's cultivation have, in many cases, been handicapped by inability to surmount prejudice and rules which previous bad experiences have engendered.

The coordination of industrial-plant and central-station service primarily means the possibility of parallel operation or contribution by both the buyer and the central station in serving the buyer's block of load. The cases wherein the local industrial is so situated as to be a dominant or responsible factor in rendering service to the public utility are very few and are not to be omitted, although they represent so small a portion of the total relations as to make them negligible in this discussion.

If the generation of power by the industrial plant, for its own needs, is to be an economic move, it must necessarily be that the industrial has some facility whereby the combination of the capital cost of power equipment and the operating cost of generating energy is so substantially lower than the purchase price of energy as to make it an attractive venture from the profit-producing standpoint. This is, in general, a perfectly non-competitive proposition, as central stations, even at a profit, are able by their concentrated facilities and diversity to deliver the requisite power to industrials, cheaper than they can produce it in a similar manner themselves.

The exceptions are those cases where industrials can generate part or all of their power at a gross cost which is very much less than the purchase price for a corresponding portion of their power. An industrial can generate electric energy for power purposes profitably only when one of the following conditions is satisfied: The utility must be inadequate to maintain proper service or be operating under conditions which do not make possible a reasonable power rate, or the industrial must have energy in some form available for conversion to power which is a by-product or natural result of its major manufacturing processes.

There are singular instances where energy as fuel is available as a by-product to the operation wherein the failure to use this energy would be a total economic waste. For example, a steel mill having blast-furnace gas available, which is far in excess of the heat requirements as such, has a potential possibility as to power generation to the full extent of its own requirements, and, perhaps, in excess. A woodworking plant, where the creation of wood rubbish due to manufacture, delivers in combustible condition fuel as a direct waste, can with proper facilities generate power at a much less expense than the average purchase price.

Both of these instances may not represent a true absorption of the available fuel as the creation of wood rubbish or the production of gas must obviously concur with the power demands or facilities provided for storing, and later using these commodities, and in no case is the storage of a by-product fuel inexpensive.

There are also, and in much greater quantity, conditions where waste heat enters the picture to a dominant extent as referred to power generation. This waste heat may be either in the form of gases of sufficient temperature, to be economically diverted to the generation of power, or, as is more universally true, this heat may be in the form of steam at a higher pressure than that corresponding to its ultimate use, or be exhausted at a pressure higher than necessary if utilized directly for power.

One example of the foregoing conditions is a cement plant where the exhaust kiln gases will generate adequate power for the mechanical requirements. Here the matter of concurrence enters most forcibly, as the energy is represented only in the sensible heat of the products of combustion. The storage of this commodity is obviously impossible, and the motive-power load, if served, must be identical with the kiln loading.

Another example is a forge plant where, from the necessity of past practice, steam is exhausted at a pressure above atmosphere from its useful manufacturing equipment; this permits condensing the exhaust through a turbine and extracting a very substantial increment of power.

On the other end of the scale, where the economy and a portion of the usages justify high-pressure steam, there are many applications where the steam at the high pressure cannot be applied directly to manufacture, and in its reduction from the pressure of generation to the temperature of use, there is an energy increment which represents a very substantial power output.

In most instances, the ideal arrangement and one which can withstand any critical analysis is a coordination between the power purchased and the power generated. There are many difficulties inflicted upon the utility by any permission to an industrial to operate in parallel with the system. Most of these difficulties can be absolutely eliminated by a small and logical engineering outlay. However, the public utility has a responsibility in the continuity or service to other customers than the industrial in mind, and it should allow no laxness in the construction, or interconnecting arrangements, which will result in the imposition on the utility service of hazards or difficulties which were not existent before the parallel operation was permitted.

There is, of course, the feeling on the part of the industrial executive, if this great concession of parallel operation were extended, that his plant equipment either owned or to be installed under however improvident supervision would be perfectly good

[1] Member, Sessions Engineering Co., Chicago, Ill.

Abstract of paper presented at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

apparatus when connected to the utility lines. This might be ridiculously untrue, and the author is not extending the hope that parallel operation will become seriously an element of the public-utility policy, and, parallel with that, expecting that any inadequately constructed or improperly applied equipment will be permitted for one second to encumber the public-utility service.

The possibilities of profitable generation by an industrial are not universal by any means, and unless the electric load exceeds 25 per cent load factor, and unless the demands involved are considerably in excess of 1000 kw., then the additional attention and skill, neglecting entirely the outlay, would almost disqualify such an industrial load as a possibility for parallel operation. If the steam load for all purposes other than power exceeds a demand of 100,000 lb. per hour, and the electric load is in excess of 5000 kw., then the elements of the problem will almost universally justify a thorough economic study.

There are analysts whose principal objective is to create a situation where the analysis will be productive of a construction problem. Nothing could be more destructive to progress and economy. It is necessary that the engineer who presumes to analyze a potential parallel-operating situation have the economic elements and the responsibility of the public utility to the beneficiaries thoroughly in mind, without which the true picture will not be reflected in the engineer's presentations to the owner.

The viewpoint of the owner, meaning the power purchaser, is susceptible to improvident recommendations, and the power which he purchases, as is often discussed, is a commodity which does not come in tonnage or visible quantity, and therefore he feels that, without true comparison, all his power bills are extraordinarily high. It is playing upon this angle that much improvident and destructive work is done in the development of industrial power-generating possibilities.

It is, to the author's belief, not the thought of the public-utility engineers to combat situations which are fundamentally and truly economical, where customer generation and even parallel operation are involved. Our experience shows that there are many utility organizations who are most willing to cooperate.

This paper is not intended as a plea for the discriminating engineer, except that it may open a field of record in which it must ultimately be agreed that both the industrial and the public utility must make concessions and look the economic factors in the face, before any intelligent interrelation as regards power supply can be established.

As a matter of interest, in a recent program which has accomplished all that could be expected in the line of fundamental economics, the author will describe a few features within the power rehabilitation program of the Packard motor plant at Detroit. This factory purchases its supply of power, and depends for adequacy and continuity entirely upon the serving utility. Economics, however, have been worked out both in the production of steam and in the utilization of steam which, although they are not dominant as referred to the power usage, are important as to the fundamental economy, which must not be overlooked.

Wood-mill rubbish and janitor refuse are burned in boilers of modern setting at a high evaporation, and consequently with a marked influence on the amount of coal required. High-pressure steam is generated for factory heating and passed through a turbine which operates against a vacuum in a surface condenser corresponding to the required water temperature for factory heating. The circulating water through the condenser is forced through the factory radiation, and in this way the heat is converted from the point of generation to the proper point of use, for every condition, utilizing the entire range of drop for the development of by-product power.

From an operating standpoint, an interesting application of evaporators is also involved wherein the steam used for forge-shop purposes is generated in an evaporator plant by the condensation of high-pressure steam through the evaporator and returning to the main power house, generating the steam from raw water, since its exhaust is to the atmosphere.

An isolated forge-plant boiler house is primarily one of 100 per cent makeup. While in this large factory where the total steam demand exceeds 300,000 lb. and where 100,000 lb. is used for forge-hammer purposes, the total boiler-plant makeup has been so worked out as to the accumulation of returns that the raw water is less than 2 per cent to the boiler-feed system. This installation is cited merely as exemplary of what can be done in the direction of power economy, in the average industrial.

The author wishes to visualize the electric and steam load over a year, taken from midsummer to midsummer. The industrial steam load, due to both processes, and heating will rise during the winter months. This rising peak in the industrial is also concurrent with other annual public-utility load conditions, exclusive of the connecting industrial. When this steam load rises, that portion, if the quantity is not negligibly small, which goes to building heating may be utilized as a means of power generation. With this power generation the industrial may be able entirely to cut off the rising peak represented by changing electric load in the wintertime. This not only improves the load factor so far as this customer is concerned, but relieves the utility of the necessity for preparation to meet both the rise on the part of this industrial and the natural increase in demand on all other increments of load.

This concurrence of elements influencing capital costs might develop to be very important from the standpoint of adequacy of utility service. In this direction, a rule of thumb may assist in visualizing what this by-product load from heating may be. Forty feet of building radiation will dissipate 10,000 B.t.u. per hour. With a bleeder turbine on the line, every additional 10,000 B.t.u. will develop 1 kw. Forty feet of radiation will handle slightly over 2000 cu. ft. of contained space. At an average factory-ceiling height, this 2000 cu. ft. of space will represent 130 sq. ft. or less of floor area.

The rule, therefore, for quantitative mental comparison is that for every block of floor area 10 ft. $\times$ 12 ft. or thereabouts, there is, in the conversion of heat from economical generation to economical use, the potential possibility of developing 1 kw. of load under maximum heating-season conditions, referring particularly to the suppression of the power required to be furnished by the utility at such times.

The value of power as a commodity is one factor which must be impressed thoroughly upon the industrial owner. We believe that a careful analysis will bring any owner to the admission that power, when necessary and in the quantity required, is a much different commodity than power dumped when available and in any quantity which may be excess.

We have worked on situations where the exchange of power between the public utility and the industrial is an element of the problem, and this situation is one which offers, particularly for the small utility, some distinct capital advantages. However, the occurrence of the period of available power as referred to the utility's needs is not apparent to the industrial without some study, but an analysis will show, and we believe that this thought should be introduced into every problem of coordination, that excess power turned into the utility's lines when, due to production conditions it happens to be available, is worth but a small fraction per unit of the power which is delivered by the utility when it is required and, more important, when it is demanded in utter disregard to the other beneficiaries, who may

be simultaneously in need of power at a rate which makes them more entertaining customers.

Industrial power cannot be generated under usual conditions with economy to the industrial unless:

1 The rates are inordinately high
2 The supply is inadequate or irresponsible
3 The by-products of manufacture contain an element of energy which is not usable
4 The manufacturing processes inherently contain energy uses which do not exhaust the power possibilities of the medium.

Fundamental economy demands more attention to interconnection. The author does not subscribe to wildcat engineering in this direction and also feels that the element of concurrence of responsibility and demand, together with the relative load factors, bears as great a weight on the justified interconnection as does the most attractive occurrence by-product fuel or energy.

There is one suggested solution for this problem of coordination that lies in the following direction:

Public utilities will not dispute the necessity of making proper use of waste fuel and by-product power where this can be produced in economic quantities. The author therefore suggests what could be termed an equilateral power-house proposition. The power plant at the industrial site could be built with the joint engineering work of the local public utility and the industrial's engineer. This plant would be tied into the utility system. The power would be taken in quantity sufficient for the industrial's needs from this plant; either generated therein, or furnished through it for the utility system. This plant would become a substantial support in capacity for the utility load.

Financing could be done jointly between the utility, the industrial, and public investment. The entire revenue problem could be based upon cost plus accounting, as has been successfully worked out in connection with power delivery.

In this way, full use would be made of the by-product possibilities. The construction and operation would have the advantage of the skill of the utility, and the engineer for the owner could act between the parties to see that the service to the industrial, and that the return to the generating company would be commensurate with the costs and requirements. Such a situation would enjoy best possible operation, and would attain that economy represented by the fullest consistent utilization of by-product power, and would support both the public utility and the industrial by a plant which is in every sense a joint benefit to the two, and would, in the last event, place the skill in the cheap production of steam from fuel for the industrial, in the hands of the operating staff of the utility, whose particular business it is in their other plants to produce like results.

There are several hundred situations in this country where hundreds of thousands of dollars are involved annually in the difference between the present setup and the ultimate economy, which could be worked out by such a coordination, and this equilateral power plant, so termed, is offered as a very substantial step in the satisfaction of the requirements of the industrial and the coordination of its motive—power problems with the capacity of the serving utility.

In analyzing such a situation, the author has found no problem which has not been separately worked out satisfactorily which, therefore, could be combined into such a serving unit.

Welding of Power-Plant Piping

By F. G. OUTCALT,[1] CHICAGO, ILL.

In this paper, the author discusses the possibilities offered for reducing costs of installation of power-plant piping, through welding. Erection problems are simplified when welded construction is used. Heavy fittings are eliminated and the piping is easier to handle and can be installed in less space. Many engineers are unwilling to use welded designs due to difficulty in telling when welds are not made properly. The author describes improved methods which insure that the work is of high quality and uniform character.

ECONOMIES through use of welding for power-plant piping begin in the drafting room, due to greater simplicity in designing and laying out systems for welded construction. Material costs are lowered through elimination of expensive cast or forged fittings. This is particularly important in the case of headers, elbows, bends, steam traps, anchorages, and supports, where all castings and flanges may be eliminated except at the valves. Through the use of welding, elbows and bends are made of material that is identical in strength and other physical properties with the rest of the system. Substitution of welded steel for large cast fittings results in decreased weight, thereby reducing the difficulty of supporting the line properly.

Erection problems are also simplified when welded construction is used. Due to the elimination of heavy fittings, the pipe is easier to handle and can be installed in less space. This means that the piping can be nested closer in pipe shafts or tunnels. The changes, that quite frequently occur during erection, can be taken care of quickly and easily. Even if the change may require a special fitting this can be welded from standard pipe right on the job, thus avoiding the delay that would result, if a special cast fitting had to be ordered to meet the emergency. Absence of flanges on a welded line reduces materially the cost of applying insulation. Welded construction eliminates leakage and thus results in higher operating efficiencies. To all intents and purposes there are no joints in a properly made welded line.

Where welding is done under procedure control, maintenance is eliminated. The weld is as good as the metal in the pipe itself, and consequently, the life of the line is limited only by the useful life of the pipe. In practice a welded-piping system usually becomes obsolete before any maintenance is necessary. Any changes that may be necessary in systems after they have been placed in service, can be made most readily on welded lines. When, for example, it becomes necessary to place an additional branch connection in the line, the necessary outlet can be cut quickly with the cutting blowpipe and the new connection welded in with minimum disturbance to the existing line and with minimum interruption of service.

It is evident that the full advantage of welded construction cannot be obtained unless it is specified by the engineers who design the system. Many engineers are already using this type of construction, but there are others who still hestitate to take full advantage of the welded joint in power-plant piping. They are willing to admit that all that has been said above is perfectly true of a properly made weld, but they want to know how they can make certain of obtaining high-quality welds throughout the entire system. Developments during recent years have reached the point where it is possible for the power-plant engineer to treat welded construction exactly as he does other types.

What are the steps taken by an engineer to secure high quality results in any type of installation? For convenience they may be grouped under three general heads: (1) Exact specification of materials and design; (2) Selection of competent organization to do the work; and (3) Provisions for inspection, to see that specifications have been carried out. The detailed information that the power-plant engineer requires in order to draw up specifications for welded construction is already available in large measure. Leading organizations in the welding industry have done a great deal of work along these lines and are prepared to cooperate with power-plant engineers in all phases of welded construction. In order to specify materials and design for welded piping, the designing engineer will require data on the strength of welded joints as well as on correct principles of design.

Strength of Welded Pipe Joints

Developments within the last three or four years make it possible to design and obtain welded joints that are consistently stronger than the metal joined. Two factors have had an important influence on this development. One is the introduction of high-strength welding rod, by means of which an average welder is able to obtain an immediate increase of about 10,000 to 15,000 lb. per sq. in. in the tensile strength of his welds. The other factor is the use of procedure control to insure uniform high quality. A procedure control is a detailed production specification covering the following six points:

a Check of welders' ability
b Selection and inspection of material
c Design and layout of welded joints
d Preparation for welding
e Welding technique
f Inspection and test.

Experience with procedure control in many fields where strength and reliability are important factors has shown conclusively that it does insure work of uniformly high quality. Indeed, there is less variation in welds made under procedure control than there is in the metal joined. Procedure control regulates the human element in welding by standardizing welding procedure, so that it is subject to specification and control exactly as are other methods of fabrication.

In considering strength of welded joints, power-plant engineers will be interested particularly in the recent tests conducted by the National Tube Company, to determine the strength of oxyacetylene welded joints in full-size pipe specimens. In these tests, welded specimens of 4-in., 8-in., 12-in., and 16-in. pipe were subjected to tensile tests in a 600-ton hydraulic machine capable of gripping the full-size specimens and pulling them to destruction. The tests also covered four different designs of weld. A complete report of the results will be found in a recent publication of the American Gas Association, "Report of Sub-Committee on Pipe Joints, Serial Report No. 1, Oxy-Acetylene Welding of Steel Pipe." From this investigation, the following conclusions were drawn:

1 A properly made oxyacetylene welded joint is as strong as the pipe, fully 100 per cent efficient.

2 The simple butt-welded joint is the most efficient and is recommended for use in welding pipe. This is in agreement with past experience as this design is practically universally used in pipe work.

---

[1] Development Engineer, The Linde Air Products Co., Chicago, Ill.

Presented at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

3 Very high strength and nearly equally satisfactory results were obtained with the normal socket and socket with groove joints. In joint design, however, other factors must be considered, as cost of preparation, stress distribution under strain, and ease of welding, which make these designs less satisfactory than the butt joint. The weakest joint was the socket with welded rivets. This design should not be used because of cost, and difficulties in welding, as well as lower joint strength.

4 Due regard must be given to penetration and to the shape of the joint, particularly the reinforcement of the weld. This is more important in the larger than in the smaller pipe sizes. Butt welds should be reinforced at least 25 per cent and should be built up so as to present a gradual increase in the reinforcement from the pipe wall to the center of the weld. Fillet welds, when used, should be built up well in excess of the wall thickness of the bell.

5 There is no detrimental heat effect or structural weakening of the pipe metal due to welding.

6 The uniformly high strength obtained in these numerous joint tests points out the dependability of properly made welds. With qualified welders under procedure-control methods, a pipe joint of maximum efficiency can be made consistently and uniformly by the oxyacetylene process.

Power-plant engineers will also be interested in the effect of temperature on strength of oxyacetylene welds. Elevated-temperature tests of welds have been conducted jointly by the San Francisco section, American Welding Society, and the Materials Testing Laboratory of Leland Stanford Junior University. Results were reported in the Journal of the American Welding Society for September, 1927, and September, 1928. The data indicate that strong welds at ordinary temperatures are also strong welds at the temperature range of these experiments, namely 900 to 1000 deg. fahr. That is, increase in temperature will have no more effect on a properly made oxyacetylene weld than it does on the base metal. Indeed, these tests indicate that weld metal made with high-test welding rod is superior to the base metal in this respect.

Design for Welded Power Piping

Consideration of fundamentals of design should begin logically with a discussion of the line joint since it is employed to far greater extent than all others. Although quite universally used in all other applications of pipe welding and proved from a strength and economy standpoint, both from years of service and comprehensive tests, the single-vee butt joint has not been accepted altogether for steam installations by power-plant engineers. In place of it, at times a mechanical joint provided with a lip for seal welding such as the Sargol joint, has been recommended by some engineers and others have employed the sleeve joint with fillet welds joining the sleeve to the pipe. The two reasons given by those who have employed either of these joints are that the single-vee butt joint cannot be relied upon for the strength required or that it is unsatisfactory because of the possibility of weld protrusions on the inside of the pipe which increase the friction and present a source of possible trouble, because sections of the weld protrusion may become broken off in operation and carry along the pipe system into the valves and other moving parts. With respect to the butt weld, we believe, sufficient evidence has been given in a previous section of this paper to prove that single-vee butt welds in all sizes of pipe can be made consistently which will have greater strength than the pipe itself. Through procedure control, furthermore, it can be assured definitely that such welds will be produced in any piping system.

The elimination of any protrusion of weld metal beyond the inside wall of the pipe can be controlled easily by an experienced operator. Where, furthermore, there is any question as to the skill of the operator in controlling this factor, a liner may be employed which will eliminate this possibility entirely. Recent developments by the National Tube Company have indicated, that exceedingly satisfactory results may be obtained by the use of such a liner with practically no additional cost.

It is unnecessary to go into any discussion of the merits or demerits of other types of welded joints for straight pipe line construction since the single-vee butt joint is the most economical and entirely satisfactory.

For a single-vee butt weld, the ends of the pipe should be beveled to 45 deg., with a shoulder, usually $^1/_{16}$ in., at the bottom to facilitate alignment and penetration. Specifications should give the space to be left between ends to aligning for welding, call for 100 per cent penetration to root of weld, and state the reinforcement required. Using high-test welding rod, the average reinforcement is 20 per cent, with a stated minimum of $12^1/_2$ per cent. For design purposes, the ultimate tensile strength of a butt weld made with high-test rod is taken as the strength of the pipe material up to 52,000 lb. per sq. in. This is used with the same factor of safety that is applied to the pipe itself. It is essential that the weld taper off gradually toward the toe.

For outlets and take-offs from the straight-line piping system, there are three designs which may be employed for varying conditions, namely, the straight-type nozzle, the flared-type nozzle, and the saddle-type nozzle. The straight-type nozzle is made by cutting an opening in the line pipe, shaping the end of the nozzle to fit it and welding the two together. This design is recommended for pressures which produce a line stress of less than 5000 lb. per sq. in. With this type, the weld is made at the point of maximum stress and, furthermore, a right-angle joint results which may not be entirely satisfactory from a standpoint of efficiency of flow.

The flared-type nozzle is made by pressing or forging out the pipe by means of dies so that a butt weld may be made to the nozzle. This design gives a rounded contour at the take-off, and furthermore removes the weld from the point of maximum stress. It is, however, more expensive than the straight-type nozzle and may not be practical to produce in all sizes of pipe.

The saddle-type nozzle employs a forging specially designed to reduce to normal the stresses which are ordinarily concentrated about any opening. This forging is butt welded into an opening in the header. Where the diameter of the nozzle permits, the welder may also reach in and weld from the inside. Strain-gage measurements made on welded headers using this design have shown that the stresses are normal throughout the nozzle.

The straight-type nozzle is used almost universally for low-pressure take-offs, but the latter two designs are receiving considerable attention especially for high-pressure header construction. The most satisfactory flange design for welding is one in which the hub is forged or cast integral with the flange and of sufficient length so that it may be butt welded to the pipe nozzle or pipe end for connection to flange valves. In response to a general demand for such flanges prepared for welding, one of the largest suppliers of pipe fittings has produced dies for forming forged-steel flange welding necks in all sizes of pipe to 16 in., and is prepared to supply them in any quantities desired.

Welded reducers are used in header construction and in line work. They are made by cutting vee-shaped pieces from the end of a piece of pipe, using suitable templets, so that the sections remaining will form the desired reducer after they have been heated, swedged into contact and then welded. For low-pressure service, bends may be made up from two or more pieces of pipe miter cut at the proper angle so that when welded together they will form the desired bend. The two-piece 90-deg. elbow made by welding together two lengths, each miter cut to 45 deg. is

the simplest example, but this design is undesirable in many cases due to the abrupt turn. Usually a 3-piece turn is to be preferred.

For high-pressure service, tube turns are recommended. These are designed especially for welded construction and are available in all standard sizes. They are shaped mechanically from standard pipe in such a way that the wall thickness remains uniform throughout. They have the same strength as the adjoining pipe. The end of a line may be closed by means of a welded bull plug. The orange-peel type of plug is made very much like a reducer, except that the sections when swedged down and welded, close the end of the pipe completely.

Welded construction offers special advantages in the design of anchors. An anchor sleeve carrying welded brackets, may be welded to the pipe, or preferably be shrunk on by taking advantage of the contraction during welding. The anchor sleeve is split and fitted tightly over the pipe. When the longitudinal weld is made in the sleeve, the contraction of this weld shrinks the sleeve tightly on the pipe.

Insuring Correct Fabrication and Installation

After completing the welded design, the engineer's next problem is to make sure that his designs are followed correctly during fabrication and installation. As with other types of construction this may be done by selecting competent organizations to do the work. There are a number of pipe-fabricating concerns which are qualified to fabricate and install welded high-pressure steam piping systems in strict accordance with the principles of procedure control.

Engineers may insure high-grade workmanship by specifying qualification tests for the welders who are to do the work. As an illustration, the following qualification test is taken from a specification prepared for welded construction of a 400-lb. pressure super-heated steam-piping system, maximum temperature 750 deg. fahr.

General.

1 Only competent gas welders, having experience in welding steel piping of the sizes involved herein, shall be employed for the welding of the piping covered by these specifications.

2 Any welder employed for this work shall be required to pass the following qualification tests, before starting work on any of the piping to be welded under this specification.

3 The contractor shall at all times, during the course of construction, maintain on file for the inspection of the engineer or his authorized representative, a record of the welders employed for this work, together with a copy of the report of the results of each welder's qualification test as required herein.

4 The qualifications of welders shall be arranged for by the contractor within —— days, after the formal award of contract and shall be done in the presence of engineer or his authorized representative. This may be done in the contractor's shop or on the premises of the work. The contractor shall notify the engineer —— days in advance of the date set for the qualification test.

5 The material for these tests shall conform to the material specifications herein for piping and welding rod.

Leak-Proof Test. This test requires the welding of the joints in one pipe bomb to be made up of 6 or 8 in. extra-heavy pipe containing two circumferential position butt welds approximately 8 in. apart, one of the joints to be welded with the bomb lying horizontally, the other to be welded with the bomb vertical. The bomb shall not be rotated during welding. The preparation of the joint shall coincide with the welded joint detail as shown on engineer's drawing ——. Weld reinforcement to be $^1/_8$ in. gradually tapered where it approaches the base metal. Penetration shall be to the inside wall of the pipe. The ends of the bomb are to be closed in a suitable manner to withstand the test pressure to which it shall be subjected. At completion of welding and after the bomb has cooled to room temperature, the bomb shall be subjected to an hydrostatic test of 600 lb. per sq. in. or $1^1/_2$ times working pressure, after all air has been expelled therefrom. While under this pressure, the welds shall be struck with a 4-lb. sledge at four equi-distant points, the blows being struck with a full-arm swing. Under these conditions the welds shall not leak or develop any visible imperfections.

Tensile Test. This test requires the position welding of a joint between two pieces of 8-in. extra-heavy pipe, 9 in. long, to form a single piece of 8 in. diam., 18 in. long. The joint edge, reinforcement and penetration shall be specified similarly to that for the leak-proof specification above. The pipe shall not be rotated during the welding operation. Upon completion of welding and the cooling of the pieces to room temperature, standard tensile-test coupons shall be taken therefrom, one from the bottom of the joint, one from the top of the joint and one from each side of the joint, four in all, and be tested by a recognized testing laboratory to rupture, at a testing speed not to exceed $^3/_8$ in. per minute within the yield point. All weld reinforcement shall be removed by machining or grinding. Under this test, the coupons shall break outside of the weld or otherwise develop an average tensile strength of not less than 52,000 lb. per sq. in. with a minimum tensile strength of not under 50,000 lb. per sq. in. The cross-section surfaces of the coupons at the weld shall show complete fusion and penetration to the bottom of the vee.

Ductility Test. When this test is required, two additional coupons 2 in. wide × 18 in. long are taken from the tensile test specimens between the quarter-points. This test requires that the coupons be clamped in a vise, with the edge of the weld in line with the top of the vise jaws, in which position the exposed section of the coupon shall be rotated in either direction gradually until the section is bent through an angle of not less than 90 deg. Under this test, the weld shall not develop any visible surface cracks or fractures.

Inspection and Test

For inspection of welding, if the organization does not have a qualified inspection staff, there are several commercial testing laboratories now fitted to render the service. Furthermore, several of the larger laboratories of companies interested in the promotion of welding will gladly aid in training employees of purchasers of equipment so as to obtain satisfactory shop inspectors.

In distinct contrast to other types of construction, welded construction can be tested up to the yield point of the material used. It is customary to specify that headers and specials fabricated in the shop be tested hydrostatically at three times the working pressure.

Installations may be tested under high pressure if desired by blanking off sections between valves. Where welding is done under procedure control, the line is frequently not tested above the safety blow-off pressure.

From the foregoing discussion, it is evident that through the application of procedure control, power-plant engineers can now specify welded construction with complete assurance of obtaining an installation that will reflect credit on their organizations.

FSP-51-18

High-Pressure Turbine Installation of Kansas City Power and Light Company

By EDWIN JOWETT,[1] KANSAS CITY, MO.

This paper describes the high-pressure turbine installation at the Northeast station of the Kansas City Power and Light Company. An operating pressure of 1200 lb. at the turbine throttle and a total temperature of 725 deg. are used. It is believed that the heat consumption of the station will be lowered 1830 B.t.u. by the operation of the high-pressure equipment. With an annual output of 530,201,400 kw-hr. and with fuel at 67,000 B.t.u. for one cent, the saving in fuel will result in an annual reduction in cost of $144,700. This is nearly three times the fixed charges on the difference in cost of the two installations.

FROM its two generating stations in Kansas City, the Kansas City Power and Light Company, furnishes electrical energy to Kansas City proper and 102 outlying communities in Missouri and Kansas. Its development has, of necessity, been very rapid in order to keep ahead of this fast growing industrial center. It has been the demand for cheap dependable power for industries that has been the stimulus, in working for higher economies in power production.

The Northeast Station which has for nearly eight years carried the entire system load was designed originally by Sargent & Lundy of Chicago, and the first 23,000-kw. unit was put into service in the fall of 1919. Since that time it has had a continual expansion, under the direction of the company's own engineers, until at the present time it contains 140,000-kw. generating capacity. While the initial steam pressure of 300 lb. has been maintained throughout all additions, many other changes and improvements have been made, both in new and old equipment, which along with improving load factor, has reduced the B.t.u. per kw-hr. of the station from about 21,000 to 16,700. By the addition of radiant-heat booster superheaters, the operating steam temperature has been raised from 600 deg. to about 650 deg. fahr. Original boilers were fired with natural-draft-type chain grates, later boilers with forced-draft chain grates, and within the last year one boiler has been converted to unit-type pulverized-coal firing.

It was quite evident that with the existing steam pressure and temperature, practically no further substantial improvements could be made in the economy of the station. The plant contains three 23,000-kw. turbines and two 30,000-kw. units served by twelve 1350-hp. boilers. With a limitation of approximately 250 per cent of boiler rating as the economical load with the fuel used, the present plant was lacking in boiler capacity. The existing building contained space for four additional boilers, at least two of which would have been required for the 1928–1929 peak. Accordingly, following up a line of study made by the company's engineers in 1922–1923, a decision was reached to install two high-pressure boilers and a turbine which would exhaust through reheaters to the station 300-lb. header. In this manner, the desired additional boiler capacity would be obtained along with some additional turbine capacity. When the original studies were made, it became evident that the installation of the equipment would have to be delayed until the minimum load on the system had grown to a sufficient amount to permit operation of the high-pressure equipment, and its compliment of low-pressure turbines at a very high daily load factor. This point was reached in the fall of 1928, shortly after which, the high-pressure equipment was ready for operation.

An operating pressure of 1200 lb. at the turbine throttle and a total temperature of 725 deg. was chosen for the turbine. The pressure was but little above that which had already been tried at Boston and Milwaukee, and the temperature such that the expansion to the present station header pressure through the turbine would give steam of a temperature but slightly above the saturation point. The size of the turbine was chosen such that its output, together with that of the present turbines using its exhaust steam, would practically meet the minimum-load requirements, and at the same time could normally be supplied with steam from two boilers of a size that could be fitted into existing vacant boiler bays. While two boilers will normally be in service to carry full load on the turbine, the furnaces and fuel-burning equipment is proportioned so that 3000-kw. load can be carried on one boiler.

The investment costs for this particular installation were considered more as the difference between the installation cost of two boilers of 300-lb. pressure and equal capacity, and two high-pressure boilers with reheaters. The turbine gave additional plant capacity at practically the same cost per kw. as a 300-lb. turbine, condenser and its auxiliaries. Furthermore, it was possible to locate this high-pressure turbine in the boiler room adjacent to the high-pressure boilers, where an addition of a like capacity of 300-lb. turbine would have necessitated an expensive addition to the turbine room. The proximity of the high-pressure turbine to its boilers and reheaters helped materially to reduce the additional cost of high-pressure piping over 300-lb. piping. It also served to hold down the pressure losses through the steam connections. The design of the turbine and generator was such, that no trouble is anticipated from dust of the boiler room. Fig. 1 shows the general arrangement of the equipment in the station.

From a close analysis of the probable system load and the proposed equipment, it was concluded that the following operating schedule could be followed in 1929:

Expected kw-hr. generated on 1200-lb. unit (82.5 per cent L.F.) (Based on expected turbine and boiler outage and load conditions)	=	72,200,000
Expected kw-hr. generated on present units with exhaust steam from hp. unit	=	245,600,000
Expected kw-hr. generated on balance of present units	=	212,401,400
		530,201,400
On the above basis, the consumption would be:		
Average B.t.u. per kw-hr. on 1200–300-lb. combination (Assuming full load on hp. unit).	=	13,810
Average B.t.u. per kw-hr. on balance of 300-lb. units (Assuming the same as for 1928 performance)	=	16,800
Composite average B.t.u. (net)	=	14,970

A careful analysis of the relative costs of a 1200-lb. installation

[1] Vice-President in Charge of Power Plants, Kansas City Power & Light Co., Kansas City, Mo. Mem. A.S.M.E.

Presented at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

and a 300-lb. installation at Northeast station afforded a means of determining whether the saving in fuel would justify the investment. In order to put the two installations on a strictly comparable basis, both installations were figured on the most economical size of equipment for this station and reduced to unit costs.. The high-pressure job furnished 10,000 kw. electrical energy and steam for a total of 45,000 kw. The boilers for the 300-lb. unit would be capable of furnishing steam for 30,000 kw., and the turbine would be a 30,000-kw. unit. From the unit costs so figured, the comparison was worked out for 10,000 kw. electrical output and sufficient boiler capacity for 45,000 kw.

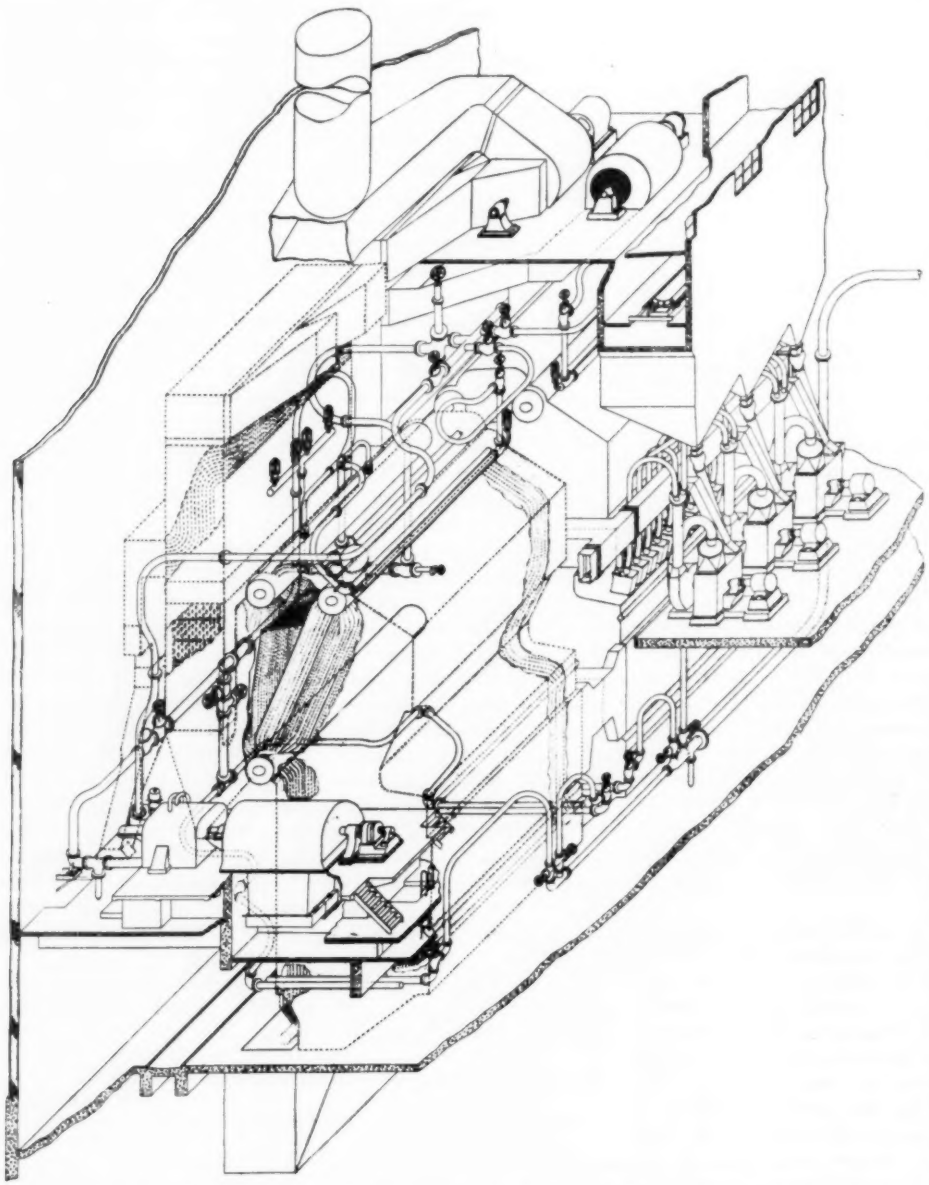

FIG. 1 BOILER AND TURBINE INSTALLATION, NORTHEAST STATION; KANSAS CITY POWER & LIGHT COMPANY

A summary of the costs for the 10,000-kw. turbine installation is as follows:

1400-lb. boilers (steam for a total of 45,000 kw.)	$1,342,138.00
1200-lb. turbine	307,246.00
	$1,649,384.00
300-lb. boilers (steam for 45,000 kw. total)	918,000.00
300-lb. turbine	335,000.00
	$1,253,000.00

From the above, the high-pressure installation costs $396,384 more than the 300-lb. installation of like capacity. This is an increase of 31.6 per cent. It must be borne in mind that these figures apply only to the particular job in question. If fixed charges at 13.25 per cent are figured on the difference between these two investments, the annual saving from the operation of the high-pressure equipment must at least equal 0.1325 × $396,384 or $52,500.

As previously shown, it is estimated that the heat consumption of the station will be lowered from 16,800 B.t.u. per kw-hr. to 14,970 B.t.u. or 1830 B.t.u. by the operation of the high-pressure equipment. For the annual output of 530,201,400 kw-hr. and with fuel at 67,000 B.t.u. for one cent, this saving in fuel will result in an annual reduction in cost of $144,700. This is nearly three times the fixed charges on the difference in cost of the two installations.

Whether or not the new equipment will involve higher maintenance is problematical and can only be determined by time. The practically completely water-walled furnaces of the two high-pressure boilers should result in lower furnace maintenance than the old masonary-lined furnaces.

A detailed description of the various parts of the equipment is given below:

GENERAL OPERATING CONDITIONS

Maximum pressure for which boilers are designed	1400-lb. gage
Normal operating drum pressure	1280-lb. gage
Pressure at turbine throttle	1200-lb. gage
Temperature of steam at turbine throttle	725 deg. fahr.
Back pressure at turbine exhaust at full load	315-lb. gage
Superheat in exhaust at full load	40 deg. fahr.
Pressure steam out of reheater	290-lb. gage
Temperature steam out of reheater	700–725 deg. fahr.

Many studies and investigations were made on the two general types of high-pressure boilers now in service in this country. While it appeared that both types were working out quite well, several points seemed to favor the bent-tube boiler in the minds of the company's engineers. It was felt that better circulation obtained in the steeply-inclined tubes and the number of high-

pressure joints were reduced to a minimum. It was also believed that the divided feed in the lower drum would aid circulation. As explained later, this feature had to be abandoned. Where head room was limited, a higher furnace could be obtained with the bent-tube boiler. Numerous arrangements of boiler, economizer, air heater, and furnace were made and in practically all respects the bent-tube boiler fitted best into the allowable space. Investigation showed remarkable success in maintaining the drum water level without priming with this type of boiler.

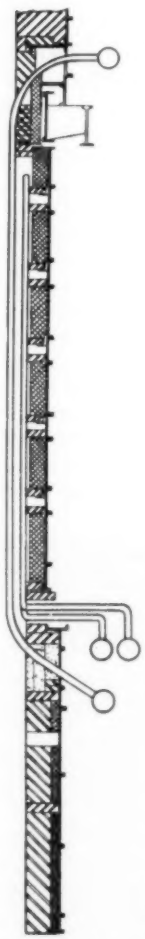

FIG. 2 SIDE WALL CONSTRUCTION

The largest boiler that could be installed in the existing bays contained about 17,000 sq. ft. Two boilers of this surface would be sufficient to carry full load on the turbine at an economical boiler rating. However, even for boilers of this size, many changes had to be made in the existing steel framework of the building to increase clearances, support new floors and to carry the greatly increased weight of equipment. Two hundred and fifty tons of additional structural steel were required to carry the boilers and turbine, and some new concrete footings had to be installed.

It was the original intention to fire the boilers with forced-draft chain grates. It was, however, found next to impossible to get sufficient grate area under the boilers to carry maximum load with the low grades of bituminous coals used at the station. Stokers of greater width than had yet been built would have been required, and manufacturers were very reluctant about building them.

An experimental installation of two unit pulverizers firing a 1350-hp. boiler had been in operation in the station about six months at that time. To date it had proved very satisfactory both from the dependability and efficiency standpoint. Largely on the performance of this installation, it was decided to follow the same general scheme for the two high-pressure boilers. The plant is situated away from the business and residence district, so that the problem of removal of fly ash did not influence the decision. It was possible to install a water-cooled furnace of sufficient size to keep the combustion rate down to 20,000 B.t.u. per cu. ft. of furnace at maximum rating and about 17,000 B.t.u. per cu. ft. at normal rating. This is based on a furnace volume of 15,670 cu. ft.

The furnace below the burner line is made up of fin-tube water walls on the front and back, and bare tubes on $7^1/_2$ in. centers on the two sidewalls; all tubes being 3 in. outside diameter by $^1/_{16}$ in. thick. Immediately back of the side-wall water tubes are the reheater elements made up of single loops of $1^3/_4$ in. outside diameter tubes about 17 ft. 6 in. long. Fig. 2 shows the construction of these side walls. Secondary air ports are provided in the front wall with independent control in horizontal rows. A typical form of water screen is provided at the bottom of the furnace with tubes arranged on 12-in. centers.

Nine 8-in. forced-blast Lopulco burners fire downward at a slight angle with the vertical through a tile-backed, water-cooled arch. These water-cooling tubes bend upward and form the front wall and also the top arch. These backing tiles are hung on independent cast-iron hangers and do not rest on the tubes. The upper side walls are made of firebrick and insulating material. The entire furnace, ash hopper and boiler is steel encased.

A very effective means of providing these water walls with water has been employed. A large header at the lowest part of the furnace at the rear is supplied with water from the lower drum by fifty-two 3-in. downcomer tubes outside of the furnace. This header is a forging 18-in. outside diameter by 3 in. thick and 36 ft. 8 in. long. The rear water-wall fin tubes rise directly from this header to the lower drum passing through connecting tubes to one row of the first-bank boiler tubes, thence to the front steam-liberating drum. The water-screen tubes come out of the back of this header, pass between the rear water-wall tubes and

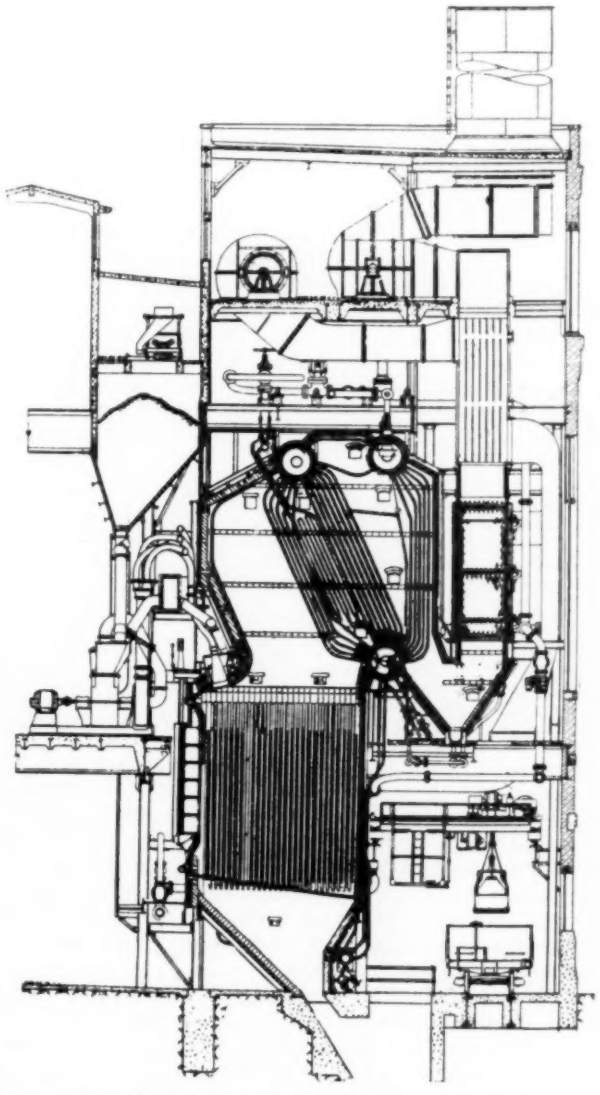

FIG. 3 CROSS SECTION OF PLANT SHOWING SLOPING-FURNACE BOTTOM FOR CONVENIENT ASH HANDLING

across the furnace to the lower front header, thence the circulation is through the front-wall fin tubes to an intermediate header. From this header, the arch and upper front-wall tubes carry the water on up to the front drum. Eight short tubes from each extended end of the lower rear header supply water to the lower side-wall headers. The water rises through the side-wall tubes to the upper side-wall headers, thence through twelve external-riser tubes on each side of the boiler to an extension of the front drum outside the furnace casing.

An ash-handling arrangement similar to that employed in the

other part of the plant will be used on these two boilers. A sloping furnace bottom as shown in the cross-section drawing, Fig. 3, empties into a more or less shielded water-sealed pit. From this pit the ash is removed by a clam-shell bucket and bridge crane also shown in the cross-sectional view.

The two high-pressure boilers are of the three-drum Stirling type, so baffled that the gas makes three passes in traversing the boiler. A convection-type primary superheater is located between the first and second passes. The drums are seamless steel forgings 40 in. inside diameter and $5^1/_4$ in. thick. The lengths of the three drums vary from 29 ft. 8 in. to 34 ft. 2 in. The heaviest drum weighs about 77,000 lb. All tubes in the boilers are 3 in. outside diameter by $^5/_{16}$ in. thick. Fig. 4 shows the manner in which the tube holes in the drum are counterbored and the tubes rolled therein. The two small grooves shown are about $^1/_{32}$ in. deep. The large counterboring is to facilitate tube renewals. These boilers do not employ the standard Ladd method of feed. Contrary to what was first planned, the water is fed direct to a feedbox in the upper rear drum. Steam is taken off of the rear drum through two 6 in. nozzles studded and step jointed to the drum. Each outlet is provided with a steam purifier drained externally. Water columns are of forged steel with flat glasses mica protected. General boiler data follows:

FIG. 4 ROLLED-TUBE JOINT

Normal boiler evaporation per hour, lb.	170,000
Maximum boiler evaporation per hour, lb.	200,000
Heating surface in boiler, sq. ft.	16,950
Wall surface: water screen (plain tubes), sq. ft.	330
Lower front finned tubes, sq. ft.	415
Upper front plain tubes, sq. ft.	670
Rear finned tubes, sq. ft.	765
Two side walls, plain tubes, sq. ft.	870
Total wall surface, sq. ft.	3,050
Reheater surface each boilers, sq. ft.	470
Primary superheater surface each boiler, sq. ft.	2,650
Safety valves each boiler	Four 4-in., one 2-in.

Each boiler is provided with three impact-type mills each with an hourly capacity of 15,000 lb. of bituminous coal containing 15 per cent moisture. The primary air entering the mills will be heated to any desired amount up to 400 deg. fahr. The mills are direct connected to 200-hp. motors. As previously mentioned, each boiler is equipped with nine forced-draft Lopulco burners. Heated secondary air is admitted at the burner, and tertiary-heated air through the front furnace wall below the burners.

Economizers. Each boiler is provided with a fin-tube economizer having 10,891 sq. ft. of effective heating surface. The tubes, which are $2^1/_2$ in. outside diameter No. 2 gage, are arranged in staggard rows. The inlet ends of the upper row of tubes as well as the outlet ends of the lower row are rolled into headers. The water passes through each vertical row of tubes from top to bottom, adjacent tube ends being rolled into forged-steel junction boxes provided with inside oval handhole plates. The economizer is designed for a working pressure of 1490 lb. per sq. in. The junction boxes are a unique type of forging which under test of 4750 lb. per sq. in. showed no serious deflection.

Water will be fed to the economizer at a temperature of 210 deg. fahr. and will leave at a temperature varying from 319 deg. to 324 deg. depending on the boiler rating.

Air Heaters. The gas after leaving the economizer on each unit, passes up through a plate-type air heater of 39,270 sq. ft. heating surface. The air heater is typical in every way of this type of equipment. The final air temperature of about 425 deg. is obtained, while the leaving gas temperature is about 330°.

Draft Fans. The induced-draft fan on each boiler is designed for a maximum draft of 10 in. water and is driven by a 450-hp. motor. The forced-draft fans are designed for $7^1/_2$ in. and are driven by 225-hp. motors. One short steel stack supported on the building steel serves both boilers.

Boiler-Feed Pumps. Two motor-driven boiler feed pumps each of sufficient capacity to handle both boilers have been provided. Each pump is of 800 gal. per min. capacity against a total discharge head of 1500 lb. The pumps are provided with water at their suction from the present station boiler-feed pumps at 350 lb. pressure. The pumps operate at 3550 r.p.m., and are direct connected to 900-hp. induction motors. The pump discharge pressure is controlled ahead of the economizer, by a differential pressure regulator which maintains a constant differential between the drum pressure and the water entering the economizer. Its chief purpose is to protect the economizer against the high shut-off pressure of the feed pumps, and incidentally to improve operation of the automatic feedwater regulators.

Turbo-Generator. The turbo-generator is of the combined impulse reaction type. The generator is rated at 10,000 kw. at 80 per cent power factor. Fig. 5 shows a general view of the unit. The turbine cylinder is machined from steel forgings as is also

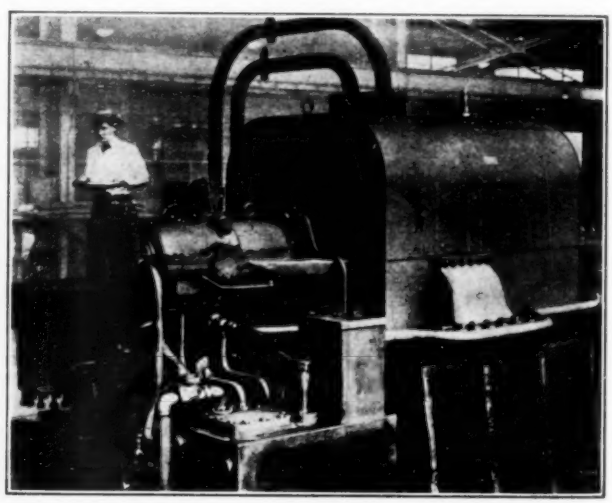

FIG. 5 TURBO-GENERATOR IN NORTHEAST STATION

the steam chest which sits along side the unit. The throttle valve and single governing valve is located in this chest. The steam chest is connected by four flexible pipes to the turbine cylinder. The cylinder is supported in a novel manner from the exhaust casting suspended by steam-heated steel links from stationary brackets attached to the foundation. Fig. 6 shows the essential elements of this support. This type of support allows free cylinder expansion and at the same time maintains a fixed center line regardless of what pipe strain might be imposed upon the exhaust casting by the exhaust pipe.

The impulse element of the turbine consists of two rows of revolving blading and one row of stationary blading made of stainless steel. This is followed by 14 rows of reaction blading, made of pure nickel. All blades are shrouded and of the end-tightening type. A stainless-steel built-up nozzle block expands the 1200-lb. steam down to 845 lb. before it enters the first impulse blades. The dummies are of a special design so that should any rubbing occur, either in the dummy packing or in the blading.

the area of the contact is exceedingly small and the intensity of rub very light.

The high-pressure gland has the same arrangement of end tightening strips as the high-pressure dummy. The gland at the exhaust end is fitted with radial contact strips because of their remoteness from the thrust bearing. A Kingsbury thrust bearing with ready handwheel adjustment of the axial position of the rotor is provided. Stops for limiting the movement of the thrust are provided so that starting and running positions are found readily.

When operating under the conditions hereinbefore described, the turbine will have a water rate varying from about 34 lb. per kw-hr. at full load to 45 lb. per kw-hr. half load. The superheat in the exhaust at the above loads varies from 22 deg. to about 60 deg., respectively.

Piping Connections. Fig. 7 is an isometric showing the piping arrangement. It will be noted how the proximity of the boilers and high-pressure turbine has permitted exceedingly short pipe connections. The scheme of the connections is more or less typical of installations of this sort except that some additional complications arose, due to the fact that it was a two-boiler installation, whereas all high-pressure jobs in operation at the time were single-boiler installations.

The problem of the correct distribution of steam from the ex-

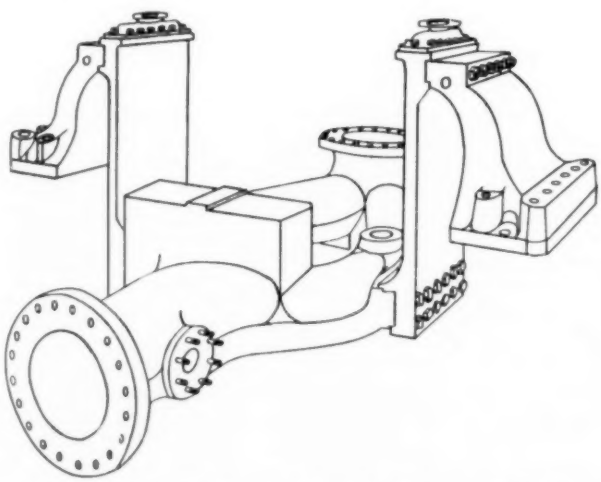

FIG. 6 CYLINDER SUPPORT FORMED BY EXHAUST CASTING

haust of the high-pressure turbine, to the four sections of reheaters (two in each boiler) presented a problem. The two reheaters in each boiler were piped together to a single connection with duplicate lengths of pipes, bends and fittings to give equal pressure drop from the single-branch connection to the reheater in each side of each boiler. The pair of reheaters in each boiler is then supplied with steam from a reheater supply header. An electrically operated regulating valve is placed in the connection between this header and the single connection to each pair of reheaters. These valves are arranged so that even in the closed position they will pass sufficient steam to protect the tubes of the reheater from burning. The control for these two valves is brought to the boiler-control board beside a recording thermometer indicating the steam temperature out of each reheater. The reheater regulating valves will be so regulated as to maintain equal reheater outlet temperatures. These two reheater regulating valves are synchronized mechanically, so that as one valve opens the other closes a proportionate amount. If manual control of this steam distribution becomes too much of a problem, equipment is arranged so that it can be made automatic, actuated either by the volume of steam out of the primary superheater of each boiler or by the temperature of the steam out of the reheater of each boiler.

A connection is provided to bypass automatically the high-pressure steam through a reducing valve and desuperheater, in the event of complete loss of load on the high-pressure turbine. This bypass can also be put into service should it be desired, to use the high-pressure boilers on the present 300-lb. system with-

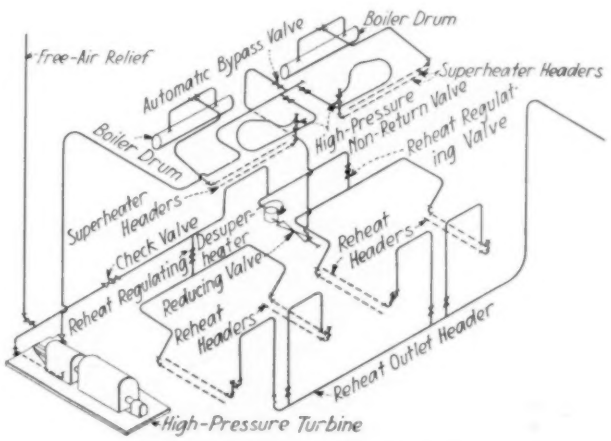

FIG. 7 DIAGRAM OF STEAM PIPING

out the use of the high-pressure turbine. The reducing valve is a motor-operated variable-orifice arrangement, actuated by an automatic control. The desuperheater is of the absorption type with automatic temperature control.

All high-pressure steam joints, 6 in. and above, are Sargol type except those connecting immediately to the boilers, superheaters and turbine. These particular joints as well as all steam joints between 6 in. and $1^1/_2$ in. are small tongue and groove. Steam joints below $1^1/_2$ in. are large male and female. Only lap joints are used, all tongue-and-groove or male-and-female facings being made in the lap of the pipe. All joints in the boiler feed pipes are small tongue and groove. In most cases, Norway iron gaskets are used in the tongue-and-groove and male-and-female joints.

Feedwater. It was realized that probably the most important factor in the successful operation of high-pressure boilers is pure feedwater. In the present part of the plant, no evaporators or feedwater treatment was used; complete deaeration of the feedwater has, however, been affected for several years and no trouble from oxygen pitting has been experienced. The undesirability of using untreated make-up in the high-pressure boilers even in as small a percentage as 2 to 3 per cent was realized. The general arrangement of the station piping and heat balance was such that an installation of evaporators would have been difficult and expensive. An arrangement has been worked out for feeding the high-pressure boilers entirely on condensate. A hot-process lime and soda ash treating plant has been installed for treating the make-up for the low-pressure boilers. It is possible that an after treatment, with trisodium phosphate may be added. Special precautions have been taken to reduce condenser leakage to an absolute minimum and condenser-leakage recorders have been installed on all condensers.

Boiler Control. Centralized manual control of the boilers is provided. It is arranged so that such parts of it as may prove desirable, after some experience with the operation of the equipment has been obtained, can be made automatic.

FSP-51-19

Power-Plant Maintenance and Engineering Insurance

By J. P. MORRISON,[1] CHICAGO, ILL.

EARLY boiler-insurance policies written in America, as do the policies written today, furnished a specified indemnity for loss resulting from explosion, rupture or collapse of the boiler, and further defined the explosion or rupture, or collapse as a sudden, substantial tearing asunder of the boiler caused by the pressure of steam, or as the sudden crushing inward of its furnace or flue. The expressions used are intended to define the occurrence insured against, as an accident of a disastrous or violent character. The boiler-insurance policy is not intended to furnish indemnity for the cost or expense of maintaining a boiler in serviceable condition, nor to guarantee it for any period of usefulness under normal operating conditions; nor does it include any damage from fire resulting from any cause whatsoever.

Of course, the steam-boiler policy does not provide indemnity for an accident which would have occurred if there had not been the timely discovery of the unsafe condition; nor to the loss which proceeds the occurrence of the accident insured against. Practically the same definitions and provisions apply to the unfired pressure vessel.

Our first policy was a valued form, providing specific indemnity in case of damage to each of the scheduled boilers and a specific indemnity for damage to the surrounding property. However, the policy as now written is a blanket form, in which the principal sum is applied to the payment of loss due to damage to any property of the assured, or to the property of others for which he may be liable.

The continued development of the steam prime mover resulted in many designs of a purely experimental nature which effected not only the dependability of the engine, but also the safety of the flywheel which all recognize as a magazine of stored energy. The numerous failures of engine flywheels, some of which were accompanied by loss of life and great property damage, created a market for protection against the loss which followed the accidental liberation of the energy stored up in the rapidly revolving mass. As there was no question but the explosion of a flywheel could rightly be termed a catastrophe, the accident insured against, in the flywheel policy, was termed an explosion and was defined as the sudden and substantial bursting and disrupting into two or more parts while revolving, whereby one of those parts was separated completely and dislodged from the other part of the wheel. The definition leaves the distinct impression that the accident insured against was to be a violent one.

It has been the underwriting practice to specify the limits of speed of the wheel, stated in terms of revolutions per minute, but really based upon the rim speed and the type of joint securing the parts of the rim together, just as we approve a maximum working pressure in the boiler policy. The presence of a flywheel, of course, implied the existence of an engine which likewise is subject to difficulties of an accidental nature as distinguished from those repairs due to wear and use. The framers of the engine policy broadened the protection afforded the owner of the flywheel, so instead of limiting the loss to those accidents having the characteristics of a catastrophe, the accidental breaking of any part of sufficient importance to require immediate repairs was defined as an accident and the loss was covered up to the face of the policy.

The engine insurance policy, instead of being referred to as explosion insurance, is known in insurance circles as "breakdown" insurance, for a modern engine may be damaged, and in fact its value destroyed entirely by the breaking which originated in a minor part.

The steam turbine did not require a very great length of time to refute the statement, that all it needs, is to be let alone, but on the other hand it displayed its ability to disrupt, explode, breakdown, burn out and do other things which contribute to the entertainment of the power-plant operator, and to the financial loss of its owner. So insurance protection has been provided to cover not only the driving steam rotor, but also the driven generator, driven compressor, driven pump, or other driven objects forming a part of the turbine unit. The most complete turbine protection afforded is termed "Breakdown Insurance" and includes, practically, all parts of the turbine above the foundation.

The owner may desire limited protection, and that can now be afforded under policy condition to suit the ideas of most any one. The protection can be restricted to the steam end of the machine and may be limited to the explosion of the rotor, or the steam casing exclusive of loss which results from damage to stationary or revolving plates or buckets.

The electrical generator operated by a steam turbine or by an engine, may be protected by insurance independent of the driving unit. The electrical policy contract defines the accident as including any disturbance which prevents the machine from functioning somewhat similar to the broad definition of an engine breakdown. The object insured may include also, motors, rotors, transformers, and types of revolving and stationary electrical equipment.

The engine, flywheel, turbine, and electrical policies have been combined under one contract form now known as the machinery insurance, which may also include pumps, compressors, and other objects having the engine operation peril, although the losses and inspection expense are classified separately.

It is doubtful if any other line of insurance has been broadened and modified within reasonable limits, to afford the protection desired by the owner of the equipment, to a greater extent than has the engineering-insurance policy, so at this time the power plant can obtain insurance protection against minor accidents, as well as those of a violent nature, in as small or as great an amount as the value of the exposure justifies.

The standard policy written by companies engaged in engineering insurance affords protection against loss due to direct damage to property of the owner, and of others for which the owner may be liable, and may be extended to include personal injuries and death to the public, as well as to employees in those states having no legislation to the contrary.

The loss of profit, loss of production, loss of sales, loss of rents, loss of tuition fees, and similar losses, are not included in the protection afforded by the direct-damage policy, which specifically excludes, any loss from delay or interruption of business or manufacturing process. However, complete protection against loss of that kind may be obtained under a "Use and Occupancy"

[1] Chief Inspector, Hartford Steam Boiler Inspection and Insurance Co., Chicago, Ill. Mem. A.S.M.E.

Presented at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

policy which affords a specific daily indemnity for each day that production is wholly prevented as the result of an accident insured against, under the terms of the direct damage policy, and affords pro rata protection when the production is but partially prevented. The use-and-occupancy policy may become effective at the time of the accident, or at any subsequent midnight, and may continue for any predetermined length of time, although 100 days is the average duration of the protection.

In connection with every business there are a great number of expenses which must continue with regularity regardless of whether or not the plant continues to operate. They must be paid, production or no production, and without use-and-occupancy coverage the owner will find taxes, guarantee dividends on stock, interest on bonds, and other indebtedness, insurance premiums, salaries to executives and other employees whose services cannot be dispensed with in case of shut down, auditor's fees, director's fees, advertising if under contract, penalties for failure to fill contracts, agency contract expense, expenses of branch and local offices, depreciation of plant machinery not damaged by the accident, so not to be considered when the direct damage claim is filed. Use-and-occupancy insurance is becoming a vital necessity, for regardless of how well the owner is protected against direct-damage loss from a power-plant disaster, without the additional protection afforded by the use-and-occupancy policy, he is exposed to heavy financial drains which might completely ruin his business.

Another probable source of loss is the freezing of growing plants, and the spoiling and fermenting of articles of food in storage or in process of preparation for use. Loss of this kind is covered under the "Consequential Damage" policy, and the protection becomes available immediately following the accident.

The direct-damage insurance premium, to an extent, depends upon the amount of financial protection afforded, but the premium increment is not proportionate to the increase in the face of the policy. This is due to the inspection expense being carried by the lower bracket, while the excess premium is based upon the cost of carrying an inspected risk. Too much insurance protection is a waste of money and too low protection is sure to lead to regret when the extent of the damage is determined following an accident. The exposure is difficult to estimate with any degree of certainty, for no one can tell the direction to be taken by the drum of an exploding boiler, which may damage property one-half mile or more from its original setting, while objects in the immediate vicinity escape injury.

The boiler of the modern power plant is of more value than the cost of the complete power plant in use when steam-boiler insurance was inaugurated, and the insurance protection should be proportionately greater, although local conditions must be the determining factor.

The protection carried under the steam-boiler explosion policy, should surely be sufficient to cover any loss which might result from the explosion of one of the boilers. In a large central station, this loss might not exceed the value of the boiler plant above the foundation, but in the average industrial plant, the exposure will include other buildings and property within a radius of possibly 150 ft. of the boiler plant, and, of course, if public liability is to be carried under the boiler policy, that hazard, too, should be taken into consideration when the total amount of coverage is determined. There have been numerous cases where the loss was total, that is, the amount of the loss exceeded the face of the policy, and the insurance protection was not sufficient, although a few dollars spent for additional protection would have been of great help toward placing the industry on its feet after the boiler accident had occurred.

The present level to which the insurance rates have decreased is due, not only, to the efficiency of the inspection service, but also to the ability of the plant operators, and the respectful promptness given the demand for repair. The dependability of operation varies directly as the maintenance varies, so the underwriters feel privileged to expect the owner and his employees to use reasonable care in operating, and due diligence in maintaining the power-plant equipment, for any other attitude must be reflected in the insurance rates even if the plant does not reach a condition where insurance protection is not obtainable.

Modern Stoker Equipment

By C. F. HIRSHFELD,[1] and G. U. MORAN,[2] DETROIT, MICH.

This paper describes improvements that have been made in stoker construction to adapt them to modern needs. Improved types are constructed carefully, are capable of accurate control and are used in large sizes. In choosing stoker equipment, the authors feel that generous allowance should be made above the apparent maximum requirements for fuel feed.

FORCED-DRAFT traveling grates were developed in two different sections of the country, for two different purposes. In the Chicago district this type of stoker was developed for burning the types of fuel mined in the neighborhood. These fuels are characterized by low softening temperature of the ash and, generally, by comparatively high water and ash contents and low heating value per unit of weight. They are also non-coking coals in the ordinary meaning of that expression.

In the eastern section of the country a somewhat similar type has been developed for burning the smaller sizes of anthracite. This coal is characterized by very low volatile content, high ash content, high ash softening temperature and, frequently, fairly high moisture content. The sizes are generally very small and are constantly getting smaller as the ability to burn small sizes becomes greater.

These stokers are definitely not well adapted to the burning of coals containing small amounts of ash, as a certain, rather large quantity of refuse is required to protect the grate itself. Also, if reasonably good efficiency is desired, the discharge end of the chain should be fairly well covered to prevent excessive air leakage into the furnace in that region. They were developed, as stated, for the burning of certain types of fuel which could not be satisfactorily dealt with by other means. When properly designed, installed, and operated they are capable of giving remarkably good results with such fuels.

The underfeed stoker of the modern multiple-retort type was developed primarily for burning the better grades of bituminous coals with rather low ash content of high softening temperature. During the past few years, however, models have been produced, which give very satisfactory performance with Illinois and similar varieties of coal. This type of stoker appears to be undergoing most rapid improvement at the present time, both with respect to increase of size, increase of fuel-burning capacity, improvement in thermal performance, and improvement with respect to maintenance.

It would not be correct to consider the evolution of stokers alone. Certain other factors have been active and they must all be considered together, if a true picture of the situation is to be obtained. Beginning about twenty years ago, there was a definite movement toward increased size of steam generating units and increased steam output per square foot of boiler surface. This in turn brought about both increase of stoker size, increased size, and particularly height of furnace. The weak point, at this stage of the development, was the refractory which was being subjected constantly to more severe usage and which definitely set a limit to possibilities.

Water cooling of furnace walls and even furnace arches was resorted to. There was doubt in the minds of many regarding the virtues of water protected furnace walls, in spite of the fact, that other and less perfect forms of such construction had been used for years in other places, such as in the railway and marine fields. Eventually, however, it was demonstrated that properly used water- and steam-cooled furnaces opened up possibilities for further improvement, increase of size, and increase of capacity which could not be ignored.

At about the same time that water- and steam-cooled surfaces came in for serious consideration, the use of preheated air began. The driving force behind this development came through a change in the type of steam cycle. At first, it was assumed that the use of preheated air would yield only an approximation to a certain calculated thermal saving, the calculation being based upon the degree to which the temperature of the flue gases could be lowered by this means. It was, however, discovered early, that the use of preheated air resulted in rather remarkable improvement of combustion, so that an unexpected gain was realized. The use of preheated air and the use of water-cooled surfaces in the furnace are really tied together to a certain extent. High preheat, with a great extent of refractory wall, is apt to cause trouble through too early failure of the refractories. Too great an extent of water-cooled furnace surface, with a low degree of preheat or no preheat, is apt to cause trouble through too low a furnace temperature. Great progress has been made in deriving satisfactory working rules with which to connect these factors, but much still remains to be done before we can be sure of obtaining the most economical arrangement for each case.

There is still much discussion as to the maximum permissible temperature of preheated air in stoker firing. Stoker manufacturers will say that their stokers are perfectly satisfactory for use with air up to 550 deg. or 600 deg. fahr. This may be true, but the authors confess that they are inclined to be more conservative as yet. At present, they prefer to limit the temperature of preheat to about 300 deg. or 350 deg. fahr. They do not mean that it is necessarily impossible to operate with higher values; this has in fact been done and is being done today. They mean simply that they believe that under what we may call normal conditions, much more certain and satisfactory results with minimum investment and minimum maintenance are expectable with the lower values.

Stoker design must be modified for different air temperatures. The stoker which is proportioned properly and designed for use with air at room temperature will, in general, not perform satisfactorily with highly-preheated air and vice versa. Use of highly preheated air sometimes radically changes the way in which fuel acts on the stoker. It is therefore not wise to take too great a step in the direction of increased air temperature, without preliminary experiments or observations under conditions similar to those contemplated.

Stokers have been made both wider and longer. Increase of width may be said to increase the fuel-burning capacity in direct proportion to the increase of stoker width. This is true, except for a slight difference due to the diminishing effect of side wall conditions as a per cent of the total, as the stoker gets wider. Increase of length, on the other hand, produces more than a proportionate increase in fuel-burning capacity, at least up to a certain limit not yet determined.

In the case of the chain grate, the increase of width and length bring in very serious design problems, both of a purely mechani-

Presented at Midwest Power Engineering Conference, Chicago, Ill., February 12 to 15, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

cal character and also with respect to air distribution. In the case of the multiple-retort stoker, increase of width is a comparatively simple matter, but increase of length brings up problems of mechanical strength, problems of adequate coal feed, and of adequate coal forwarding.

The increase during the past few years in coal-burning capacity per stoker fired furnace, is well shown in Fig. 1 in which results obtained with both chain grates and underfeed stokers have been combined. The figures used are those given by the manufac-

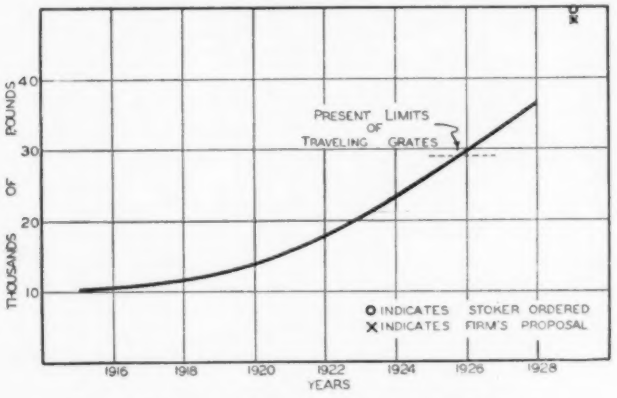

FIG. 1 MAXIMUM CONTINUOUS COAL CONSUMPTION PER FURNACE PER HOUR

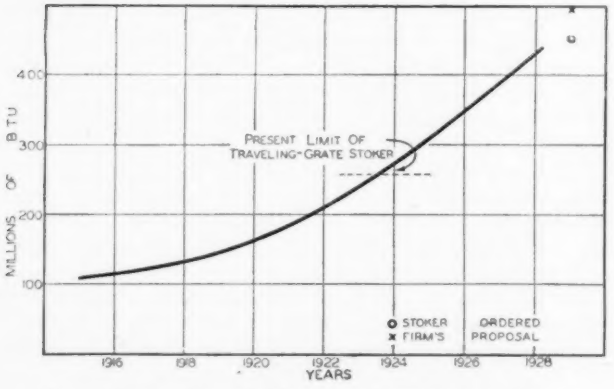

FIG. 2 TOTAL HEAT RELEASE PER FURNACE PER HOUR SHOWN GRAPHICALLY

turers of the stokers as maximum continuous possibilities. Even though they may represent a certain degree of optimism on the part of the manufacturers, it is reasonable to assume that the same degree of optimism prevailed throughout so that the relative values for different years may be accepted, even though the absolute values may be incorrect.

A more significant curve is given in Fig. 2 in which the total heat release per furnace is given, thus eliminating variations in heat value of coal. It will be observed that both figures have more than tripled in a period of thirteen years, a very remarkable performance for so short a period.

The data presented in Fig. 3, giving the increase in the rate of heat release per sq. ft. of grate surface over the same period, show a less rapid change. It must be inferred that a great part of the increase of output per furnace has resulted from increasing the dimensions, rather than from increasing the intensity of use.

It has long been known that stoker-fired equipment is not so limited with respect to rate of heat release per unit of furnace volume as is equipment fired with pulverized fuel. Cases are on record in which reasonably good results have been obtained with stoker-fired furnaces, in which the rate of heat release approached 100,000 B.t.u. per cu. ft. per hr. There is, however, a realization that furnace volumes have been increased greatly since the early years of this century and naturally there is some confusion as to the exact status of the art at the present time. It is impossible to give any simple rule for furnace volume. Too many variables are concerned. However, it may be said that as walls are protected better with air-cooled, water-cooled, or steam-cooled surfaces and as more highly preheated air is used, the rate of heat release per unit of volume may increase without affecting materially the operating results. The principal limit is set by the tendency to deposit fused ash on the boiler tubes nearest the furnace. This can be obviated by the use of an adequate slag-screen arrangement, that is, by the use of one or more rows of widely spaced tubes which cool the molten fly ash before it strikes closely spaced tubes.

It may be useful to show how improvements in furnace con-

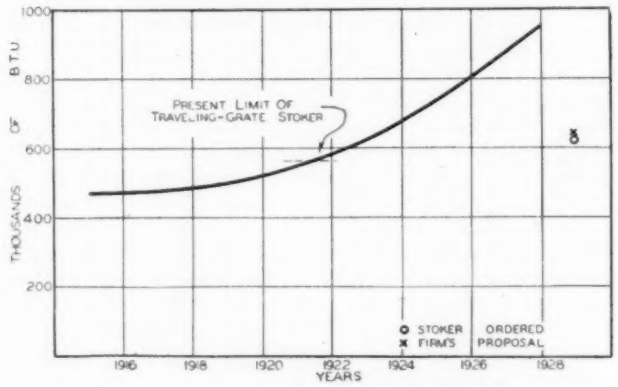

FIG. 3 HEAT RELEASE PER SQUARE FOOT OF GRATE AREA PER HOUR

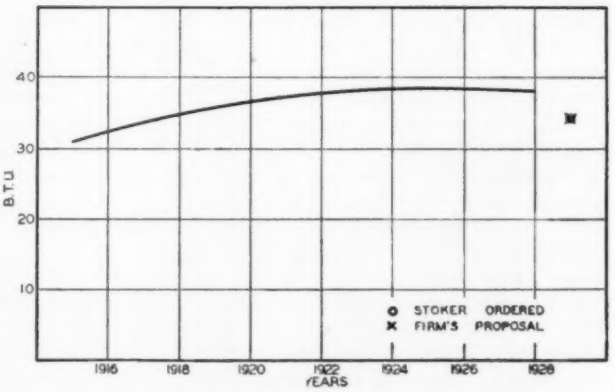

FIG. 4 HEAT RELEASE PER HOUR PER CUBIC FOOT OF FURNACE VOLUME

struction have affected the rate of heat release in recent years. The trend is shown in Fig. 4 and it may surprise many to discover that the general trend has been toward relatively smaller furnaces, with stoker firing during the past decade. This is explained partly by the facts stated above and partly by a certain sacrifice of the advantages of very large furnace volume in exchange for smaller investment.

The effect upon the boiler, of high rates of heat release per furnace and per unit of furnace volume, is exceedingly interesting. This is shown graphically in Fig. 5. Apparently we have not increased boiler area continuously at the same rate as we have the rate of heat release per furnace. This is equivalent to saying

that we have operated the boilers at successively higher rates of output in recent years. This fact is already well known, and it is also well known that the tendency toward lowered thermal efficiency has been balanced by the extensive use of economizers and air preheaters.

The most astounding picture results from a consideration of the increase in the quantity of steam produced per furnace. This is shown in Fig. 6. While it is true that the highest values shown do not as yet represent accomplished facts, it should be noted that they do represent actual orders placed. It is certainly a far cry from the "large Delray boilers" of twenty years ago with an output of about 140,000 lb. of steam per hour to the unit now available and capable of producing 500,000 lb. per hour.

A typical arrangement of forced-draft chain grate of the largest size as used with Illinois coal is shown in Fig. 7. This is a section through one of the Crawford Avenue boilers and furnaces. The small extent of the uncooled refractory arch and the extensive use of water-cooled surface are notable developments in this

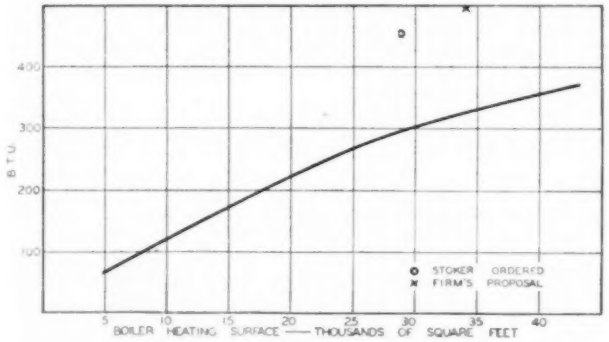

FIG. 5 HEAT RELEASE PER BOILER VS. BOILER SURFACE IN SQUARE FEET

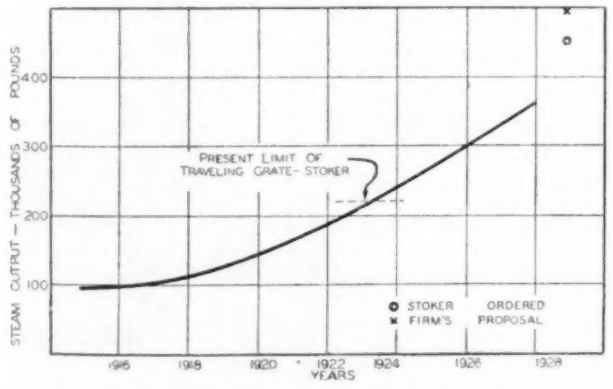

FIG. 6 MAXIMUM CONTINUOUS EVAPORATION PER BOILER PER HOUR

class of stoker. This represents one of the largest installations of its type being designed to produce 150,000 lb. of steam continuously and to carry peaks of 190,000 lb. The stoker pictured is 24 ft. wide by 20 ft., 6 in. long, giving a total area of 490 sq. ft.

An arrangement of the forced draft chain grate, as used with small sizes of anthracite, is shown in Fig. 8. The reversed arch over the discharge end of the stoker is a characteristic feature of this type of furnace. The construction shown in full lines was adopted after that shown in dotted lines was found to have undesirable operating characteristics and limitations. The original design had a throat of only 3 ft. 6 in. The later design gives a much wider throat with a very long rear arch and almost no front arch. It was found that the lean and rich gases mixed very satisfactorily and combustion was more nearly complete with the second arrangement. Combustion rates as high as 75 lb. per sq. ft. per hr. have been attained with this design but the

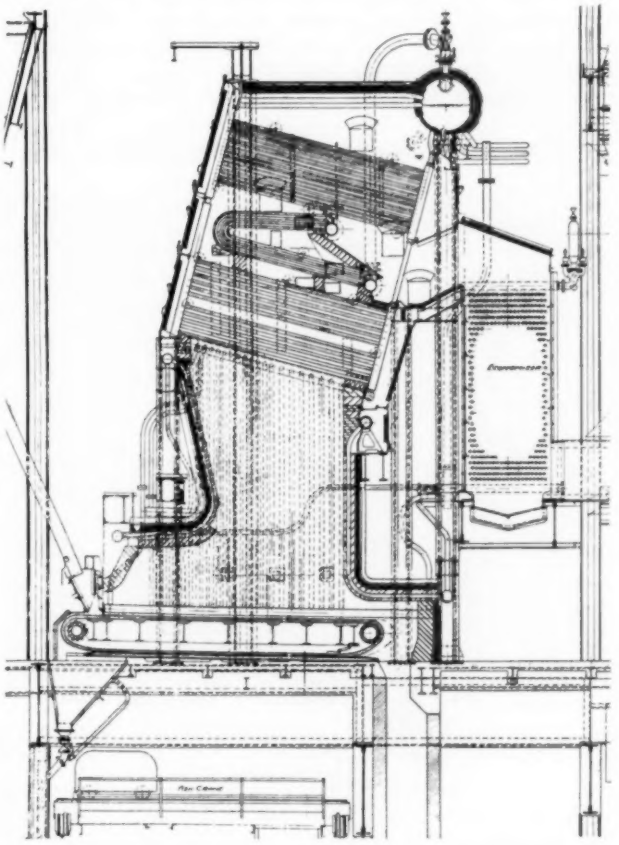

FIG. 7 ARRANGEMENT OF LARGE-SIZE FORCED-DRAFT CHAIN GRATE AS USED WITH ILLINOIS COAL

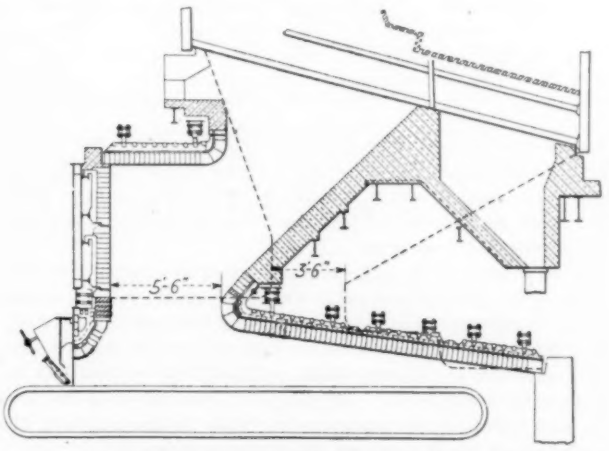

FIG. 8 ARRANGEMENT OF CHAIN GRATE USED WITH SMALL SIZES OF ANTHRACITE COAL

fuel bed must be thin and the stoker speed high (about 100 ft. per hr.) in order to maintain this rate.

A very modern arrangement of a multiple-retort stoker is shown in Fig. 9, as applied to bent-tube boilers in an English power plant known as Deptford East. This is an 11-retort, 37-tuyere stoker. A similar unit of 17 retorts and 49 tuyeres produces

350,000 lb. of steam per hour continuously. The cast-iron covered water tubes along the clinker line and those which form the bridge wall are particularly noticeable. In this way, the most critical wall sections are protected amply in a relatively inexpensive but effective manner, while cheaper masonry construction can be used for the remainder of the furnace enclosure. Incidentally the front wall construction shown is not to be recommended as it may be expected to have a comparatively short life.

A somewhat similar arrangement, but one which makes a

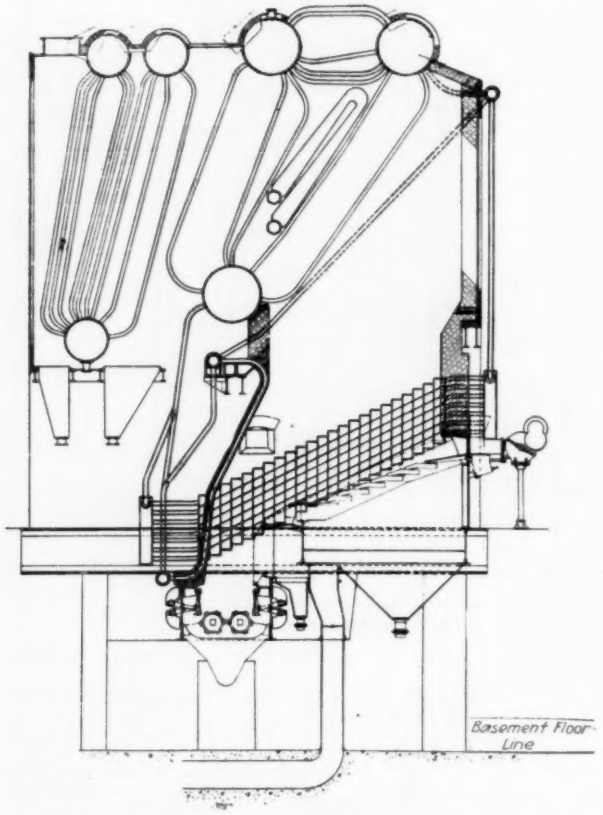

FIG. 9 MODERN ARRANGEMENT OF A MULTIPLE-RETORT STOKER

more extensive use of water-cooled walls as developed for the Richmond Plant in Philadelphia, is shown in Fig. 10. The preheated-air temperature in this case is about 330 deg. fahr. under maximum conditions and the maximum continuous steam output is 190,000 lb. per hour.

A very interesting, high-capacity installation with a double-ended firing arrangement under two single-ended boilers, is used by the Allegheny County Steam Heating Company, Pittsburgh, Pa. The stokers have 14 retorts each and are 36 tuyeres long. The maximum continuous rating is 300,000 lb. of steam per hr. with peaks of 400,000 lb. Fig. 11 gives a view of one of the stokers and parts of the water-cooled walls, looking toward the upper end of the stoker from the clinker-grinder pit.

A single-ended setting of very modern design is used in the Hudson Avenue Station, Brooklyn, N. Y. This unit has a maximum continuous output of 345,000 lb. of steam per hr. with a peak capacity of 410,000 lb. per hr. Water-cooled walls are used extensively. The stoker is 33 tuyeres long with approximately 6 ft. of overfeed rocking grate surface. A unit of similar capacity is now under construction for Delray No. 3, Detroit. The stoker in this case has 15 retorts and is 57 tuyeres long. The continuous steaming capacity is placed at 350,000 lb. per hr. and this is believed to be very conservative as stokers are in successful operation at much higher unit combustion rates. A design prepared in connection with a proposal for a unit capable of producing 500,000 lb. of steam continuously has 18 retorts and is 65 tuyeres long. It is intended to be used with highly preheated air. Although this unit has not been ordered, one very much like it and intended to produce substantially the same output is on order for a station near Berlin, Germany. This stoker has 20 retorts and is 49 tuyeres long, with an estimated maximum continuous capacity of 450,000 lb. per hr.

In the day when the stoker was itself a crude device and was used in small sizes under boilers of small output, it did not pay to attempt many refinements in associated equipment, or frequently even in operation. The modern types, constructed much more carefully, capable of much more accurate control and used in much larger sizes, make possible and even call for things not previously justifiable. The authors would like to call attention to some of the things that they think they have learned from experience in the use of stokers. What they have to say applies more to the underfeed stoker with which they have had the most experience but much of it is easily translated into terms of the forced-draft chain grate.

They have found that it pays to allow a very generous amount of leeway in all respects. Thus, while it may seem like throwing

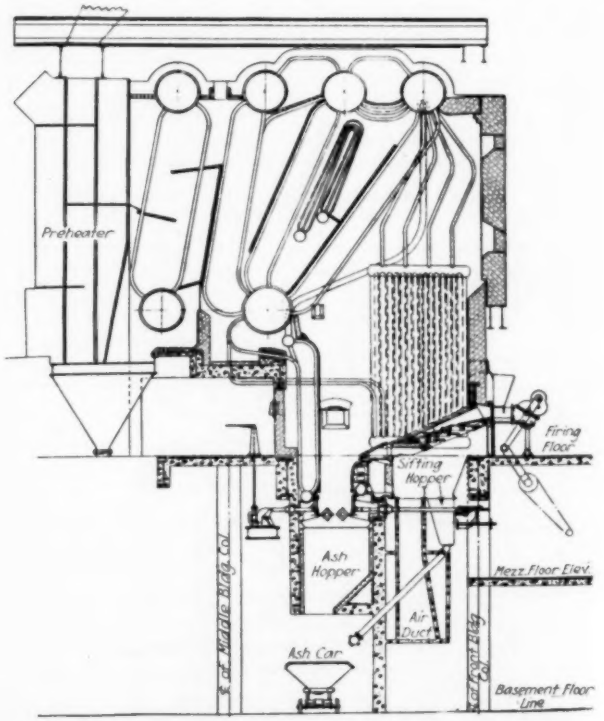

FIG. 10 EXTENSIVE USE OF WATER-COOLED WALLS USED IN THE RICHMOND PLANT, PHILADELPHIA

money away, it will be found usually that the purchase of stokers which are generously large for the job will pay handsomely as an operating proposition. Such action makes the user more independent of variation in the quality of fuel supply and much better able to cope with the various vicissitudes of daily operation.

Similarly, when choosing the motive power for stokers, one should not be satisfied with something that figures just large enough on the basis of calculated maxima. There should be a

very generous allowance above the apparent maximum requirements for fuel feed. It is frequently necessary to build up a fire rather hurriedly while at the same time burning at a rapid rate and this obviously calls for a great surplus over the calculated maximum speed. Too many installations are undesirably limited in this respect. At the present time most stokers, and particularly those of large size, are motor driven, and it pays to expend the few extra dollars required to obtain a generously large motor. Again, it generally pays to have a great many control points, or the equivalent, so that when the character of the load permits, the speed can be adjusted so as to prevent undesirable building up or thinning of the fire. This is particularly true at the lower speeds. It is also important to make certain that the motor, when operating at the lower speeds, will have sufficient torque to drive the stoker satisfactorily.

The authors have also found that it is usually not safe to base the choice of forced-draft fan characteristics upon too optimistic a conception of the performance of the stoker and furnace. Even though it is expected to maintain, say, 14 per cent CO_2, a fan should be big enough to deliver the air required for maximum combustion with a much lower CO_2 performance. As a general rule, something of the order of 11 per cent should be used for cases in which 14 per cent is to be expected. With such capacities, emergency conditions can be met with an assurance of safety. Similarly the maximum air pressure at maximum output should, in general, represent a generous margin of safety over the discharge pressure called for by the stoker manufacturer.

Here also proper speed regulation is important. This is a problem that many believe has not as yet been solved satisfactorily. Direct-current drive is beautifully flexible, but costly in all respects. Alternating-current drive becomes complicated and costly if the desirable flexibility is approximated. It seems as though the best present solution for general application is a mixture of damper and speed control, in which the power losses resulting from dampering, are offset by lower first cost, less complication, and less maintenance expense. Similar remarks apply, in general, to induced-draft fans although possibly they are not considered properly as part of the stoker installation.

It is also very important to distribute coal properly to a stoker. The stoker cannot be held responsible for results if coarse coal is fed to one or two retorts and much finer coal to the neighboring retorts. This fact has been known for a long time and appreciated by some, but ignored by most. There are now several different devices on the market which are capable of producing a very satisfactory distribution of coal in the stoker hopper and it is believed that they should be used more frequently than they now are.

The authors do not believe we need contemplate in the near future automatic combustion control, which will give results better automatically than, or even as good as, can be obtained by a conscientious, careful, and skilful operator assisted properly by instruments and other facilities. This is not to be interpreted as meaning that there is no field for automatic control in connection with stoker operation. In the first place, operators of the type indicated are rather rare and there are now available, automatic combustion-control systems capable of giving better results than are obtained by many of the stoker operators now employed. In the second place they believe it is wrong to expect the best results when a man is used for doing that which a machine

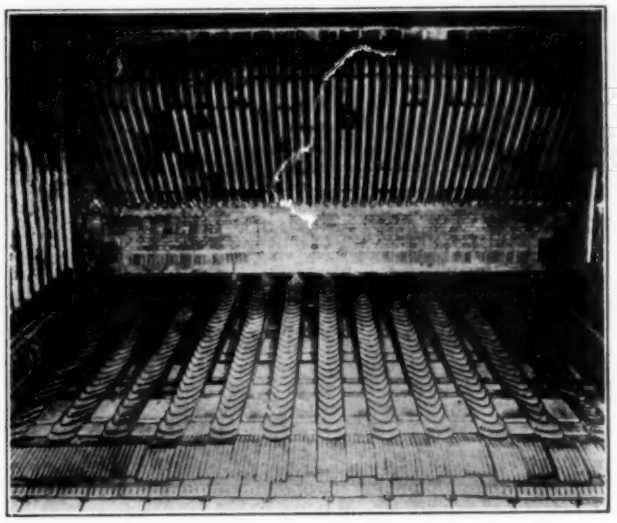

FIG. 11 VIEW OF A STOKER AND PARTS OF WATER-COOLED WALLS LOOKING TOWARD THE UPPER END OF THE STOKER FROM THE CLINKER-GRINDER PIT

can do as well or better, and thus use up a good part of his energies, instead of conserving them for doing only those things that he can do better than an available machine. For this reason they personally favor automatic control to a certain extent even when exceptionally good operators are available. The degree must vary with the economics of the particular situation as determined by cost of fuel, cost of labor, size of unit, etc. In the simplest case the automatic feature may be confined to boiler damper control, while at the other extreme will fall complete automatic control of all factors in an overall way and according to certain mean requirements, leaving the skilled operator free to make such secondary refinements in the relations between the different parts of the equipment as his experience may indicate to be necessary from time to time.

List of A.S.M.E. Transactions Papers Published Since January 1, 1928

BELOW is published a complete list of the papers which have appeared in the various sections of Transactions since January 1, 1928, together with references to the issues of "Mechanical Engineering" in which abstracts of them may be found.

FSP-51-21

Progress in Fuel Utilization in 1928

Contributed by the Fuels Division

Executive Committee: Victor J. Azbe, *Chairman*, Wm. G. Christy, *Secretary*, E. C. Schmidt, John Van Brunt, R. T. Haslam, and Geo. A. Orrok

IN ALMOST all phases of fuel utilization the past year has been characterized by consistent development of methods previously introduced and of equipment, the use of which had already been initiated. The greatest advances have been made in those branches of fuel utilization in which the largest quantities of fuels are employed. However, the predominant tendency to increase the effectiveness of fuel-utilization processes generally has caused an increasing amount of attention to be paid to combustion processes in those industries which have hitherto not shown active progress.

The report of this Committee is intended to summarize the more important advances which have been made during the past year. So many detailed improvements have been noted, however, that for a more complete statement reference must be made to the appended bibliography.

Specific attention must be drawn to the very valuable material reported at the three principal symposia on fuels conducted during 1928; namely, the fall meeting of the Fuels Division of the A.S.M.E. in Cleveland, the Fuels Conference of the World Power Conference held in London, and the more recent Second International Conference on Bituminous Coal in Pittsburgh. The transactions of these three meetings are replete with the most advanced material of interest to those concerned with fuel utilization.

Production, Preparation, and Storage of Fuels

Bituminous coal is the principal source of energy for the generation of power. Such an industry should be characterized by stability, constant output, and consistent earnings. Its present condition, on the contrary, is not far from one of distress. The maximum producing capacity of the bituminous-coal industry is variously estimated to be from 700,000,000 to 850,000,000 net tons, and shows no steady rate of increase. The production data for the period 1925–28 clearly indicate the present trend.

Year.....	1925	1926	1927	1928
Net tons.....	520,052,741	573,366,985	517,763,352	500,000,000 (estimated)

Comparative data indicating the relative use of coal are available for only a few industries. Those for central stations, however, show the present tendency.

	1927 Jan.–Aug.	1928 Jan.–Aug.
Energy generated from fuel, 1000 kw-hr..	29,556,431	30,941,071
Coal used, net tons.....	23,638,154	23,914,597
Fuel oil used, bbl.....	4,414,761	4,219,881
Gas used, 1000 cu. ft.....	38,454,403	47,280,154

The only material change noted is the increase in the use of gas. The figures for the last four months of this period show a decrease in coal used, and marked increases in oil and gas used for power generation in central stations. The increase in total energy generated in central stations noted elsewhere is due to a steady upward trend in the amount of power produced in the hydroelectric plants.

Coal-Producing Methods

In the mining of coal the efforts to reduce production costs and increase the percentage of recovery have been vigorous. This work has largely centered in the more extensive use of mechanical cutters, loaders, and conveyors, and in the adoption of improved mining systems. New types of mining equipment of practically all kinds have been introduced, and the older ones have been improved. Of particular significance is the work along these several lines by the larger coal producers. Much interest is being displayed in the development of a CO_2 cartridge for shooting the coal, a method which would eliminate flame. An outstanding activity is the increased attention paid to safety measures. The problem of supplying bituminous coal on a basis of quality and adaptability to specific purpose or type of combustion equipment has attained major importance, and hence producers are paying much attention to methods of cleaning and preparing coal. The labor situation in the bituminous industries is satisfactory, and there are no indications of potential strikes.

Anthracite

In the anthracite industry cumulative production for the first seven months of 1928, as compared with the corresponding period of 1927, shows a decrease of 4,500,000 net tons. Competition from oil and coke is severe. The decrease in production has caused the anthracite mining companies to make more intensive efforts to improve mining methods and to add labor-saving equipment. Old and expensive workings are being abandoned, and the larger mines are being equipped with automatic machinery in place of the old equipment. Extensive changes in auxiliary appliances are being made. The organization of the anthracite operators to carry on a well-planned research program, which has been effected, is undoubtedly an event of far-reaching importance in this industry. The anthracite industry has definitely started a series of investigations, the purpose of which is, first, to increase the efficiency of utilization of anthracite fuel generally, second, to develop means for applying steam sizes of anthracite to domestic use, and third, to carry on investigations which will enable the anthracite industry to turn some of its output into materials of greater value. The industry is having the close cooperation of domestic-heater manufacturers, and it is believed that this work will result in a distinct increase in the use of anthracite for domestic heating.

Coke

By-product coke for the first eight months of 1928 showed an increase of 2,000,000 tons over the same period for 1927. Beehive-coke production dropped 2,500,000 tons, and the net production is just under the figure for 1927 for the corresponding period.

Liquid and Gaseous Fuels

The increased use of natural gas for power generation has been referred to. During the past year at least three large gas lines have been completed which bring natural gas in increasing quantities into such centers as Denver, Omaha, and Kansas City. Considerable effort is being made by oil and gas producers to reduce the tremendous wastage of natural gas which has occurred and to divert it into domestic use, power generation, and to the repressuring of oil wells. This fuel is now being found in such

large quantities that the fears felt some years ago for its rapid extinction no longer exist. Production of crude petroleum for the first ten months of 1928 has been 4 to 5 per cent under that for the corresponding period during 1927. A very concerted effort was made to control petroleum output in the United States, both as a means of conserving this natural resource and as a necessary method of insuring the financial stability of the oil industry. At the present time the known oil reserves of the world are greater than at any other time. The petroleum industry is still in a critical state as far as the regulation of the supply of crude petroleum is concerned, and the efforts made this year to cooperatively hold down production in the U. S. must undoubtedly be extended to the principal foreign producing districts.

Furnaces

No radically new types appear to have been developed during the past year, but distinctive development along two lines has taken place, i.e., the further extension of water- and steam-cooled wall surface, and the decided increase in the use of automatic combustion-control equipment. Increased water cooling of the walls through water screens, which are a part of the boiler circulatory system, or by the use of radiant superheaters is taking place, because such development is found to reduce furnace maintenance costs and to facilitate improved combustion. Refractory surfaces continue to be used in the smaller installations, and particularly when the use of certain varieties of fuel is required. Furnaces with air-cooled walls are still being built, but operators believe that this type of wall will be gradually superseded by the water-cooled type, despite the higher cost of the latter.

Stokers

Reports from manufacturers indicate that the principal changes in stoker design which have taken place during the period covered by this report are: first, strengthening of those parts subject to strain by substitution of steel for cast iron; second, increase of the ruggedness of the ash-disposal mechanisms; and third, increases in both length and width. Last year this report mentioned the trend toward specific control of air admission to different parts of the fuel bed. This trend has continued uninterruptedly, and the newest stokers are being supplied with air-control systems intended to permit highly selective admission of air to the different portions of the stoker. Moreover the advantages of controlled supplies of air over the fuel bed are now thoroughly appreciated, and many such installations are being made. The burning of low-grade and clinkering coals at high percentages of rating on stokers has been successfully carried out by means of stokers specifically designed for this type of operation. The limit for air preheat in ordinary installations continues to be 400 to 500 deg. fahr., although the presence or absence of an air preheater in a given installation is dependent on the particular heat-balance conditions of a given installation. Corrosion of air preheaters which has been experienced has been eliminated by increasing the exit gas temperature, and the burning of stoker tuyeres has been corrected by using greater clearances and in some cases using coal with a higher ash-fusion point. A great deal of attention is being paid to tuyere and retort design, notably in altering the tuyere-to-retort area ratio, the overfeed-underfeed ratio, and the use of large rams with variable-width tuyeres. Sufficient data are now available so that stoker manufacturers are designing equipment with constantly increasing exactitude.

This year has seen a real tendency toward the installation of mechanical stokers in marine practice, and this type of equipment is being tried out in a sufficient number of ships to indicate that progress in this direction from now on will be rapid. The trial installations seem to be proving successful.

Pulverized Fuel

The increased use of pulverized fuel both in converting old equipment and as regards new installations continues at about the same rate as for the preceding year. In public-utility plants the central storage system predominates over the unit system in the ratio of 2.4 to 1, whereas in the industrial plants the installed horsepower supplied by the unit system is greater than that of the central system in the ratio of 1.7 to 1. The rate of increase of the unit system has been greater than that experienced by the central system, and a few installations of the unit system have been made in connection with large boilers. The use of preheated air in the mill for drying coal seems to be prevalent in new installations, except for those fuels which have a low ignition point. In these cases the use of steam for drying reduces the tendency to take fire in the drier. The elimination of dust in the stack gases from pulverized coal is giving concern in a great number of cases. This problem is being attacked in a variety of ways, e.g., by the use of cyclone collectors in series, water sprays, electrical precipitation, etc. As may be expected, no one method seems to be uniformly applicable, and the particular means used have to be specifically selected for each installation. Installations have been made in which the regular bank of boiler tubes is protected by an extra series of tubes on extended centers below the regular bank as a means of chilling the ash in such a way that it does not cause slagging on the boiler tubes. This method may prove to be of particular advantage in small furnace chambers where short-flame burners are used. No new significant points in the design of furnaces for use with pulverized fuel are noticed, the trend being the same as for stoker-fired furnaces in that the use of water- and steam-cooled walls practically enclosing the combustion space is almost universal.

The more extensive use of the turbulent-type burner referred to last year continues to be noted, the principal advantages being increased combustion rates per unit of furnace volume, reduction of excess air, and facilitation of ash separation.

The turbulent-type burner has been successfully applied to Scotch marine boilers. While the extension of the use of pulverized fuel to marine practice in the United States has been slowed up by the low prices of bunker fuel oil, it is certain that interest abroad in this development is constantly becoming more intense. On at least three British ships at the present time a part of the boilers are being fired with pulverized fuel. The bunker-fuel situation in England will encourage intensive work to perfect the use of pulverized fuel for cargo carriers. The British government is expected to appropriate £100,000 for such development during the coming year.

Steam Pressures

Aside from the fact that additional 1400-lb. units have continued to be built, no radical change has taken place in steam pressures and temperatures, although in the larger stations the trend seems to be from the 400-lb. to the 600-lb. range. A consistent realization of steam temperatures of about 750 deg. fahr. has not yet taken place.

Two-Fluid Systems

In last year's report the possibility of the bi-fluid system, using organic compounds of the type of diphenyl oxide as a substitute for mercury, were indicated. Research work carried out during the past year has indicated that whereas the thermal stability of such compounds at operating temperatures can be assured, the peculiar thermodynamic properties of such organic

liquids requires the use of such large heat-exchange equipment that the necessary capital cost of the equipment is so high as to render the use of an organic-boiler-fluid system non-competitive with the 1400-lb. steam system at present.

Locomotive Practice

In this field the selection of fuel has been one of the major means of conserving fuel. The pounds of coal per thousand gross ton-miles continues to decrease at the rate of about four per cent per annum, and the corresponding figure per passenger car-mile is decreasing nearly two per cent. The number of locomotives in service which are equipped with mechanical stokers has increased until about one-fourth of the total number have stokers installed. Over one-half of the total number of locomotives employ superheaters, and the use of automatic fire doors on locomotives is now general practice. Railroads are paying particular attention to the proper selection of fuel and to supplying divisions constantly with the same kind of fuel. This permits effective training of firemen.

A great deal of interest is displayed abroad in the Schmidt high-pressure locomotive which employs two steam pressures, 850 lb. and 205 lb. The 850-lb. steam is expanded in a center cylinder, the exhaust from which is mixed with the 205-lb. steam, which is then expanded in two outside cylinders. This development has presaged the building of additional locomotives to operate on a similar principle, in that the high-pressure portion will be further enlarged at the expense of the low-pressure system. In addition a locomotive working at 1700 lb. pressure according to the Loeffler principle is now under construction. The advantages for this particular design are fuel economy, with only slightly higher first cost than that of existing locomotives. In Russia particularly, as well as in other European countries, the application of Diesel engines to railway work continues. This is being facilitated by a solution of some of the difficulties of gear transmission previously experienced.

Gas Manufacture

This field of fuel utilization is becoming distinctly interested in two auxiliary processes, namely, the dry quenching of coke and the dehydration of gas. The economical advantages incident to using the sensible heat of the coke for producing steam are beginning to be appreciated as the success of existing installations becomes better known. This type of plant is adaptable to a large variety of carbonizing units and conditions, and the facts indicate that the dry-quenched coke produces less breeze and has some advantages as water-gas fuel over water-quenched coke.

Meter repairs have always been an appreciable item in the cost of manufactured gas. Data gathered both in the United States and England indicate that substantial savings on this item may be made by dehydrating the gas before distribution. Certain processes for dehydration are being installed in the United States, and the forthcoming year should produce data really indicative of the value of these processes. Research in England has indicated that specific constituents of the ash in coal may have significant effects on the properties of the coke in so far as its ability to decompose water and CO_2 are concerned. The practical aspects of this point remain to be investigated.

Low-Temperature Carbonization

The Second International Conference on Bituminous Coal at Pittsburgh brought forth many papers and considerable discussion of this topic, and still there do not seem to be definite data establishing the economic utility of this process. Until the two large-scale plants in the United States have operated for a sufficient time to demonstrate the earnings possible, little real progress can be reported. The theoretical as well as the engineering aspects of low-temperature carbonization are doubtless well worked out, but it is believed that even in England where the market for low-temperature coke should permit of a higher premium than in the United States, definite assurance as to commercial practicability seems to be lacking. The value of the tar seems to be a doubtful point. It is possible that low-temperature tar could be hydrogenated to produce such a large proportion of saturated hydrocarbons that its value could be greatly enhanced with a consequent improvement in the economic situation of the process as a whole. Continued experimentation both in the United States and abroad proceeds, as well as continued discussion of the general scheme of combined gas and electric plants. A paper by Rosin at the World Power Conference summarizes the possibilities and draws the conclusion that the combination has the best chance of economic success when low-grade fuels such as lignite are used.

Experimental work on low-temperature carbonization processes both in the United States and abroad is being actively continued on a wide variety of processes, most of which have been described fully in the literature. Taken as a whole this work is being supported financially to an extent almost unequaled in any other branch of the fuel-utilization field.

Smoke Abatement

The necessity for smoke abatement in the large cities is constantly becoming more acute. Data as to the economical losses and health hazards involved are becoming more available, and a few of the more progressive municipalities are adopting smoke-abatement ordinances and instituting control organizations to the end that only combustion equipment designed for minimum production of smoke will be permitted and that constant effort will be made to modify existing installations. Notwithstanding this interest there is as yet no effective or uniform means available for controlling or abating the smoke nuisance.

Research

Despite the interest in this phase of fuel utilization displayed at such meetings as the Second International Coal Conference and the fact that The American Society of Mechanical Engineers, the American Gas Association, National Coal Association, and other similar organizations have research committees and tentative research programs, no concrete organization fully organized to secure the necessary funds for carrying on a well-considered program of fuels research has yet been developed. This is probably the greatest single need in fuel utilization at the present time.

The papers presented at the conferences noted above constitute quite a comprehensive statement of the work completed and under way.

Mention of even the subjects discussed at the Second International Conference on Bituminous Coal would be too voluminous for this report. The impression gained by those attending the sessions was that throughout the whole world an enormous amount of well-chosen and well-conducted fuels research is being carried out. Abroad the greatest importance is attached to transformations of coal and its derivatives into materials of enhanced value such as liquid fuels.

Without minimizing in any way the importance of the other papers recently presented, attention should be called to two papers vitally affecting furnace design, namely, those by Wohlenberg and Anthony, soon to appear in the publications of the Society; and by Rosin at the Second International Conference on Bituminous Coal.

Some of the more important work being carried on in Europe on which definite progress seems to be assured includes:

Development of Internal-Combustion Engines Using Pulverized Coal as Fuel

Application of Pulverized-Coal Firing to Locomotives

Long-Distance Transmission of Coke-Oven Gas

Formation of Benzol and Other Hydrocarbons from Methane.

Details of the work done on these projects will be found in the transactions of the Second International Conference on Bituminous Coal.

Discussion

O. P. HOOD.[2] If one seeks a reason for the popularity of these national and international fuels meetings, he will find it in the breadth of subject that is brought up.

Mr. Ward's review of the year's situation has a number of points of contact between fuel and our modern civilization. This paper is not so much one for discussion, but it is certainly one for amplification or further development.

JOHN VAN BRUNT.[3] Professor Ward mentions the amount of steam fuel produced in the mining of anthracite as 30 per cent. Just what is included as steam fuel?

PROFESSOR WARD. I included everything below nut size, but others might restrict such a figure to those sizes below pea coal.

MR. VAN BRUNT. You mentioned that in the future that will increase to 50 per cent.

PROFESSOR WARD. That figure of 50 per cent must not be taken too literally. It is doubtless more correct to state that under present conditions the proportion of anthracite coal mined that is not salable as domestic fuel is approximately 30 per cent. A fair estimate of the rate of depletion of present anthracite reserves may be made, and this indicates that inside of fifty years we will be mining varieties of anthracite that upon being crushed will yield a larger proportion of sizes not salable as domestic fuel. It is estimated that these softer anthracite deposits will yield not over 50 per cent of salable domestic sizes.

Authorities agree that as time goes on the percentage of high-revenue anthracites will decrease, and the anthracite operators are in the uncertain position of any industry that foresees a decline in revenue. The remedy is doubtless research leading to the use of anthracite fines to produce products of greater value.

MORGAN B. SMITH.[4] For some time past the coal situation in Detroit and surrounding cities has been in a thoroughly demoralized state, as is evidenced by the wide price range asked for nut and slack coal of so-called 2 in. size; namely, 25 cents to $1.10 per ton f.o.b. mine. Over-production is largely responsible for this condition.

In addition bankers tell us that there has been approximately 41 per cent decrease in demand for coal because of:

(*a*) Increased efficiency of locomotives
(*b*) Increased efficiency of public-utility steam power and heating plants
(*c*) By development of hydroelectric power plants
(*d*) By the increased use of substitutes such as oil and gas.

We have in this Society men capable of studying the financial and general economic status of the coal industry and well able to assist in stabilizing the situation. With this thought in mind I wish to suggest that the Fuels Division include this phase of the topic in their work and give us a report of progress a year hence.

VICTOR J. AZBE.[5] Mr. Ward's report is not as voluminous as it will be next year. He is getting together a very able committee, and I am sure that this committee will aid greatly in stimulating the proper use of fuels in this country, and we certainly do need such stimulation.

Professor Ward's report indicates progress; you get a picture that things are all fine, everything is lovely, and that we burn coal with very high efficiency, which really on the average is far from so.

We should have still another committee, the exact opposite of Professor Ward's committee. Professor Ward's committee tells us about the progress, and the other committee should tell us about the things that are happening that are the exact opposite of progress.

Another thing that we ought to have is a committee that will evaluate the efficiency of the average engineer. I will say that his efficiency is very low. If you attempt to measure progress in some industries you actually have to use a micrometer to find it. It is really outrageous in this twentieth century to find that certain industries are about in the same state as they were some fifty years ago.

MASON A. STONE.[6] I wish to take exception to the remarks of the speaker divorcing economics and engineering. I think that a speaker before him illustrated the fact that a fuel engineer is primarily an economist and that our profession is one of those which applies political economy to the problems of industry.

The political economist theorizes about economics, but the engineer puts the theory into practice, and no engineering de-

signer is a good designer unless he takes into consideration the economic features. He may not have studied political economy, but he certainly applies it every day of his life.

MR. HOOD. I brought one major impression from the London meeting. The question of fuel is of interest to the government in England. It has been shown in many ways. It is not only of interest to the government as an organization; it is of interest to each political party. Just imagine our Republican or our Democratic platform with some really meaningful reference in it about the efficient use of fuel.

The American Government was one of the first, under President Roosevelt, to make appropriations to do something in the matter of efficient use of fuel resources. Something has been done, a little each year, since 1910. But the rate at which the Government is interesting itself in American fuel is comparatively small as compared with the interest shown in England.

The Government Research Laboratories at Greenwich under Dr. Lander propose to spend for the coming year £90,000, or $450,000, on one line of research. Our American appropriation for similar work is about $150,000, of which something more than $50,000 is taken up with routine testing for the Government itself.

I think that shows the difference in the two countries as to their interest in the fuel problem.

As has been said here, Lord Redding was quite willing to come out with a flat statement that English prosperity rested on the fuel industry. Our own people are not ready to say that as yet. We are interested in too many things. We are too rich in fuel. Perhaps it is just as well that we get along as we do, but the time will doubtless come when we, too, must take an increased interest in this basic resource that we are exploiting.

A. E. R. DE JONGE.[7] American engineers are indeed very fortunate, for the coal they use has such a small content of ashes. The coal used in power stations here has hardly more than 10 per cent of ashes. They can therefore hardly visualize the difficulties that other engineers have.

I have been associated for over nine years with the Shanghai Municipal Electricity Department and its large power station. There we had considerable difficulty with ashes and grit. The coal we were burning contained up to 25 and even over 30 per cent of ashes, and one of the most difficult problems we had to deal with was the question of reducing the amount of grit that passed out of the stacks.

I did not gather from Mr. Ward's report whether he had any data on the progress that has been made in this country on the elimination of grit and the losses of ashes from the stacks.

As I said, we had considerable difficulty and have tried various equipment to eliminate these cinders. We also installed some equipment of our own from my ideas, as we found that all the equipment we had used would not work to our satisfaction. We have, however, not been able to get rid of more than 50 per cent of what passes out of the stack, although the manufacturers of some of the equipment claimed that it would eliminate between 85 and 90 per cent.

The reason why I mention this is that we have been rather unfortunately located. The wind direction prevailing in Shanghai for practically three-quarters of the year is southeast, and this means that there is a very narrow patch of country lying to the northwest of the station on which all the grit passing from the stacks was deposited. This land is unfortunately agricultural land.

Naturally we had for some time tremendous opposition from the Chinese farmers. Tons and tons of black grit were deposited on the vegetables they were growing. They complained to the Government, and the Chinese Bureau for Foreign Affairs complained to the Municipal Council. The situation became desperate, and we had to do something. But, as I stated, we have not been able to eliminate these stack losses to any great extent.

The best results, and I think this is worth stating, were obtained through the installation of air preheaters which acted more or less as cinder catchers and eliminated about 6 per cent.

May I add one more thing to the subject? That is the domestic application of coal. A large amount of coal is burned in small boilers and in small furnaces in a domestic way, but the efficiency is frightfully low, and I think most of the pollution of the air is due to this source. In England they have attacked the problem of air pollution from this source, and as far as I know there is a definite movement on foot to reduce smoke and cinder losses, or rather soot, issuing from these small furnaces and thereby to reduce the pollution of the air. We are human beings who are living in the air, and I think that everything that can be done to do away with pollution of the air should be done.

A MEMBER. What differences are there between German brown coal and American lignite? In reading about English coal the price of patent fuel is mentioned—is that the briquet coal?

MR. HOOD. "Patent" is a term used for briquetted fuel, and it varies considerably in quality. The Englishman has not ruined his briquet market quite as much as we have by using high-ash material in the briquets.

In answer to the question about German brown coal, if one thinks of it as a fuel that has not been metamorphosed as much as lignite, you will not be far wrong. Its heating value is, in round numbers, about one-half of a fair American coal. It varies all the way from 40 to 60 per cent in inherent moisture—not wetness on the surface, but inherent moisture—and that is its main characteristic. Our own American lignites in Texas and Dakota run about 30 to 35 per cent inherent moisture. Our lignites must be mined by blasting, just the same as our bituminous coal. That is, they are hard. German brown coal is so soft, at least in some places, after the bed is stripped, that with a little exertion one can thrust a spade into it.

It varies in color all the way from deep cream color to brown-black. In Central Germany there are bands of brown coal that are deep cream in color. Even the amber that is used for jewelry, I believe, comes from a vein of brown coal. It varies widely in color, but the greater quantity of it is brown.

Occasionally one will see a pile of this brown coal exposed to the sun that shows its woody structure in a peculiar manner. One can pick out pieces where the annual layers of wood can be separated one from the other. It will curl up like drying chips. I know of no better illustration than that of the occasional hen you see with its feathers turned the wrong way, and that is the way a pile of this material looks.

According to one way of classifying coal, a German brown coal is included under the general term of lignite. But we in this country have no commercial brown coal. I am told there is a spot in Texas that has a little of it. We have read what Germany has done with its lignites and that because we have lignites therefore we can do what Germany has done. The logic is bad, since the two materials are unlike.

FREDERICK A. SCHEFFLER.[8] I would like to suggest that the Fuels Division undertake to induce the Department of the Interior at Washington to separate in their monthly report of fuels used in public utility plants the amount of coal used in pulverized form from the total raw coal used.

[7] Designer, New York Edison Co., New York, N. Y. Mem. A.S.M.E.

[8] Special Representative, Fuller-Lehigh Co., New York, N. Y. Mem. A.S.M.E.

Pulverized coal is a new form of fuel and is used now to such a large extent that it is just as important to have it tabulated as it is for oil, gas, and hydroelectric power to be tabulated.

There are installed and under construction in public-utility plants in this country over 4,000,000 kw. capacity which will use pulverized coal to the extent of approximately 13,000,000 tons net annually, which is 31 per cent of the total cost reported in 1928 bulletins.

C. Harold Berry.[9] With respect to brown coal, it might be of interest to call attention to the fact that the brown coal of Australia differs from European brown coal and from our own lignite. I understand that it has about the mechanical properties of brown sugar. A typical analysis shows fixed carbon, 14 per cent; volatile matter, 18.8 per cent; ash, 1.2 per cent; moisture, 66 per cent; heating value, 3000 B.t.u. per lb. It is burned successfully in several plants, but requires a special procedure in handling and firing.

[9] Professor of Mechanical Engineering, Pierce Hall, Harvard University, Cambridge, Mass. Mem. A.S.M.E.

Professor Ward. We will place before the Executive Committee Mr. Scheffler's suggestion that the statistics of the Department of the Interior be changed to show the amount of pulverized coal used in public-utility central stations.

Mr. Smith's suggestion that the Fuels Committee include a discussion of the economic status of the fuels industry is probably too great an increase in activities for the Fuels Progress Committee to undertake, but there is no question about the desirability of such a survey. Doubtless the Executive Committee will be glad to discuss Mr. Smith's suggestion.

In conclusion, it is doubtless sufficient to reiterate that while there is an abundance of fuel research being carried on and consistent progress is being made in fuel utilization, the past year has seen no developments so radical as to be productive of results that will change the present trend of fuel utilization either here or abroad.

FSP-51-22

Joint Research Committee on Boiler-Feedwater Studies

THROUGH the Joint Research Committee on Boiler-Feedwater Studies, six national technical organizations are cooperating actively in a study of the various processes employed in the purification of feedwater in steam power plants and on railroads. This research is being carried on to determine the fundamental principles underlying certain phenomena which take place in steam boilers. The Committee is sponsored by the American Boiler Manufacturers' Association, the American Railway Engineering Association, the American Water Works Association, the National Electric Light Association, the American Society for Testing Materials, and The American Society of Mechanical Engineers, and has been subdivided into nine sub-committees and an executive committee. Each sub-committee is collecting data relating to the subject assigned to it, and has been requested to compile and submit yearly reports. After these reports are reviewed by the Executive Committee, they are presented for publication in the journals of the organizations participating in these studies.

Progress Report of the Boiler-Feedwater Studies Committee

Report of the Executive Committee[1]

By SHEPPARD T. POWELL, BALTIMORE, MD., CHAIRMAN

[1] The personnel of the Executive Committee of the Joint Research Committee on Boiler-Feedwater Studies is as follows:

S. T. Powell, *Chairman*, 213 St. Paul Place, Baltimore, Md.

W. L. Abbott, Chief Engineer, Commonwealth Edison Company, Chicago, Ill.

A. J. Authenreith, Vice-President, Middle West Utilities Company, Chicago, Ill.

R. C. Bardwell, Superintendent of Water Supply, The C. & O. Railway Company, Richmond, Va.

Prof. Edward Bartow, The State University of Iowa, Iowa City, Iowa.

James H. Buell, Middle West Utilities Company, Suite 1500, Edison Building, 72 West Adams Street, Chicago, Ill.

Prof. A. G. Christie, Department of Mechanical Engineering, The Johns Hopkins University, Baltimore, Md.

Wellington Donaldson, Consulting Engineer, Fuller and McClintock, 170 Broadway, New York, N. Y.

Harold Farmer, Chief Chemist, Philadelphia Electric Co., Central Service Building, 23rd and Market Streets, Philadelphia, Pa.

Prof. C. W. Foulk, Analytical Chemistry, Chemistry Department, Ohio State University, Columbus, O.

Vincent M. Frost, Assistant to General Superintendent of Generation, Public Service Electric & Gas Co., 80 Park Place, Newark, N. J.

Clarence F. Hirshfeld, Chief Research Department, Detroit Edison Company, 2000 Second Avenue, Detroit, Mich.

Clarence R. Knowles, Superintendent Water Service, Illinois Central Railroad Company, 135 East 11th Place, Chicago, Ill.

Abbott L. Penniman, Jr., Superintendent Steam Station, Consolidated Gas, Electric Light & Power Co. of Baltimore, Lexington and Liberty Streets, Baltimore, Md.

V. Bernard Siems, Vice-President and General Manager, North American Water Works Corpn., 11 Broadway, New York, N. Y.

Frank N. Speller, Metallurgical Engineer, National Tube Co., 1810 Frick Building, Pittsburgh, Pa.

George A. Stetson, Associate Editor, The American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y.

C. P. Van Gundy, Engineer of Tests, Baltimore & Ohio Railroad, Baltimore, Md.

Prof. Albert E. White, Director of Department of Engineering Research, University of Michigan, Ann Arbor, Mich.

Abel Wolman, Chief Engineer, Maryland State Department of Health, Editor-in-Chief, Journal American Water Works Association, 16 West Saratoga Street, Baltimore, Md.

Progress reports presented at a joint session of the A.S.M.E. Power Division and the Joint Research Committee on Boiler-Feedwater Studies at the Annual Meeting, New York, N. Y., Dec. 3 to 7, 1928, of The American Society of Mechanical Engineers.

THE functioning of the Committee during the past year has been along the lines originally laid down when these studies were inaugurated. The aim has been to collect information and data on various phases of feedwater treatment and allied subjects with the ultimate view of perfecting the art. The importance of such work must be apparent to all engineers who are faced with the necessity of producing an adequate and satisfactory supply of water for power-plant uses. This rapidly changing art requires continued study since new factors are constantly being injected into this phase of engineering which requires readjustment of operating methods. Under the existing conditions the art of water treatment for industrial uses has become an exact science and water is now generally classified as an important engineering material.

Although considerable apathy exists in the engineering profession on certain phases of this problem there has been manifested in general a keen interest in the work of these committees, not only in this country but among engineers in Great Britain, Europe, and the far East.

Considerable effort has been given during the year to the accumulation of a fund for carrying on research work necessary for more exact knowledge of fundamentals of the physics and chemistry of water treatment and allied problems. There has been contributed to this fund by various persons or companies interested in the work $3000. In addition to this sum, $20,000 a year for a five-year period will be available when the full budget has been raised. The release of this contribution is contingent on the availability of the full budget required for the entire research program of $60,000 annually for a five-year period. One of the larger engineering associations has under consideration at the present a contribution of $30,000 a year for five years.

No active research work is planned until the entire fund is available since the successful promotion of the work must depend upon an uninterrupted program which cannot be assured without assured financial assistance. It is the earnest desire that the program may be undertaken early in 1929 so that a full year's work may be reported next year.

Committees on filtration, corrosion, water softening by chemicals, evaporators and condensers, and embrittlement have

reported progress, but no formal reports are available from these groups this year. Committee No. 8 on water analysis has prepared a tentative method for analyses for the determination of dissolved oxygen. This method is now being employed in a large number of steam stations as a result of cooperative effort between this committee and the Chemists' Committee of the Prime Movers Committee of the National Electric Light Association. A similar coordination is maintained with the American Water Works Association which is responsible jointly with the American Public Health Association for the last edition of the Standard Methods of Water and Sewage Analysis. It is the desire of Committee No. 8 to develop a complete set of standard methods of analysis application for power-plant use.

The successful fulfilment of this program will be an invaluable contribution to the art since there is now no uniformity in methods of analysis or in reporting of results. It is the purpose of the committee to utilize the present standard of water analysis as a basis and to modify or develop new methods as may be desirable to fulfil the specific requirements in power-plant practice.

Attention is directed to the report of the committee on trade-waste disposal as it affects the quality of water used in steam stations. The importance of this report may not be fully realized except by those who have experienced heavy financial losses as a result of exaggerated cases of gross pollution of their water source. The apparent failure to recognize the importance of this matter is accountable only by lack of knowledge of the degree of pollution which may be translated into specific financial losses. Complete solution of these problems is not always apparent and frequently requires extensive research which may be relatively costly. In most instances, as has been shown by the committee's reports, this procedure is warranted. The recommendations of the committee concerning these problems are important and if adopted by the profession should prove effective in improving the quality of water used in many sections of the country which are now grossly contaminated.

Constructive work has been done by Committee No. 9. This committee has prepared for publication during the year eight series of bibliographies including 244 articles or papers on water treatment for industrial uses or allied problems. These abstracts have been published in the *Journal* of the American Water Works Association, the abstract journal of the American Chemical Society, and elsewhere. This work is a valuable contribution to the profession since it has made available for ready reference current literature on the subject from widely diversified sources.

There were presented at the San Francisco convention of the American Water Works Association in June of this year six papers on problems relating to boiler-feedwater treatment and surface-condenser operation. The papers were not committee reports but were secured as contributions by the committee's activity. These papers have been published or will be published in the journals or proceedings of the associations affiliated in this work. The previous reports of this committee have directed attention to the necessity for constructive research on numerous problems encountered in steam-station practice in the maintenance of an adequate and satisfactory water supply. The past year has completely confirmed this opinion. There is an increasing tendency toward higher steam pressures and temperatures and the introduction of many new problems, the solution of which may not be solved without fundamental knowledge on the subject.

Although progress in these studies has not been as rapid as desired, constructive work has been done. The most important accomplishment has been the lessening of duplication of effort which in the past has been a gross waste of time and energy. There has resulted a unified purpose and a more intelligent interpretation of the various phases of feedwater treatment than was formerly possible. In addition to these conditions much good has been accomplished by merely directing attention to the economic importance of these problems in the operation and maintenance of steam generation and equipment.

Zeolite Softeners, Internal Treatment, Priming and Foaming

Progress Report of Sub-Committee No. 3 on Zeolite Softeners, Internal Treatment, Priming, and Foaming[2]

By C. W. FOULK, COLUMBUS, OHIO, CHAIRMAN

[2] The personnel of Sub-Committee No. 3 on Zeolite Softeners, Internal Treatment, Priming, and Foaming, of the Joint Research Committee on Boiler-Feedwater Studies is as follows:

Prof. C. W. Foulk, *Chairman*, Analytical Chemistry, The Ohio State University, Columbus, Ohio.

Samuel B. Applebaum, Assistant Technical Manager, The Permutit Company, 440 Fourth Avenue, New York, N. Y.

Dr. Edward Bartow, State University of Iowa, Iowa City, Iowa.

A. S. Behrman, International Filter Company, 333 West 25th Place, Chicago, Ill.

Dr. A. M. Buswell, Director, Water Survey, Urbana, Ill.

R. E. Coughlan, Chicago & Northwestern Railroad, Chicago, Ill.

Prof. D. J. Demorest, Department of Metallurgy, The Ohio State University, Columbus, Ohio.

Dudley K. French, Chemical Director, Dearborn Chemical Company, 310 S. Michigan Ave., Chicago, Ill.

Vincent M. Frost, Assistant to General Superintendent of Generation, Public Service Gas and Electric Co., 80 Park Place, Newark, N. J.

Dr. R. E. Greenfield, Staley Manufacturing Co., Decatur, Ill.

E. Mandel, Commonwealth Edison Co., 22nd and Fisk Streets, Chicago, Ill.

Prof. H. L. Olin, Department of Chemistry, The State University of Iowa, Iowa City, Iowa.

Prof. O. R. Sweeney, Chemical Engineering Department, Iowa State College, Ames, Iowa.

C. P. Van Gundy, Engineer of Tests, Baltimore & Ohio Railroad, Baltimore, Md.

THE report of this Committee published in 1926 outlined the present state of our knowledge of foaming and priming and indicated the general lines of research that should be followed in the investigation of this subject. Last year's report[3] reviewed two important papers on foaming and priming and advanced a working hypothesis of foam formation to serve at least as a tentative guide in investigation. During the last year this hypothesis has been used at the Ohio State University in an extended experimental study of film formation[4] in water solutions. This study was completed too late to be written up at this time. It can be said, however, that the hypothesis presented in last year's report has proved of value in research and may now perhaps be raised to the dignity of a general theory of

[3] Trans., A.S.M.E., vol. 50, no. 15, May–August, 1928, Paper No. FSP-50-46.

[4] Doctor's dissertation by V. L. Hansley.

film formation. It should nevertheless be emphasized at this point that laboratory experiments in glass vessels cannot solve the industrial problems of boiler-water chemistry, however important they may be in suggesting general principles. Experimental and full-size boilers must be used before decisive results are reached.

The Committee has as yet made no reports on those topics other than foaming and priming that have been assigned to it, namely, the internal treatment of boiler water and the use of zeolite-softened water. These topics have nevertheless been under consideration and it is hoped that during the next year reports on the present state of the art of these two subjects can be prepared. It should also be stated that a topic closely allied to boiler-water subjects has been taken on by Committee No. 3, namely, the art of steam purification.

Future Work of the Committee

The Committee has two possible futures, one to continue as best it may without funds for research and the other, the happy contingency of having such funds at its disposal. In the first situation little or nothing can be expected beyond the preparation of reports setting forth the present-day knowledge of the topics assigned to it. This is a slavish and somewhat thankless task for busy men to perform but nevertheless we shall do the best we can. When, however, funds become available for the building of experimental boilers and for experimental work with commercial boilers, we suggest the following as important points of attack:

1 Comprehensive boiler experiments on the causes and prevention of wet steam

2 Comprehensive boiler experiments on ways of preventing the adherence of scale.

Topic No. 1 is seen to be a general statement of the problem of foaming and priming. Topic No. 2 is, however, but one of the subdivisions of the broader subject of internal treatment. It is suggested as the most important one for the first attack on the problem.

Committee No. 3 has frankly been waiting the completion of the financial program because there is little or nothing that can be done without money for equipment and technical assistance in carrying on experimental work.

Municipal Water Supplies and the Effect of Trade Wastes in Relation to the Use of Water in Power-Plant Practice

Progress Report of Sub-Committee No. 7 on Municipal Water Supply in Relation to Boiler Use[5]

By V. BERNARD SIEMS, NEW YORK, N. Y., CHAIRMAN

IN THE two former reports prepared by this Committee attention has been directed to the important effects of trade-waste pollution upon the quality of water employed for boiler-feed use and for cooling water in surface condensers. During the past year data have been accumulated on this subject which clearly indicate the growing importance of these problems. There are a large number of contributing factors to pollution of this kind but all of them may be classified under the following general headings:

(*a*) Acid wastes and salts which are converted into acid under the influence of heat

(*b*) Strong alkaline wastes

(*c*) Waste liquors high in organic solids, especially volatile organic material

(*d*) Liquids containing relatively large amounts of suspended solids, either mineral or organic.

The detrimental effect of these by-products is resulting annually in heavy financial losses due principally to corrosion and to increased maintenance and operation of boilers, condensers, and appurtenances.

A number of state and governmental agencies are actively engaged in attempting to reduce the pollution now discharged into surface streams, but such activity is confined almost exclusively to the health aspect of the problem with little or no consideration to the suitability of the supplies from the viewpoint of the industrial user. In the majority of cases, control of trade-waste pollution for sanitary reasons will improve the quality of the water for industrial use. The problems are not, however, strictly analogous and the desired result from the viewpoint of the industrial user may not be reached unless special consideration is given to these requirements.

The following specific feedwater problem and condenser operation difficulties encountered in steam-station practice have been brought to the Committee's attention:

(*a*) Active corrosion of superheater tubes resulting from high CO_2 and volatile corrosive organic solids due to direct trade-waste pollution of surface streams above the intakes of power houses

(*b*) Operating troubles in keeping surface-condenser tubes clean due to oil deposits, especially in the presence of suspended solids

(*c*) Trouble from prolific growths of algae and similar microorganisms resulting from organic trade waste, seriously affecting the efficiency of water purification apparatus and condensers.

[5] The personnel of Sub-Committee No. 7 on Municipal Water Supply in Relation to Boiler Use, of the Joint Research Committee on Boiler-Feedwater Studies is as follows:

V. Bernard Siems, *Chairman*, Vice-President and Chief Engineer, North American Water Works Corporation, 11 Broadway, New York, N. Y.

A. J. Authenreith, Vice-President, Middle West Utilities Company, Chicago, Ill.

James H. Buell, Middle West Utilities Company, Suite 1500, Edison Building, 72 West Adams Street, Chicago, Ill.

W. D. Collins, United States Geological Survey, Washington, D. C.

Charles Fox, Assistant Superintendent, Pennsylvania Water Company, Wilkinsburg, Pa.

Nicholas S. Hill, Jr., Consulting Engineer, 112 East 19th Street, New York, N. Y.

A number of important studies have been inaugurated during the past year which give promise of success in controlling the contamination of many of the more grossly polluted surface streams. Cooperation of the industries responsible for the pollution with state and Federal authorities appears to have accomplished the best results This plan of attack has a marked advantage over dogmatic legislative enactment of remedial laws.

At the present time the states of Ohio, Pennsylvania, West Virginia, Kentucky, Maryland, and New York are bound together in an agreement of uniform policies concerning interstate stream conservation. A number of other states may shortly join this group. Exhaustive studies carried on at the Wisconsin and Maryland State Departments of Health during the year have offered a number of solutions to specific trade-waste problems, including wastes from paper mills and canneries, acid wastes from steel mills, starch wastes, and other industrial by-products.

The states of Ohio, Pennsylvania, New York, Maryland, Massachusetts, Illinois, and Wisconsin have been particularly active during the past year in attempting to control the number of trade-waste nuisances. The nature and magnitude of the undertaking preclude any hope of complete success for many years to come but continued gross pollution may be eliminated by such cooperative effort.

The Fox Valley Federation is an interesting organization formed in 1923 with the ultimate object to provide pure water, to end organic-waste pollution, to regulate and control stream flow, and to restore recreation areas. This federation put through the general legislative statute providing for the organization of a conservancy district. Similar organizations, if properly set up for the specific purpose of eliminating pollution detrimental to industrial use of water, offer promise of a practical solution for the protection of surface water courses.

Much attention has been given to oil pollution of streams in the Middle West oil fields and oil refineries discharging wastes into the streams on the Atlantic seaboard. This problem is a perplexing one because of the difficulty of adequately treating these liquors and the large volume of the wastes to be purified.

There are no general methods of trade-waste treatment owing to the diversity of the problem and the variety and complexities of the constituents in the polluting liquid. Each case must be considered as an independent research study. Considered broadly, the most difficult problems to be encountered are those which involve the disposal of organic solids which are volatile under the influence of heat. Although adequate treatment of many of these trade wastes is possible, the cost of treatment is prohibitive or at least is so considered by those who have not given sufficient study to effective methods of disposal.

The most outstanding fact that has been brought to light in the Committee's work is the revelation that in practically all trade-waste problems that have been intelligently studied there has resulted a marked financial saving due either to the recovery of valuable by-products or to reduction in the cost of plant operation from better control of the processes contributing to the stream pollution. As a graphic example of this condition two cases may be quoted which have come to the Committee's attention. There has resulted in one small steel mill a net annual saving of $25,000 in pickling acid, resulting directly from better control of the pickling process in an attempt to reduce stream pollution by pickling-liquor wastes into a small surface stream. Still further reductions are expected at this plant. The company has now decided to carry on a constructive research program to eliminate completely these by-products by conversion into valuable materials.

A more impressive example is the success obtained in a cooperative study of wastes from a group of mills. This has resulted in an annual saving of over three million dollars in the treatment of their liquors. This particular problem has in the past been considered an unsolvable one which for many years has caused gross pollution of many surface water streams.

A number of tannery-waste testing stations have been established throughout the country and a number of treatment plants have been built and operated with a fair degree of success. Tannery wastes are objectionable when present in boiler-feedwater supplies and in water which is to be employed as circulating water in surface condensers. Gross pollution of streams from such wastes should be controlled, especially since methods for control are now available.

Packing-plant wastes, although not an important problem over wide areas, is a highly important one in restricted sections of the country. These by-products are highly objectionable from the standpoint of boiler-feedwater use. The grease and other organic solids are removed with difficulty and small amounts of grease remaining in the water after treatment cause serious operating difficulties, especially from the effect of these products in promoting priming and foaming and from corrosion resulting from their decomposition.

Much study has been given recently to the control of pollution from milk-product wastes. These wastes may be adequately treated by chemical precipitation followed by tank treatment and filtration. Cannery wastes such as these contain a high organic content highly objectionable when discharging into streams which are used as a source of supply for power-house use. The treatment of these wastes, although somewhat difficult, is feasible, and pollution of this kind should be given careful consideration by power-house operators, since the products, especially when decomposed, are highly objectionable from the organic matter and acid produced.

Gas-house wastes and wastes of a similar kind are difficult to control but the liquids when present in feedwater supplies are highly objectionable and make adequate purification difficult. It is the hope of the committee to collect and correlate data on trade-waste treatment of this and other by-products during the ensuing year.

The Committee has been impressed with the fact that heavy financial losses are being sustained in power-plant operation due to diversity of trade-waste pollution of surface-water courses, and there is little hope for immediate relief without the concerted interest of the industry in the intelligent and cooperative study of these problems.

The Committee presents the following specific recommendations for control of the problem:

1 Cooperation with state and Federal bureaus in intelligent study, leading to constructive legislative enactment for general stream-pollution control
2 Collection and interpretation of steam-station records to determine the effect of trade-waste pollution on the cost and operation of boilers, condensers, and allied equipment
3 Cooperative study by steam-station operators of surface water in areas grossly contaminated, to allocate the source and degree of trade-waste pollution
4 Distribution of scientific literature on trade-waste control to industries responsible for such pollution
5 Enlisting the interest and cooperation of industries contributing to the pollution of surface water.

Standard Methods of Water Analysis

Progress Report of Sub-Committee No. 8 on Standardization of Water Analysis[6]

By HAROLD FARMER, PHILADELPHIA, PA., CHAIRMAN

DURING the past year the Committee on Standard Methods of Water Analysis has devoted its efforts to a satisfactory test for dissolved oxygen in boiler feedwater.

The Committee presents the following method as a *tentative method* for trial and criticism by the various industries represented by the joint societies.

The method as it is here presented has been accepted by the N.E.L.A. Chemists' Committee as a tentative method of that group, and at the present time is in daily use in the majority of the large power plants.

Reports from the power plants indicate that the tentative method is very satisfactory. This is of considerable interest because the set-up in a modern power plant is such that any erroneous results would be readily apparent. The Committee, therefore, feels that the use of this method by the N.E.L.A. group will furnish some valuable information.

It was the early object of this Committee to indicate or develop a test that would be satisfactory for water-works practice, railroads, power stations, and other uses. It may be that a universal test is not possible; however, only general use of the tentative test by the interested groups will indicate the limits and possibilities of the proposed test.

The Committee has received some criticisms of the proposed method. These are chiefly relative to the reagents employed and the reactions involved. One objection to the method is here cited because it illustrates the need for further research on this subject:

"Objection to the use of manganese chloride and sulphuric acid or to hydrochloric acid, on account of the danger of introducing *free chlorine* which liberates *iodine*."

Such being the case it would appear to be more desirable to employ manganese sulphate and sulphuric acid. On the other hand, we have considerable evidence to show that operators using hydrochloric acid and manganese sulphate, or manganese chloride and sulphuric acid have no difficulty in obtaining *zero oxygen*.

The objection here raised is of considerable interest and shows the necessity for some extensive research work before any *standard* for dissolved oxygen in water can be acceptable.

In the absence of any standard test for dissolved oxygen in boiler feedwater we recommend that the tentative method herein described in detail be given general use wherever possible.

CHEMICAL REACTIONS INVOLVED IN THE WINKLER METHOD

(1)	$MnCl_2 + 2\ KOH$	=	$Mn(OH)_2 + 2\ KCl$
	manganous chloride + potassium hydroxide		manganous hydroxide + potassium chloride
(2)	$2\ Mn(OH)_2 + O_2$	=	$2\ H_2MnO_3$
	manganous hydroxide + oxygen		manganous acid
(3)	$2\ KCl + H_2SO_4$	=	$K_2SO_4 + 2\ HCl$

PROF. O. R. SWEENEY, Chemical Engineering Department, The Iowa State College, Ames, Iowa.

Tentative Method for Determination of Dissolved Oxygen in Boiler Feedwater

SCOPE

The presence of dissolved oxygen in water used for boiler feed is objectionable, since it increases the corrosive properties of the water. It is essential in steam-station operation that the dissolved oxygen content of the feedwater be kept as low as possible. In order to control the dissolved oxygen, tests should be made at frequent intervals.

APPLICATION OF TEST

The application of the Winkler method, herein described in detail, is intended for use on all boiler feedwater supplies except raw water.

If organic matter, nitrites, or iron salts are present in appre-

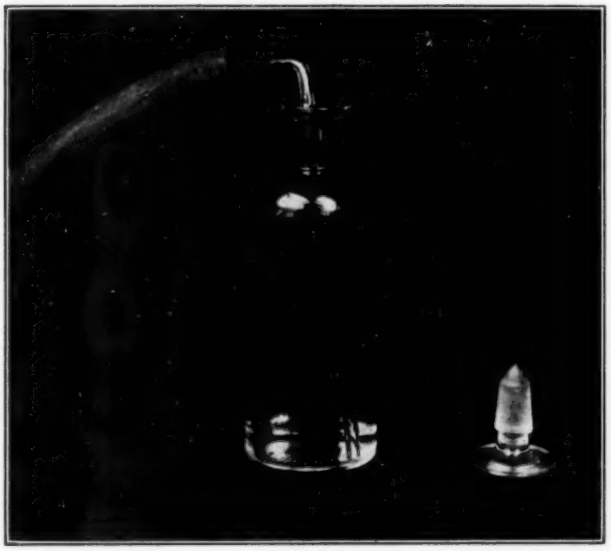

FIG. 1 SET-UP OF BOTTLE FOR COLLECTING WATER SAMPLES FOR DISSOLVED OXYGEN SHOWING STOPPER GROUND TO POINT

FIG. 2 SAMPLE OF WATER BEFORE TREATMENT WITH REAGENTS TO FIX DISSOLVED OXYGEN SHOWING PIPETTES FOR REAGENT ADDITIONS

ciable amounts, the Rideal-Stewart method (appearing in "Standard Methods of Water Analysis," A.P.H.A., 6th edition, 1925) should be applied.

After further investigation it may be possible to indicate the permissible amounts of organic matter, nitrites, or iron salts under which the method outlined may be employed.

WINKLER METHOD FOR DETERMINING DISSOLVED OXYGEN

The Winkler iodimetric method depends upon the liberation in the solution of an amount of iodine exactly proportional to the amount of oxygen dissolved. Chemically, it amounts to the oxidation of the manganous-chloride solution to manganic acid by the oxygen present, and a subsequent reduction of iodide by the manganic acid. The starch indicator indicates the presence of iodine, and the standardized solution of sodium thiosulphate has a definite iodine absorbing value. The calculations by the formula are in terms of oxygen, but the intermediate steps are computed in terms of iodine.

The chemical reactions are given on page 6.

REAGENTS

1 *Manganous Chloride.* Dissolve 425.5 grams of crystalline manganous chloride c.p. ($4H_2O$) in 1000 cc. of distilled water.

2 *Alkaline Potassium Iodide.* 700 grams of potassium hydroxide c.p. and 150 grams of potassium iodide c.p. are dissolved separately in distilled water and the mixture diluted to 1000 cc.

3 *Sulphuric Acid.* Equal volumes of c.p. concentrated acid (sp. gr. 1.84) and distilled water.

4 *Starch Solution.* Dissolve 5 grams of Litners soluble starch

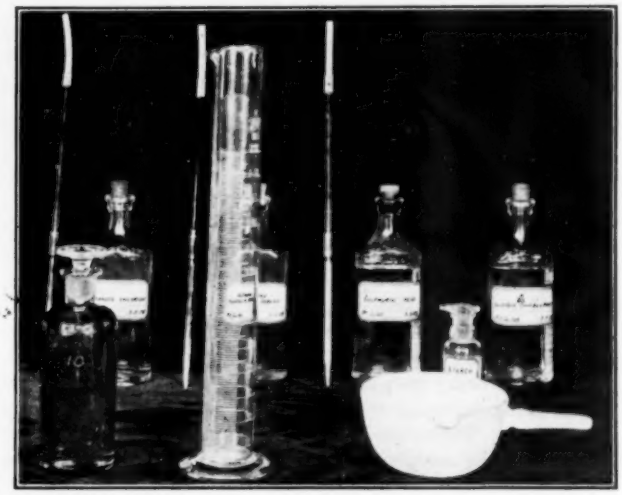

FIG. 3 SHOWING SAMPLE OF WATER AFTER REAGENTS HAVE BEEN ADDED TO FIX DISSOLVED OXYGEN AND APPARATUS AFTER MEASURING OUT NECESSARY VOLUME FOR THE TEST

FIG. 4 SAMPLE TRANSFERRED TO CASSEROLE SHOWING APPARATUS AFTER ADDITION OF REAGENT TO ESTIMATE DISSOLVED OXYGEN

in 50 cc. of distilled water to make a thin paste and then pour into 200 cc. of boiling distilled water and continue boiling for 4 or 5 min. When cold add a few drops of chloroform and keep this solution in a dark glass-stoppered bottle. Starch solution does not keep well and should be made up fresh every week.

5 *Sodium Thiosulphate: 0.025 N Solution.* Dissolve 6.205 grams of chemically pure recrystallized sodium thiosulphate in distilled water and dilute the solution to 1000 cc. with freshly boiled and cooled distilled water. Each cc. is equivalent to 0.2 mg. of oxygen or to 0.1395 cc. of oxygen at 0 deg. cent. and 760 mm. pressure. Inasmuch as this solution is not permanent it should be standardized weekly against a 0.025 N solution of potassium dichromate or 0.025 N solution of potassium permanganate. If special investigations are being made the thiosulphate should be calibrated daily.

Note: When facilities for the preparation of the above reagents are not available they can be purchased from any reliable chemical supply house.

Collection of Sample

Water supplied in excess of 125 deg. fahr. and above atmospheric pressure shall be cooled through a copper coil condenser, throttled at the discharge end, to room temperature.

A narrow-necked glass-stoppered bottle of 250 to 300 cc. capacity is satisfactory. To the end of the sample connection, attach by means of heavy-walled rubber hose, a glass tube, which will permit filling the bottle by displacement of the air and water by overflowing. The minimum rate of filling should be 250 cc. per 30 sec. and the sample bottle should be permitted to overflow not less than 5 min. This procedure insures the complete removal of air in the bottle and subsequent solution in the water of such air. Make certain that the sample line from the source of sampling to the bottle has been freed of air bubbles and deposits by a strong flushing of the line. After the water has been displaced in the specified time, the glass tube admitting the water is removed and the glass stopper quickly inserted in place to prevent exposure of the sample to air. Make certain that no air space is left between the stopper and water. The glass stopper should be ground to a point or cone to eliminate trapping of air.

The next step of adding the reagents should proceed immediately.

Adding the Reagents

Remove the stopper from the sample bottle and add immediately 2 cc. of manganous chloride and 2 cc. of alkaline potassium iodide in the order mentioned and quickly replace the stopper. The pipettes used to deliver these reagents should extend to the bottom of the bottle and the additions made in sequence with individual pipettes should be rapid. A short length of rubber tubing should be attached to the upper end of the pipettes to reduce the possibility of drawing the solution into the mouth. Do not expel solution by breath.

After the addition of the alkaline potassium iodide, replace the stopper, mix by shaking, and *permit the precipitate to settle.* Then add 2 cc. of sulphuric acid and mix by shaking.

The procedure to this point must be carried out in the field, but after the acid has been added and the stopper replaced the rest of the test shall be performed as soon as convenient, preferably within one hour.

Titrating the Sample

Measure 250 cc. of the sample and transfer to a 300-cc. porcelain casserole. (The entire sample may be conveniently transferred and titrated if the volumes of the sample bottles are previously determined.)

Titrate the sample with 0.025 N sodium thiosulphate until the solution becomes a pale yellow color, then add 3 cc. of the starch solution and titrate until the first disappearance of the blue color.

If the sample contains oxygen in excess of 0.5 cc. per liter the water will have a decided yellow color.

If zero or only traces of oxygen, the water will not appear yellow. The starch solution should then be added and if any blue color appears thiosulphate should be added until the blue color disappears. The difference between the initial and final

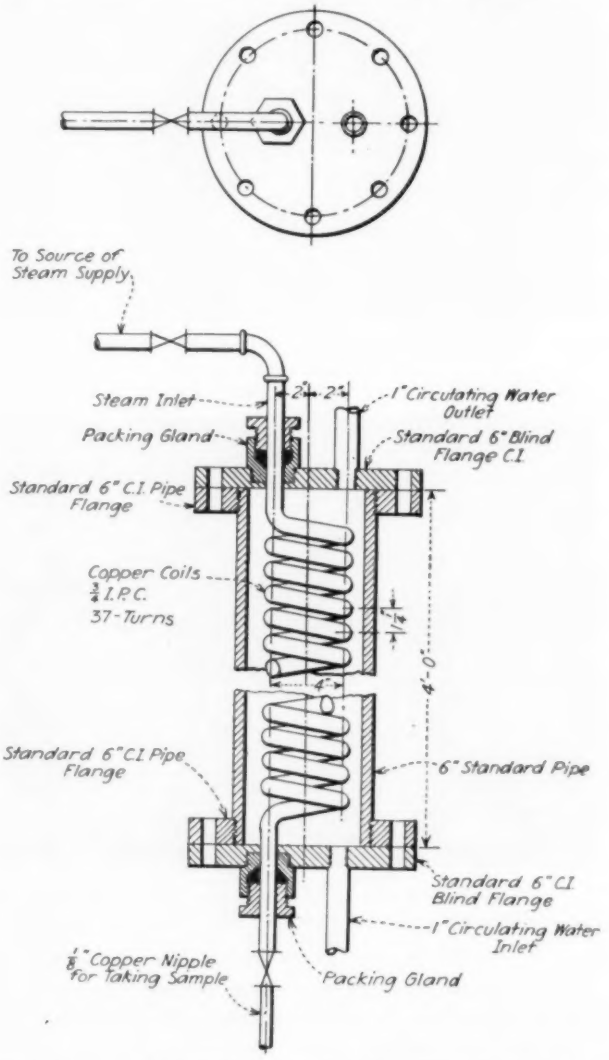

Fig. 5 Sketch of Cooling Coil for Dissolved Oxygen Test

readings of the burette will be the number of cubic centimeters of thiosulphate used, which is proportional to the amount of oxygen present.

Calculations

If 250 cc. of water were titrated the calculations will be as follows:

$$\frac{1000}{250} \times (\text{cc. of 0.025 N Thio.} \times 0.1395)$$

Apparatus

= cubic centimeters of oxygen per liter standard condition (0 deg. cent. and 760 mm.). Express individual results to the second decimal place. Report values below 0.03 cc. as "trace."

NOTES WHEN MAKING THIS DETERMINATION

1 When the manganous chloride and alkaline potassium iodide are added a white precipitate will be noticed (manganese hydroxide).

2 If oxygen is present a brown-colored precipitate will be noticed which is manganous acid depending upon the amount of oxygen present.

3 The addition of the sulphuric acid dissolves the brown precipitate and sets free an amount of iodine equivalent to the quantity of oxygen in the sample.

4 The solution at this time will be yellow in color; the depth of color depending upon the amount of oxygen present.

5 If oxygen is present and starch is added to the solution at this stage the color will change to a deep green or blue color depending upon the amount of iodine (oxygen) present.

TOLERANCE

With care, the above procedure will give reproducible results as low as 0.03 cc. of oxygen per liter.

The illustrations in Figs. 1 to 4 show the apparatus and steps in the operation. An itemized specification of the apparatus follows. Sufficient construction details for making the cooling coil are shown in Fig. 5.

1 Copper cooling coil.

2 Rubber tubing, heavy wall, 1/4-in. bore, 1/8-in. wall.

3 Flint-glass bottles, narrow mouth with mushroom glass stopper ground to a point. Capacity 8 ounces for collecting samples.

4 Flint-glass bottles, narrow mouth for rubber stoppers, capacity 8 ounces for reagents. (The number of sample bottles required is optional depending on the number of sampling points in the station.)

5 One bottle dropping TK type, flat glass stopper, 125 ml. capacity, for starch solution.

6 One glass cylinder, heavy base, and lip for pouring, capacity 250 ml., subdivisions 2 ml.

7 One casserole, porcelain, glazed both sides, flat bottom pour out, and porcelain handle, capacity 375 ml. Size No. 4.

8 One burette with straight glass stopcock, capacity 10 ml., subdivision 0.05 ml.

9 One apparatus support, rectangular base 4 × 6 in., length of rod 18 in.

10 One universal burette clamp, rubber-covered jaws.

11 Four pipettes, transfer type, bulb in center, graduated to deliver 2 ml. fitted with 2 in. of pure gum-rubber tubing.

Bibliography

Report of Sub-Committee No. 9 on Bibliography[7]

BY GEORGE A. STETSON, NEW YORK, N. Y., CHAIRMAN

[7] The personnel of Sub-Committee No. 9 on Bibiliography of the Joint Research Committee on Boiler-Feedwater Studies is as follows:
GEORGE A. STETSON, *Chairman*, Associate Editor, The American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y.
DR. EDWARD BARTOW, The State University of Iowa, Iowa City, Iowa.
A. S. BEHRMAN, International Filter Company, 333 West 25th Street, Chicago, Ill.
DR. A. M. BUSWELL, Director, Water Survey, Urbana, Ill.
FRANK HANNAN, Chemist, Filtration Plant, 285 Willow Ave., Toronto, Ontario, Canada.
CLARENCE R. KNOWLES, Superintendent of Water Service, Illinois Central Railroad, 135 East 11th Place, Chicago, Ill.
PHILIP W. SWAIN, Managing Editor, *Power*, McGraw-Hill Publishing Company, 10th Ave. and 36th Street, New York, N. Y.

THE extension of the Engineering Index Service has made possible more frequent publication of the bibliographies issued by the Committee. The chairman receives daily from the Engineering Index Service every indexed item pertaining to subjects of interest to the technical committees and from time to time items from *Chemical Abstracts* which are furnished by Dr. A. M. Buswell.

Up to October 1, 1928, there had been issued 13 of these bibliographies containing a total of 368 items. Since last year's report 8 bibliographies containing 244 items have been issued.

The Committee expects to continue the service during the coming year and will be grateful for any suggestions as to means by which its usefulness can be increased.

Discussion

SAMUEL B. APPLEBAUM.[8] One of the subjects that Committee No. 3 handles is zeolites. A sub-committee has been formed for that purpose, and as chairman of that sub-committee I wrote a report which was confined to a statement of what is known about zeolite water softening, as used in the industry today. But in addition to the work of designing, installing, and operating water-softening plants, there is a great deal of work that may be done of a research nature to find the theoretical explanations for some of the practical results that have been empirically obtained. This work belongs, more or less, in the field of pure research which the committee is anxious to do with the assistance of university men when the financial facilities are at hand.

For example, from a practical point of view we know what causes a boiler to foam and what steps should be taken to stop a boiler from foaming, but theoretically the explanation as to the fundamental cause of foaming has not yet been worked out, and research work on this subject may result in an entirely new point of view which may be of great help to the practical boiler operator. A boiler operator knows that to prevent foaming he must keep oil out of his boiler, he must keep the concentration of soluble solids down, and he must keep the water in the boiler free from suspended matter. But the influence that various salts may have, such as sodium sulphate, sodium carbonate, or calcium salts, and the influence of other similar factors can best be determined in a research laboratory.

Frequently pure scientific research results in disclosing factors of a very novel nature which open up a new field of application. As an illustration of this, the origin of zeolites for water softening may be mentioned. A professor in a college was engaged in research work in agricultural chemistry and developed a synthetic zeolite to prove his theory as to the reasons for the different behavior of various soils. From this purely scientific work the application of zeolites to water treatment developed and resulted in an entirely new method of softening water. Thus, though one starts far away from a practical result, pure scientific research may result in a very practical suggestion.

[8] Technical Manager, The Permutit Company, New York, N. Y. Assoc-Mem. A.S.M.E.

However, in the experience of the average commercial company manufacturing water-treatment apparatus, new problems do arise from time to time, which makes this field of water treatment so intensely interesting. As an illustration, the use of natural impure brine for the regeneration of zeolites may be mentioned. This problem was presented to us not long ago by an oil company out West which had such impure brine available, because oil wells do contain brine in various stages of their development. The problem presented was whether such brine could be used to regenerate zeolites. It has been the practice, in offering zeolite apparatus, to specify pure salt; that it, containing not less than 98 per cent sodium chloride. The brine from the oil wells contained considerable amounts of calcium and magnesium hardness, and the effect of such hardness on the regeneration had to be investigated. Large samples of brine were obtained and regeneration experiments conducted, and the design of the zeolite softener, together with the regeneration equipment, was based on these experiments. A large zeolite plant has been in use at this refinery since then, successfully operating with this impure brine for regeneration purposes. This experience has suggested a new field for the use of natural sea water for regenerating zeolites, because sea water has about the same amount of calcium and magnesium salts as the natural brine from the oil wells. We ran experiments with sea water for regeneration purposes, and on the basis of those experiments, we installed four large plants using sea water for that purpose. Wherever industrial plants are located along the Atlantic or Pacific coasts and where these plants can obtain strong sea water, not diluted by fresh river water, there is the possibility of using such sea water for regenerating zeolite plants, and thus the zeolite plants can function without any cost for chemicals.

Another problem which has been presented to manufacturers of water-treating equipment recently is the suggestion to increase the sulphate-carbonate ratio in waters used in boilers. This has required considerable experimentation to develop reliable acid feeds. Boiler operators are averse to using acid unless they can be shown that it can be fed with impunity. To do this, feeds of a dependable and accurate nature had to be designed and tested out, and the materials out of which these feeds were built had to be chosen to withstand the corrosive effects of acid, and means also had to be provided for insuring non-corrosion of the water system using the acid-treated water.

A successful method of accomplishing the latter result was worked out, and this method consists of returning a portion of the alkaline boiler blow-off water into the acid-treated feedwater stream. This is particularly practicable where the boilers are being blown off continuously and where a portion of the continuous blow-off stream may thus be conveniently diverted and pumped back into the outlet of the feedwater heater. Since the boiler blow-off water is concentrated and alkaline, a mixture of only a small amount of this water with the feedwater raises the pH value of the feedwater, so that considerable assurance is thus provided of the water being non-acid.

With the usual acid feed, the precaution should be taken of thorough mixture of the water with the acid so as to avoid streaks of acid passing through the feedwater system, and in addition means should be provided for aerating the water after acid treatment to rid it of the CO_2 which has formed by the reaction between the acid and the bicarbonates in the natural feedwater. Then in most boiler plants the aerated, acid-treated water is passed into an open heater where all the oxygen and free CO_2 is released by heating. At that point the small stream of alkaline blow-off water can be added, which raises the pH value and thus protects the feedwater system and economizers. The boilers themselves usually would not need such protection because there would be a storage of alkaline water in them.

With regard to the illustration showing a sketch of a cooling coil to cool hot water in which oxygen tests must be made, we have used a similar coil, but with a slight modification. Instead of using two stuffing glands, one at the top flange and the other at the lower flange, we have used an open piece of 8-in. pipe with a cap only at the bottom, and the inlet and outlet of the coil both pass out of the open top of the pipe. This has a further advantage in that the coil acts as a trap, so that if one is trying to condense steam to determine oxygen in the steam, a more complete dissolving of the gases as the steam condenses is insured.

While on the subject of oxygen testing I have a suggestion to make for a rapid qualitative method, which our laboratory has devised, of determining the absence of oxygen in feedwater. In this method the reagents are a mixture of pyrogallic and sulphuric acid and some potassium hydrate solution. These two reagents are added in succession, and if a brown coloration is obtained it indicates the presence of dissolved oxygen. If the water remains either colorless or with a slight violet or blue coloration, then the water is free of dissolved oxygen.

We had occasion to use this method in several plants where it was desired to remove oxygen by chemical means after the feedwater left the open heater. The ordinary open heater may leave a small amount of oxygen in the feedwater, ranging from several tenths of a cubic centimeter of oxygen per liter of water up to about 1 cubic centimeter per liter. Where steel tube economizers are employed these small amounts of oxygen may cause corrosion of the tubes. One of our clients asked whether they could remove this small amount of oxygen chemically, rather than install the apparatus on their open feedwater heater to permit the heater itself to remove this oxygen more completely. We accomplished this by feeding small amounts of sodium sulphite or sodium bisulphite, which, in the presence of suitable catalyzers, rapidly reacted with the oxygen and thus rendered the water oxygen-free.

The foregoing qualitative test was worked out to help the operators in these plants to determine quickly whether their chemical feeds are working properly, so as to be certain that the oxygen was completely removed from the water.

JOSEPH D. YODER.[9] The illustration given in the progress report of the Boiler-Feedwater Studies Committee shows a method of obtaining and condensing a sample of steam with a view of determining the oxygen in the steam, although the test refers only to determining the oxygen in water. The inference is that if steam is condensed and a sample collected in the manner shown by the diagram, the amount of oxygen originally in the steam can be accurately determined by analyzing the condensate for oxygen by the Winkler test.

Observations that our engineers have made in the field where such attempts were made to determine oxygen show that this method is not dependable, for the reason that the oxygen in the steam is disposed to bubble up through the condensate without being dissolved. The oxygen is not absorbed by the condensate nearly as rapidly as might be expected by the person not having actually made the attempt to determine the oxygen in this way. My opinion is that the method illustrated is worthless for the purpose of determining oxygen in steam.

HAROLD FARMER.[10] Mr. Yoder's statement that the sketch of the condensing coil shown in the report is presumably for steam whereas the method refers only to water needs explanation. The cooling coil is intended for use with hot water (above 125

[9] Manager, Water Purification Department, Cochrane Corporation, Philadelphia, Pa. Mem. A.S.M.E.

[10] Chief Chemist, Philadelphia Electric Company, Philadelphia, Pa.

deg. fahr.), and no mention is made of its use for sampling *steam* in the report.

Unfortunately the sketch, employed to illustrate only the principle of the cooling coil, was one which we had employed for steam, and there appears a note on the sketch "steam inlet." This should have been changed to read "source of hotwater supply."

JOSEPH D. YODER. In discussing the report of Committee No. 3 on zeolite softeners, I would say that it is unfortunate that Professor Foulk is not present to read his paper, for I have heard that his recent experiments are very interesting and valuable. A great deal should be accomplished by attacking the problem of foaming in a scientific and unprejudiced manner. The author has nothing to guide him as to the way in which he should go except a desire to find the truth. With this in mind I predict that his accomplishment will be well worth while.

The foresight of the chairman of the Executive Committee of the Joint Research Committee on Boiler-Feedwater Studies, Mr. Sheppard T. Powell, who is also absent, is commendable in that he has succeeded in holding together a large committee to give consideration to a number of subjects related to feedwater treatment. The broad scope of the work and the variety of subjects considered by the committee is an active example of the fact that feedwater treatment is not merely the simple problem of preventing scale in boilers. It covers much more.

It involves a genuine, complete, and adequate protection of the boiler metal. This demands the prevention of deposits that would interfere with the free exchange of heat from the metal to the water. It demands that the metal be protected from pitting and corrosion and calls for the maintenance of boiler-water conditions that guard against embrittlement of boiler plate. All of these problems must be properly solved and at the same time a condition of boiler water must be maintained that avoids priming and foaming and insures steam as dry as possible.

The subject of foaming and priming of boilers demands a healthy respect from every engineer in water purification. Its solution is difficult and complicated. There is a great variety of possible causes of foaming and priming, of which several are likely to be active at every plant.

In practice it is impossible to isolate the various factors which may cause foaming and priming, and therefore to properly evaluate each one. Possibly Professor Foulk in his laboratory will be able to do that by working with the individual factors, and then in learning the value and characteristics of each, he may be able to reconstruct the problem as a whole, and thus be able to predict with a fair degree of certainty whether under any given set of conditions the boilers will or will not prime, and if priming does occur, just what can be done to prevent it.

Some of the factors which have an important bearing on foaming and priming and to which Professor Foulk is undoubtedly giving his consideration are sodium salts, the suspended solids, organic matter, the rate of liberation of steam per given unit of water surface, uniformity of steam load, design of boiler, etc. Many of these factors come beyond the province of the water-purification engineer, as he can only be concerned with the improvement of water supply.

It must be assumed that the demand for steam will be made as uniform as possible, and likewise the firing. The factors with which the water-purification engineer is therefore chiefly concerned are the sodium salts, the suspended matter, and the organic solids, the effects of which must be observed in connection with the rates of steaming the boilers.

Among water-purification engineers there seem to be two schools; one places the emphasis chiefly on the suspended solids as the cause of foaming and priming and advocates that the sodium salts make relatively little difference providing the suspended solids are kept as low as is possible of attainment by various methods of water purification, and the other school takes the position that the foaming is caused almost entirely by the soluble salts and that the suspended matter is of comparative insignificance.

My opinion, based upon the observation of boilers operating at steaming rates varying from 30 lb. of steam per hour per 10 sq. ft. of heating surface or nominal boiler horsepower to more than 200 lb. per hour per 10 sq. ft. of heating surface, is that both the suspended solids and the solids in solution are important contributing factors to priming. Whether a given amount of suspended matter will cause more or less priming than the same quantity of sodium salts is a difficult question to decide.

It is obviously true that the goal for the water-purification engineer should be to prepare a water that will give the smallest quantity of sodium salts and suspended matter within the boiler, if consideration alone is to be given to the foaming and priming. The problem may be stated in another way, i.e., that if water is to be treated so as to protect the boilers from scale and corrosion, that method of treatment should be selected which will introduce the smallest quantity of mineral solids into the boiler in order that the boiler may deliver as dry steam as possible.

Many of the boilers now installed and operated at high ratings are supplied with distilled water, although there are also boilers operating at high rating evaporating more than 200 lb. of water per hour per 10 sq. ft. of heating surface which are fed with 100 per cent make-up water.

To my knowledge all of these boilers, which are necessarily equipped with water-cooled walls and screens, are fed with a water properly softened to reduce the amount of mineral solids to a minimum. If the water concentrates in the boiler to the extent that causes foaming or priming for the given rate at which it is desired to operate the boiler, it becomes necessary to blow it down and thus correspondingly dilute the water in the boiler with fresh water.

Whereas the greatly increased pressures and ratings placed upon boilers have made the task of feedwater treatment far more severe, the evidence is that the water-purification engineers have kept pace with the development of boiler design, so that if any industrial plant which is compelled to use chiefly make-up water finds it economical to install high-pressure boilers to operate at high ratings, it is entirely practical to treat the water so that a satisfactory quality of steam will be delivered at these ratings and at the same time to protect the tubes from scale.

To insure a satisfactory quality of steam it is commonly advisable to place a good-sized receiver separator or steam purifier between the steam drum and superheater so that any mineral solids which concentrate in the boiler and may be carried off as moisture in the steam will be removed before the steam enters the superheaters. Very efficient steam purifiers are now available for this work. Accordingly if the power-plant engineer takes the proper precautions for treatment of the feedwater and the purification of steam by the installation of such equipment as is now available, he can feel assured that his high-pressure high-ratings boilers may be successfully operated even though he has 100 per cent make-up water relatively high in mineral and scale-forming solids.

In discussing the report of Committee No. 8 on "Standard Methods of Water Analysis," the illustration given in this report shows a method of obtaining and condensing a sample of steam with a view of determining the oxygen in the steam, although the test refers only to determining the oxygen in water. The inference is that if steam is condensed and a sample collected in the manner shown by the diagram, the amount of oxygen origi-

nally in the steam can be accurately determined by analyzing the condensate for oxygen by the Winkler test.

Observations that our engineers have made in the field where such attempts were made to determine oxygen show that this method is not dependable, for the reason that the oxygen in the steam is disposed to bubble up through the condensate without being dissolved. The oxygen is not absorbed by the condensate nearly as rapidly as might be expected by the person not having actually made the attempt to determine the oxygen in this way. My opinion is that the method illustrated is worthless for the purpose of determining oxygen in steam.

R. E. Hall.[11] In discussing Professor Foulk's paper, permit me to present a few facts that pertain to boiling conditions in boilers.

First, I wish to emphasize the importance of the work Professor Foulk is doing in obtaining exact data in order to build a comprehensive theory. He speaks of the accumulation of existing data as a slavish task, and from personal experience I fully agree with him. But, also, the further work of choosing and inventing apparatus for obtaining new data and, with methods established, the routine of careful data taking are fully as slavish. If Professor Foulk can realize, however, how keenly we appreciate the results of his work, and how definitely they are needed as a guide in the problems confronting us, he will feel repaid, in part at least, for his effort.

I have read the thesis referred to in the footnote, and advise all of you to watch for its publication. I believe Professor Foulk has struck at the very root of this problem and has presented supporting data to prove his points. Even though funds are not available, let us hope that he will continue with the glass-boiler experiments and laboratory data which are largely directly applicable to operating practice.

Mr. Yoder has spoken of the influence of suspended matter on boiling conditions. Doubtless suspended matter is of influence, but let us consider two factors relating thereto, namely, its amount and its character.

In any well-operated boiler the suspended solids in the boiler water will not amount to more than 500 p.p.m., or as an extreme maximum, 1000 p.p.m., and usually very much less than the lower figure. On the other hand, concentrations of dissolved solids vary from a few to several thousand parts per million. As dissolved solids in general exercise greater influence on boiling conditions than suspended solids, the conclusion is unavoidable that, in an uncontaminated water, the effects of dissolved solids far outweigh those of suspended solids.

If however, contamination is present in the form of soaps, or of oil, adsorption thereof by the suspended material may and practically always does occur. This destroys homogeneity of distribution of the suspended material in the boiler water and gives rise to segregation thereof at the steam-separating surface because the particles are no longer easily and uniformly wetted by the boiler water. Under these conditions, with but a few parts per million of dissolved solids in the boiler water, very bad boiling conditions may obtain. Of course, the answer is stoppage of the contamination before its entry into the boiler water.

Two materials common to boiler water are of interest in connection with foaming qualities of the water. Hydroxide plays a multiplicity of roles. In low concentration, it is protective to the boiler metal; in higher concentration, it may deteriorate the metal. It saponifies any organic fat—for instance, that used in compounding a cylinder oil—thus forms soap, and thereby works havoc with boiling conditions.

In conjunction with calcium, however, hydroxide makes the water boil very much more smoothly than the same water would boil without the hydroxide. Likewise, if the calcium is removed, boiling conditions become much worse. These observations probably are an explanation why sodium carbonate has been considered a primary cause of foaming. It is doubtless the removal of calcium thereby that increases foaming rather than any intrinsic property of the sodium carbonate itself. Undertreated waters give better boiling conditions than fully treated waters, doubtless because of the calcium content of the former.

If to the components calcium and hydroxide in the boiler water we add one of the tannates, as cutch, or any one of the multitudinous forms in which it occurs, boiling conditions are still better. In the absence of saponified material, tremendous concentrations of dissolved and suspended materials may be present, and yet boiling conditions be practically equivalent to those of pure distilled water. If the calcium is removed, however, as by addition of sodium carbonate, tremendous foaming occurs.

The reason why these effects occur must be answered by work such as that of Professor Foulk. Unless that work can point the way, there is a definite limit to what can be done chemically. This is especially true in view of the trend to higher operating pressures, and the consequent more exact limitations on the boiler water. At those pressures, calcium cannot be tolerated, concentration of hydroxide must be extremely slight, and any organic substance as tannate more readily undergoes decomposition. Thus the chemist is limited to obtaining cleanliness of the boiler water, and to maintaining those concentrations best suited to protect the boiler metal. Other measures, protective to the quality of the steam, must be mechanical.

K. Von Eltz.[12] We all hope that Professor Foulk will be able to carry on the experiments regarding foaming and priming. It would seem very important that not only each salt is tested individually in these experiments, but also a number of salts together, because only tests made thus will represent the actual boiler-water conditions. Occasionally one finds a statement such as this: The boiler is able to carry so many thousand parts of sodium chloride, or sodium carbonate, or sodium sulphate. But it is not stated how high the concentration could be if any two or all three of these salts were together in the water.

In a recent publication in Germany there was given a number of allowable concentrations for different salts. It was also stated there that the correct thing to do would be to judge, not only each salt individually, but to judge a mixture of the different salts. The allowable concentrations were greater for the lower pressures. With increasing pressures the concentrations had to be reduced.

This is contrary to the general belief that with higher pressures the danger of foaming and priming was lessened. That is not true according to these figures, which show that the concentrations had to be kept lower with the higher pressures.

This seems very important, since nowadays the tendency is to go to extremely high boiler pressure, up to 1800 lb.

Dr. Hall's observation regarding calcium seems to be borne out by our own experience. In most of the water softeners built by my company, barium carbonate is used instead of soda ash, therefore no sodium salts are added to the water by the treatment. I can say that foaming is practically unknown in boilers using barium carbonate treated water, even in spite of the fact that in some cases the raw water contains over 22 grains per gallon of sodium chloride and a considerable amount of sodium sulphate, as much as 8 grains per gallon.

Here I should state that the sodium sulphate present in the raw water is not changed into soda ash, as it is generally believed. The reason therefore is that the reaction between barium car-

[11] Director, Hall Laboratories, Inc., Pittsburgh, Pa.

[12] Manager, Reisert Automatic Water Purifying Company, New York, N. Y. Mem. A.S.M.E.

bonate and sodium carbonate requires much time and agitation. Actually in our softeners the raw water is in contact with the barium carbonate only a short time, so that the before-mentioned reaction does not take place.

In not one of the cases mentioned, where a large amount of sodium sulphate is present in the raw water, has any sodium carbonate been found in the treated water.

Since with the barium carbonate treatment no sodium sulphate is formed, nor any free soda ash present in the treated water, boilers fed with such a water do not have the least tendency to foam even if worked at very high ratings.

Not long ago I had occasion to look over a boiler plant worked at 400-lb. pressure and having ratings up to 480 per cent. These boilers have no steam purifiers. At the time the boiler manufacturer made the test it was found that the maximum moisture in the steam going to the superheater was $^{3}/_{10}$ of 1 per cent.

Mr. Yoder mentioned that it should be the endeavor of water purification to have as little as possible of dissolved as well as solid matter in the treated water. Both requirements are met by the lime barium carbonate treatment.

DR. A. M. BUSWELL.[13] The method for the determination of dissolved oxygen as described by Mr. Farmer is essentially the same as the method adopted as a standard jointly by the American Public Health Association and the American Water Works Association. However, the American Public Health Association standard uses manganous sulphate, whereas the one described by the previous speaker uses manganous chloride. If it were possible to adopt the use of manganous sulphate in the determination of dissolved oxygen in boiler feedwater, we would then have essentially one standard method.

Unfortunately it is not possible for the American Public Health Association and American Water Works Association to change to the chloride, since we have found that the interference of certain substances, notably iron, is more serious when the chloride is used instead of the sulphate. (See Buswell and Gallaher, *Industrial and Engineering Chemistry*, 15, p. 1127; and Theriault, U. S. Public Health Bulletin 151.)

In writing the reactions for classes of engineering students the speaker has followed the plan of writing *KI* instead of *KCl* in Equation [3], thereby producing *HI*, which then reacts with the manganous acid in Equation [5], producing iodine instead of chlorine. This makes Equation [6] unnecessary. It would also seem possible to eliminate Equation [4], since it does not enter into the actual determination and merely represents the re-solution of any excess manganous hydroxide above that which is oxidized by the dissolved oxygen. This reduces the number of equations from seven to five.

HAROLD FARMER. Might I answer Dr. Buswell? So far as the use of manganous sulphate is concerned, I see no objection to that. The method as we have it here is a method which by common usage has become very nearly a standard of the utilities, and a survey showed that they were practically all using manganous chloride. We saw no reason why we should ask them to change their method until we had definite information that the same results could be obtained by using manganous sulphate. It would be very desirable if manganous sulphate could be employed, because then we would be right in line with the method of the American Public Health Association.

DR. FRANK E. HALE.[14] The following discussion is given at the request of Mr. Powell. The statements made are the result of a very wide experience in determination of dissolved oxygen, in salt water, in the polluted harbor waters about New York City, in thermocline studies in reservoirs in which the oxygen reduces to practically zero in the summer period at the bottom in contact with organic matter and also just below the thermocline where dead microscopic organisms collect, in condensed steam in heating system returns, and in corrosion tests with iron pipes, etc. Under these conditions oxygen has varied from complete absence to supersaturation, organic matter from little to large quantities, chlorides to that of ocean water, iron to many parts per million. Under all these conditions the method used has been that described in the 1912 edition of Standard Methods of Water Analysis of the American Public Health Association, including the reagents manganous sulphate and potassium hydrate and iodide, but concentrated hydrochloric acid has been used instead of 1 : 1 sulphuric acid. The reason for the use of hydrochloric acid is that sulphuric acid does not dissolve the manganese hydrate sufficiently quickly, and any undissolved oxide introduces an error.

It is my opinion that hydrochloric acid or chlorides do not interfere with the oxygen determination. Neither does ferric iron. How can iron interfere when it is possible to obtain oxygen values as low as 0.1 p.p.m. in water which has corroded iron pipe and contains 30 or 40 p.p.m. iron? The interfering effect of many substances has been overemphasized including organic matter, nitrite, etc. In the ordinary amounts found in water an error of 0.2 p.p.m. oxygen would not be exceeded, and yet it is recommended in present Standards Methods that correction is unnecessary for displacement of liquid by added reagents, which causes an error of 0.2 p.p.m. oxygen on 16 p.p.m. oxygen content, or 0.1 on 8 p.p.m. The ordinary Winkler method may be used on the great majority of waters without resorting to the permanganate–oxalate modification.

The proposed method specifies 700 grams of potassium hydroxide and 150 grams of potassium iodide, whereas the regular quantities, 360 and 100, respectively, have been found sufficient in all of our experience.

The proposed long pipettes with rubber bulbs seem to be an unnecessary and cumbersome refinement. In rapid work it is simpler to use short tubes, closing the top with the finger, and with two marks near the lower end measuring 2 cc. between them. It is only necessary to insert about 1 inch (up to lower mark) as the heavy solutions drop immediately to the bottom of the bottle. Also one precaution is not mentioned. These tubes should be rinsed on the outside under running water each time they are introduced into a bottle of water before inserting again into the reagent bottle, otherwise contamination and precipitation of manganese hydrate will result in the reagent bottles. The addition of this precipitate to the bottle will cause error.

With regard to starch solution one must guard against amidulin, a form of soluble starch giving blue with iodine, but readily oxidized by iodine to erythrodextrin. Such red end-points mean a loss of iodine. The formula we use and recommend is that of Gaston. Starting with as pure potato starch as possible to procure, rub to a thin paste with a small amount of cold water 5 grams of the starch mixed with 10 milligrams of mercuric iodide, pour into a liter of boiling water and boil for one-half hour. Allow to settle. The foregoing produces a stable starch emulsion for a considerable time.

Regarding the thiosulphate, dilute solutions do not keep well. We prefer to keep the stock as N/10 solution, which does keep well. N/100 is then made up as required. Correcting for displacement by the first two reagents added, a factor is used ranging from 0.811 to 0.813, depending on the size of bottle used.

Titrating 100 cc. instead of the entire bottle gives a chance for check in case of necessity.

[13] Chief, Illinois State Water Survey, Urbana, Ill.

[14] Director of Laboratories, New York Water Department, Bureau of Water Supply, Brooklyn, N. Y.

In the collection of the sample, the minimum rate of filling is given as 30 seconds and to overflow for 5 minutes. It would seem more important that the flow be quiet so as not to mix air and water and therefore not too rapid. Overflowing about one-half bottle in our experience has been found ample to remove the first water in contact with air and get results as low as 0.1 p.p.m. oxygen. Oxygen does not absorb in water very rapidly.

The question of replacing the stopper in the bottle was brought up in the discussion. It should be replaced after each reagent is added, as oxygen is absorbed from the air in the alkaline condition, i.e., after adding the second reagent. Also catalytic increase of iodine takes place in contact with air after the addition of the acid.

Also if the bottle has been filled with slightly warm water, on cooling, air may be sucked into the bottle and a bubble of air will cause error.

I should like to correct the statement that a grain per gallon of soda ash was used. The dosage was half a grain. There was no excess of soda ash in the water. It reacted with the permanent hardness and merely increased the alkalinity from 8 to 15 parts per million. The total hardness of the water was 17 parts per million.

DUDLEY K. FRENCH.[15] I am very glad to be able to support the comments of Mr. Hall with considerable confirmation, both from research and practical results.

I think I may say, literally, with regard to the opportunity of observing the results in using various chemicals with waters, that there are few people who have had the opportunity to observe such conditions with as many kinds of water over as long a period of time as I have.

This period covers between 20 and 25 years and involves results on all sorts of water from Canada to South America.

With regard to foaming, I think that not enough attention has been paid to the tannin extracts. They have properties which we do not yet understand thoroughly. It is perfectly true, from a standpoint of the number of foaming waters that we have treated, that probably less than one-half of the treatment that we supply is treatment containing saponifiable oils. There are a great many cases where tannins with or without coagulants meet the situation more satisfactorily; in fact, when using saponifiable oils and castor oil is the principal in this class, we think that there must be enough lime in the water in the boiler to make insoluble soaps out of the fatty acids before the other elements upon which we depend are made effective, and we have been able to demonstrate from the analysis of sludges blown from such boilers that calcium soap is formed.

Castor oil has eeveral substances in it that other vegetable oils do not have, and it is apparently an effect of the solution of some of these in the interfacial film between the water and the steam space that permits the dropping out of some of the suspended matter and increases the ease with which the steam bubbles go through.

Frankly, I believe that the tannins do more to the surface film than the ingredients from the oil. Furthermore, I think that we are apt to overlook other effects which can be brought about by these vegetable materials. There has been a great amount of data printed about tannins. Go to almost any text on water treatment and it states that tannins are objectionable because they act as acids upon the metal. Well, the tannins are rarely present in a boiler water where there is enough acid to permit such a condition. They are almost invariably present in an alkaline condition.

In so far as their action in controlling corrosion is concerned, I might state that our experience with reference to oxygen-absorbing properties of the oxygen tannates shows that certain of the extracts are as effective as alkaline tannic acid or sodium tannic, and that the amount of oxygen that can be absorbed by as small a quantity as 1 grain exceeds 200 cc. It is really a very large amount when one considers the smallness of the material itself.

We have had opportunity to analyze waters going to boilers and waters coming from boilers, under all sorts of conditions, and it is a hope of mine that some time some condition may be worked out whereby certain types of water treated under certain conditions can be brought to the attention of some group in this committee whereby it can send out an observer and collect samples as it wishes, and analyze them as it wishes, in an effort to indicate in some unbiased, scientific way what is actually being accomplished.

From eight to ten thousand waters pass through our laboratory annually, and there are few days in which we do not make at least forty complete analyses, but many of these waters come to us with a fair background of operating and plant information, and the amount of information of a practical but unscientific nature that we collect is enormous. It is our hope that in some way means can be developed whereby this information that we accumulate can be converted into some scientific form or can be utilized so as to be of value to this committee in its investigations.

R. C. BARDWELL.[16] In stressing the report presented by Dr. Foulk, it is desired to call particular attention to the necessity for some accurate determination of the fundamental factors involved. Practically all the men and laboratories engaged in the correction of water supplies are so busily occupied in the actual operation of plants and handling matters pertaining to troubles with these supplies that they do not have the time or research facilities necessary for investigation of the fundamental facts.

In railroad practice we do know that boilers will foam at different points, probably due to three different conditions, such as (1) the amount and type of suspended matter present, (2) the concentration of dissolved solids, and (3) the working conditions. Not knowing the exact cause or the influencing ratio of the fundamental factors, it is necessary to determine the particular foaming point for the locomotives on the individual districts and apply the well-known rule-of-thumb methods for correction, which consists of either blowing down the boiler and removing the objectionable solids, preferably in accordance with predetermined program, or using a method of internal treatment which, as Mr. French says, is usually a compound of castor oil.

It is rather surprising to hear the interpretation which Mr. Hall has placed on the presence of calcium in quieting foaming in water. This is practically the opposite of our experience. We have found that, where waters were treated with soda ash alone, considerable foaming complaints resulted and this has been expected. However, on one division where this was particularly aggravated, the soda-ash treatment was changed to sodium aluminate and caustic soda. The scaling matter composed of calcium and magnesium salts was removed to a greater extent than with the soda-ash treatment. With less calcium in the water the foaming was greatly reduced.

This same treatment was extended to other divisions with similar satisfactory results. Therefore, we cannot help feeling that there is a controlling factor radically different from the presence of calcium which influences foaming, in locomotive boilers at least.

It is believed that there is a large number of fundamental facts which will require detailed investigation and impartial study to

[15] Chemical Director, Dearborn Chemical Company, Chicago, Ill. Mem. A.S.M.E.

[16] Chesapeake and Ohio Railway Company, Richmond, Va.

determine the relative importance. I fully believe that Dr. Foulk is working along the right line and sincerely hope that funds will be available which will permit him to continue the valuable work which he has started.

It is believed that most of us have had experience with trouble caused by stream pollution. Damage to power-plant boilers along the Ohio River caused by contamination by coal mine drainage is an example.

About six years ago a conference was held in Philadelphia to consider means for offsetting the bad results from stream pollution. At that time I mentioned as an estimate an annual expense of $10,000,000 either in damage or in cost, to offset the trouble caused by sulphuric acid drainage from coal mines in the Ohio River basin. It is believed that this figure is reasonably conservative.

This is a very big problem which may require settlement by the National Government or a conference of state authorities. The information and data that are being accumulated by this sub-committee should be of considerable assistance when the time comes for definite action to be taken.

FSP-51-23

Orifice-Steam-Meter Coefficients

By ROBERT W. ANGUS,[1] TORONTO, ONT.

THE value of the thin-plate orifice as a fluid meter has been established beyond all question, and many very successful commercial applications of it are on the market. There are, however, not many tables of actual orifice coefficients, these being apparently retained by the manufacturers. Recently, the author was conducting some tests on a steam turbine of about 100 hp. which was not equipped with surface condenser, and as it was connected to the main header from a large battery of boilers, the feedwater method of measuring the steam consumption was not available. An orifice meter was then decided on, and after making the turbine tests, the orifice was set up in the steam laboratory of the Department of Mechanical Engineering of the University of Toronto and calibrated.

So far as the test was concerned, the coefficients under the test conditions were all that were necessary, but it was decided to enlarge the scope of the work and to determine the coefficients under a wide range of conditions, and this paper is the result of such work.

The orifice used in the test had a diameter of 1.838 in. and thickness of 0.015 in. It was set concentric with a 4-in. extra-heavy pipe having an internal diameter of 3.826 in. The set-up in the laboratory was therefore based on these dimensions, and a drawing of the experimental equipment is shown in Fig. 1. The 6-in. main steam pipe from the experimental boilers is shown at *S*, and by means of a 6-in. by $1^1/_2$-in. tee, connection was made to the experimental piping shown in Fig. 1. The 4-in. extra-heavy pipe started 1 ft. $10^3/_4$ in. from the center of the 6-in. main, and the 4-in. section had a total length of 7 ft. $10^3/_{16}$ in., with a pair of companion flanges in the center for insertion of the experimental measuring orifice. The pipe was again reduced to $1^1/_2$ in., which in turn delivered steam to a small steam turbine in the laboratory.

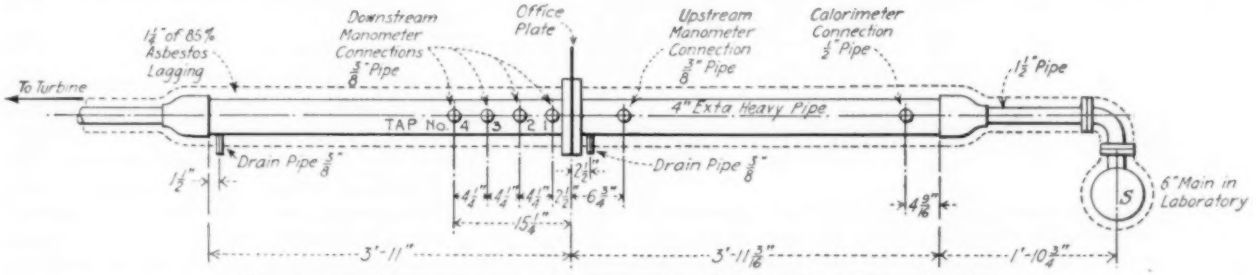

FIG. 1 PIPE CONNECTIONS FOR CALIBRATION OF ORIFICES (ALL PIPING LAGGED)

The entire piping was lagged with $1^1/_4$ in. of 85 per cent magnesia, and $^3/_8$-in. drains were placed at the two points shown, to prevent the collection of water. A throttling calorimeter was connected at the point indicated, and the orifice plates were inserted between the two companion flanges, and very carefully centered. Only one pressure tap was used on the upstream side for all experiments, this being placed $6^3/_4$ in., or 1.76 times the internal pipe diameter, above the orifice. Four taps were used on the downstream side, being placed in the positions shown in Fig. 1, and all of the pressure taps were made of $^3/_8$-in. pipe, screwed into the side of the 4-in. pipe so that they just came flush with the inside of the latter.

The differential pressures across the orifices were measured by a differential mercury manometer, reading to 0.05 in. mercury, and very great care was taken in every case to see that the connecting pipes were free of air and contained water up to the point of connection with the 4-in. pipe. Frequent readings were taken on this manometer for each test.

The orifice plates were made of galvanized iron 0.016 in. thick, the orifice being very carefully bored out in the lathe and afterward calipered, when hot, to thousandths of an inch. Each plate contained a $^9/_{32}$-in. hole as well as the orifice, this hole being placed so that its lower side was flush with the bottom of the pipe. Three orifice plates were used, with orifices A, B, and C, respectively 2.66 in., 1.838 in., and 1.33 in. in diameter, as indicated in Fig. 2.

A large number of experiments were made with the four downstream taps and the three orifices, each experiment lasting for from thirty to forty minutes. In all cases the steam pressure at the orifice was kept as close to 125 lb. per sq. in. gage as possible, and was very steady during any given test. The moisture of the steam entering the 4-in. pipe was also maintained very uniform by keeping the drip on the 12-in. main partly open; the quality remained uniformly constant at 98.5 per cent, and this quality was used in all calculations. Before each test the $^3/_8$-in. drains on the bottom of the 4-in. pipe were opened, and after they were closed the brake load on the turbine at the end of the $1^1/_2$-in. pipe was adjusted, and this load was kept constant, within a fraction of 1 per cent, during a test, thus producing a constant differential across the orifice. The steam passing through the orifice and turbine was then condensed and weighed, the average of at least eight weighings being taken in each case, and no test was used where the several weighings showed any material variation.

The maximum weight of steam that could be put through the equipment was 2423 lb. per hour, and the discharge varied from this amount down to a minimum of 510 lb. per hour; these ranges corresponded to differentials of from 0.13 in. to nearly 5 in. of mercury, and to orifice velocities of from 32.8 ft. per sec. to 161.2 ft. per sec. Unfortunately the steam available did not permit the use of these velocity ranges with each orifice.

Table 1 gives a summary of the results of the tests, which were made in February, March, and April, 1928. The calculations are based on Goodenough's Steam Tables, and the formula employed in getting the coefficient c was—

$$V = \frac{c\sqrt{2gH}}{\sqrt{1-\left(\frac{A_2}{A_1}\right)^2}}$$

where V denotes the velocity through the orifice in feet per second; A_1 and A_2 are the areas, in square feet, of the inside of the 4-in. pipe and of the orifice, respectively, the area A_2 including that of the small hole in the plate; H is the head, in feet of steam, corresponding to the differential mercury-gage reading, and c is the coefficient sought. The velocity V was found by taking the weight of steam discharged per second, multiplying it by the volume of the actual steam per pound, and then dividing the product by the orifice area, while the head H was given by the formula

$$H = \text{inches of mercury} \times \left(\frac{13.6 - 1}{12}\right) \times 62.4 \times \text{volume of 1 lb. of steam}$$

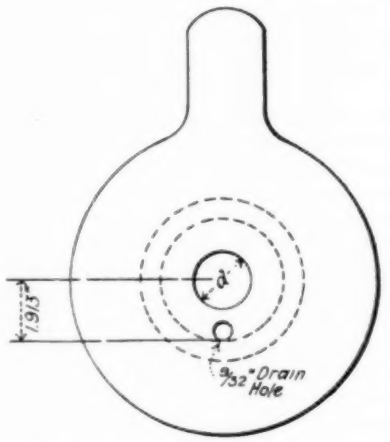

FIG. 2 DETAIL OF ORIFICE PLATE

Orifice	A	B	C
Diameter, in.	2.66	1.838	1.33
Inside diameter of pipe, in.			3.826

For the lower differentials the expansion of the steam through the orifice may be neglected, and the above formula treats the fluid as incompressible. The higher differentials, however, were nearly 5 in. of mercury, which was slightly under 2 per cent of the steam pressure, and in this case the expansion of the steam would have a slight effect. In Table 1, column 9 gives the value of the coefficient without making any allowance for expansion, as the latter should not affect the coefficients over about one-half of 1 per cent in the worst cases, and the effect would be negligible in the greater part of the work.

The results of the tests are plotted on the curve sheets Figs. 3 to 7, inclusive. In Fig. 3 the base is velocity V through the orifice, in feet per second, and three sets of curves have been plotted, one for each orifice. The three curves of the upper set all belong to the smallest orifice, of diameter 1.33 in., and show how the coefficient varies with the position of the downstream tap, the numbers referring to the position of the tap as indicated in Fig. 1. Unfortunately, it was not possible in the time available to get a curve for the fourth tap, but the middle group of curves for the 1.838-in. orifice gives the complete results for the four taps. The lower group, for the 2.66-in. orifice, was very limited owing to the steam capacity available.

The curves in Fig. 3 are very useful in showing how the position of the downstream tap affects the coefficients for a given orifice. All of these curves slope upward at first, indicating that the coefficient for a given orifice, and a fixed pair of pressure taps, varies with the velocity through the orifice, that is, with the differential manometer reading. The curves clearly flatten off and tend to become horizontal beyond a certain velocity; for example, above a velocity of 110 to 120 ft. per sec. the coefficients for the 1.33-in. orifice are constant.

The curves for the 1.838-in. orifice are not as evenly spaced as one would desire, and there may be some errors, even with the extreme care used in the work.

The curves of Fig. 4 are copies of those on Fig. 3 but grouped so as to show the effect of the size of the orifice on the coefficients,

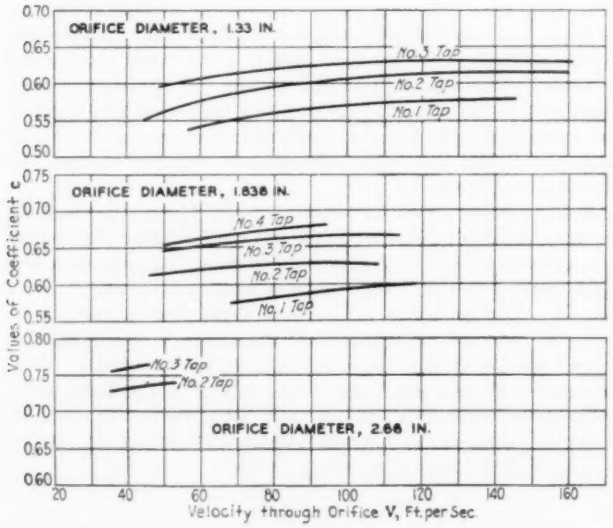

FIG. 3 VALUES OF COEFFICIENT FOR VARIOUS VELOCITIES OF FLOW THROUGH ORIFICES, SHOWING HOW POSITION OF DOWNSTREAM TAP AFFECTS THEM

for each given pair of taps. In this case the experimental points used in plotting the curves are shown. The upper group of curves belongs to No. 1 downstream tap and shows a marked change in the coefficient with the size of the orifice, for a given velocity in the orifice; and the same thing is true of each of the other three groups, which were taken with the second, third, and fourth downstream taps, respectively.

The curves in Fig. 5 show the relation between the coefficient c and the ratio A_2/A_1 of the area of the orifice to the area of the

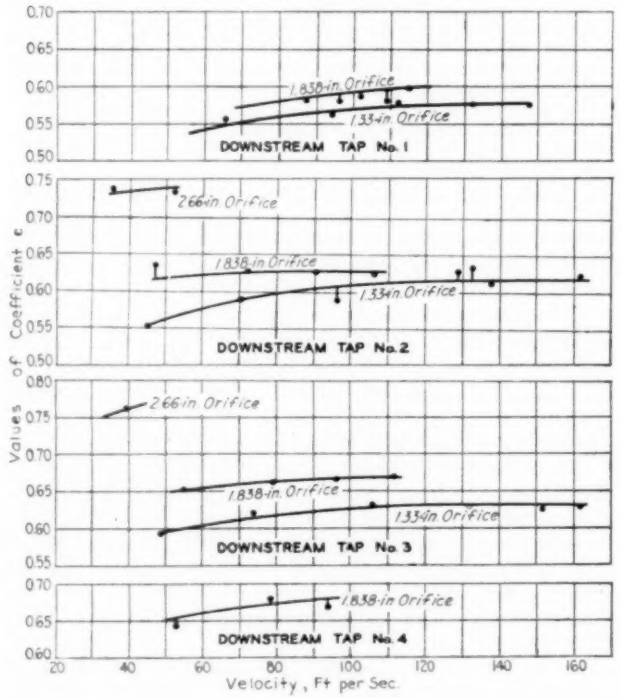

FIG. 4 VALUES OF COEFFICIENT FOR VARIOUS VELOCITIES OF FLOW, SHOWING FOR EACH PAIR OF TAPS THE EFFECT OF SIZE OF ORIFICE

pipe, these coefficients varying, as in the other curves, with the position of the downstream pressure tap.

The curves in Fig. 6 give the same information but referred to a base showing the ratio d_2/d_1 of the diameters of the orifice and of the pipe, respectively. It should be noted that the ratio A_2/A_1 takes account of the small $^1/_{32}$-in. hole in the orifice plate, whereas the ratio d_2/d_1 does not. In plotting these curves approximate average values of the coefficients were used as obtained from Figs. 3 and 4.

The final curves in Fig. 7 give the coefficients for the three orifices in relation to the position of the downstream pressure tap. As in the case of Figs. 5 and 6, the shape and position of the curves in Fig. 7 will vary with the coefficient adopted, as obtained from Figs. 3 and 4. The curves shown are based on approximately average values for each of the curves, although it might have been better to have used the coefficients corresponding to the horizontal parts of the curves.

A fairly complete discussion of the orifice meter is found in "Fluid Meters, Their Theory and Application," Part I, Report of The American Society of Mechanical Engineers' Special Research Committee on Fluid Meters.

This report was published by the A.S.M.E. in 1927 in a revised edition, and gives a complete bibliography on fluid meters, so that references are not necessary in the present paper.

The author's coefficients differ from those shown in this report, as none of the experiments discussed there takes account of the variation of the coefficient with the orifice velocity—and the author's experiments apparently establish such a variation. The author's upstream pressure tap was 1.76 pipe diameters above the orifice, whereas the curves of Fig. 14 in the report referred to were obtained with the tap one pipe diameter up-

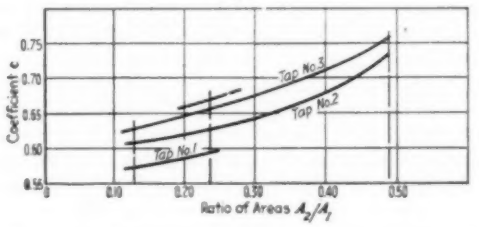

FIG. 5 RELATION BETWEEN COEFFICIENT c AND RATIO A_2/A_1 OF AREA OF ORIFICE TO AREA OF PIPE

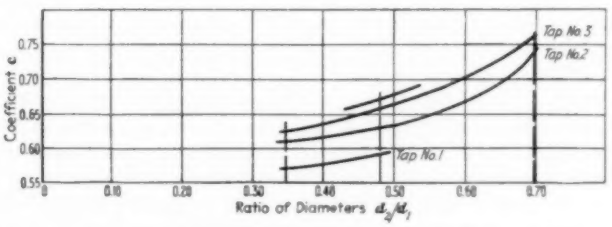

FIG. 6 RELATION BETWEEN COEFFICIENT c AND RATIO d_2/d_1 OF DIAMETER OF ORIFICE TO DIAMETER OF PIPE

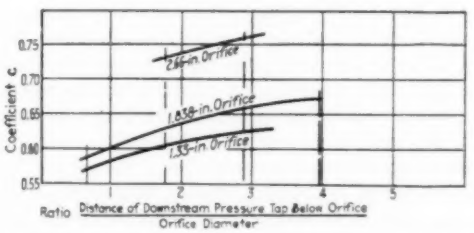

FIG. 7 COEFFICIENTS FOR THE THREE ORIFICES IN RELATION TO POSITION OF DOWNSTREAM PRESSURE TAP

stream; but tap No. 1 used by the author is very close to the vena contracta, and hence the author's coefficients should agree closely with those in the report.

In Fig. 14 the report gives a value $c = 0.608$ for a ratio of diameters $d_2/d_1 = 0.48$, a ratio corresponding to the 1.838-in. orifice used by the author with tap No. 1. For this case the author's values varied from 0.57 to 0.60, although the curve suggests that the value would be about 0.61 at the higher orifice velocities.

The author's smaller orifice had a ratio $d_2/d_1 = 0.348$, and with tap No. 1 the coefficients vary from 0.54 to 0.575, the latter value corresponding to the horizontal part of the curve. For the same ratio d_2/d_1 Fig. 14 of the report shows a value of about 0.602, although for this case the author's pressure tap was probably not at the vena contracta.

The experimental work described herein was carried out in the Steam Laboratory of the Department of Mechanical Engineering, University of Toronto, Canada, and the author acknowledges the help of Messrs. DeLaplante and Saunders, demonstrators in the laboratory, who did the actual experimental work.

Discussion

HORACE JUDD.[2] In looking over the paper it seems to the writer that the coefficients thus obtained would be applicable only to a layout similar to the one used in the tests, and could not be used, with assurance of accuracy, with other layouts differing in pipe size and in other proportions from the 4-in. test line used. With only twelve diameters' length of straight pipe above the position of the orifice meter, there would be danger of error due to the distorting effect of the small elbow near the entrance to the 4-in. pipe.

The differential head across the orifice for any given flow will be greater at the vena contracta than if read at any other downstream point of attachment of the manometer. It follows, then, that tap No. 1 would be the preferable point of attachment for this orifice meter in order to reduce the error of observation as much as possible. The number of tests for each orifice and for each tap position and the range of orifice diameters used appear to be too limited for more than general inferences to be made.

However, the writer agrees fully with the author's opinion that the thin-plate orifice is a valuable fluid-meter element and also that very few reliable data, especially for steam flow, are available for the general user. It is probable, also, that the manufacturers themselves have but a limited fund of reliable data at their command on steam flow under low differential heads. In these days of extended and increasing use of orifice meters for steam-flow measurement it is important and highly commendable that those who make such use of the orifice meter should be willing to share their experiences with others so that the all too limited field of practical knowledge may be enlarged and that much uncertainty now existing may be cleared away. This paper points out a great need for an exhaustive research of steam flow under varying flow conditions, using the orifice meter operating under relatively low differential heads. The ease with which orifice-meter coefficients for water and air have been and can be determined and the assumed adaptability of these coefficients to steam-flow measurement, together with the difficulty and increased expense encountered in conducting tests of steam-flow measurement, are probably the reasons why so few reliable data are available for orifice-meter coefficients for steam flow.

The Engineering Experiment Station at Ohio State University, recognizing this great need of more accurate information concerning orifice coefficients for steam flow, is now engaged in such a research in collaboration with the Bailey Meter Company. The limited number of tests made thus far has shown that for steam at 100 lb. gage pressure, 100 deg. fahr. superheat, and with differential pressures ranging from 2 in. to 10 in. of mercury, the coefficients are in fairly close agreement with those given in Fig. 14, p. 39, Fluid Meters Report, part 1, second edition.

C. D. NORTHAM.[3] The writer has endeavored to compare the coefficients given in the paper with those shown in Fig. 14 of the paper "Orifice Coefficients—Data and Results," by J. M. Spitzglass, presented at the 1922 annual meeting. In order to do this the tabulation given herewith was made.

It is at once evident that on the two orifices whose conditions approximate those of the Spitzglass paper the coefficients shown by the two papers disagree to the extent of from 6 to 7.5 per cent. The coefficients used by other authorities and shown in other papers and reports fall between or near the curves of the two papers compared. From the standpoint of the user this evident disagreement of the authorities does not add much to the confidence one can place in the accuracy of the orifice-type meter.

In other words, in order to know how accurate any orifice meter is, the user must know the basis of the coefficients employed and judge the probable accuracy of the coefficient on the basis of the extent and accuracy of experimentation involved in the finding of these coefficients. The writer believes there should be agreement on some set of coefficients applicable to certain conditions of flow, pipe, and orifice. However, before such a standard could be formulated an investigation similar in the scale to the A.S.M.E. Steam Table Research should be undertaken.

In considering probable sources of difference in the two papers compared it must be remembered that the Spitzglass experiments were carried out using air at low pressures whereas the Angus experiments were made using steam partially saturated and at comparatively low pressures. Most new installations of steam meters today operate under conditions of high pressure and temperature, and it would be interesting to know how these affect the coefficients.

The writer was at a loss to understand the necessity for the small $^9/_{32}$ in. hole in the orifice used. Presumably this is a drain hole, but with the pipe drained as shown in Fig. 1 there should be no water on either side of the orifice; and if there is, it would probably fill this hole up, thereby reducing the effective area of the orifice. However, recalculation of the coefficient, using data in test 4, Table 1, shows that the effect of neglecting the area of this $^9/_{32}$ in. hole would change the coefficient as found on this test from 0.575 to 0.576, so it is apparent this has little effect on results except that flow through the small hole might set up eddy currents affecting the main stream.

The important point brought out by the author's experiments is the variation of coefficient with change in velocity. The writer believes this to be due to change in position of the vena contracta, with change in velocity but without change in position of the pressure taps. The curves also show that the coefficient becomes fairly constant at increased velocities.

With these points in mind it would seem important that when designing an orifice the probable flow through it be known and also that the orifice be designed for as high velocity as possible above 120 ft. per sec., and still within the limits of the manometer used, to determine the differential created.

R. E. SPRENKLE.[4] The paper presents an interesting addition to the literature already published on flow measurement work, particularly in reference to coefficient values for different sized orifices when used for steam measurement.

It is deeply regretted, however, that this work is not more

[4] Mechanical Engineer, Bailey Meter Co., Cleveland, Ohio. Assoc-Mem. A.S.M.E.

comprehensive in scope. To attempt to establish coefficient curves on the basis of tests of only three different sizes of orifices, as the author has done in Figs. 5 and 6, is both hazardous and too often misleading, especially when the slope of such curves is rather steep. For example, should the 2.66-in. orifice tests be in error, the slope of the entire curve between the 48 and 69½ per cent ratio points would be in error. Coefficient curves or tables lack authority unless supported by test data from a large number of different-sized orifices; intervals of 4 or 5 per cent in the ratio d_1/d_2 are not too large for work of this exactitude. It is presumed, however, that there was not sufficient time available for testing more sizes. In this event it would have been better to omit the final curves in Figs. 5 and 6 until they could have been substantiated by definite tests on the intermediate sizes.

No explanation is advanced in this paper as to the large increase in coefficient with throat velocity. Such a characteristic has not been found in similar orifice tests using water as the flowing medium, although with venturi meters and flow nozzles an increase of ¼ to 1½ per cent has been found for the same range of velocities. Some steam tests made at Ohio State University recently on a 6-in. line using a 49 per cent ratio orifice show a comparatively flat curve throughout a throat velocity range of 50 to 120 ft. per sec. It will be noted that the coefficient of the 48 per cent ratio orifice as used by the author of this paper varied 5 per cent, through approximately the same range of throat velocity.

If, however, we take the average coefficient for each of these three different-sized orifices tested by the author, we find for tap 1 in the case of the two smaller orifices that the coefficient is about 6 per cent lower on the flow basis than the coefficients obtained from similar-sized orifices in similar-sized pipes by other experimenters. For example, Mr. J. M. Spitzglass in his paper in 1922 gave a value of 0.618 as the coefficient for a 50 per cent ratio orifice measuring air in a 4-in. pipe; and the Bailey Meter Company value of a 48 per cent ratio, 4-in. pipe size, is 0.615 measuring water, as against the author's average of 0.583 for steam. Similarly, Mr. Spitzglass's value for a 31½ per cent ratio orifice, 4-in. pipe, is 0.614, and the Bailey Meter Company average for this same size of orifice is 0.615, as against the author's average of 0.57 for a 34.8 per cent ratio. It would have been interesting to compare the coefficient for the 69½ per cent ratio orifice, tap 1, with other experimenters' data if the author had chosen to obtain these additional data. Comparison between the coefficients obtained by taps 2, 3, and 4 and those obtained by other experimenters using the same tap locations also shows results from 8 to 10 per cent lower. However, since these taps are not at or close to the vena contracta, the results obtained therefrom are of no value whatsoever from a standpoint of commercial application. In passing, it should be pointed out that since there is such a close agreement between Mr. Spitzglass's results obtained on air measurement and the Bailey Meter Company's results obtained on water measurement, the possibility that the steam coefficient would be lower than water is very remote indeed.

Orifices of no greater thickness than 0.015 in. as used in these tests should not be used either for research or for commercial application. It is difficult to see how such thin orifices maintain the perfect vertical plane for any period of time without bulging or cracking and thereby destroying the accuracy of the machined hole. It is entirely possible for these orifices to bulge out appreciably on the high throat velocities, thus increasing the effective orifice opening and increasing the apparent coefficient of discharge. Such an action would help explain why the author's coefficients increased at high velocities, although it might be but a contributory cause.

The orifice flange should have been located about one foot from the exit end of the 4-in. pipe instead of in the middle. This would help materially in eliminating the jet effect which exists in the system due to the sudden increase in pipe size from the 1½ in. to the 4 in., and which might easily carry through in the higher velocities to the orifice flange as shown in Fig. 1. Such an effect would also tend to raise the coefficient, since the static pressure on the inlet side of the orifice would not register its full value.

It is also regretted that a high-pressure water manometer could not have been used in reading the differentials across the orifices. A description by the author would be appreciated as to the method used in reading a mercury manometer with any degree of accuracy when the differentials shown were no more than ½ in. or even 1 in. Magnification of such small differentials by water column would have reduced the possibility of error by a ratio of over 12 to 1 and thus would have made the results obtained more dependable.

J. M. Spitzglass.[5] In his introductory paragraph the author stated, "There are, however, not many tables of actual orifice coefficients, these being apparently retained by the manufacturers." As one of the manufacturers and as a member of the Fluid Meter Committee the writer wishes to take exception to that statement, because the fluid-meter manufacturers have actually, it may be said, forced themselves upon the Fluid Meter Committee by asking the members to utilize their data for publication. Some of the orifice coefficient data, as submitted by the manufacturers, are published in the Fluid Meter Committee report, to which the author refers. Other data are published in the numerous papers which are available in the literature of the Society. The writer would request that the author retract this statement, especially in view of the fact that the paper is supposed to be contributed by the Research Committee on Fluid Meters.

The field of orifice application is tremendously large, and every additional experiment adds another point to the composite curve or diagram. It is imperative to analyze the conditions of the test before the given results are registered on the list. The writer does not believe that reliable results could be obtained with a layout as shown in Fig. 1 and an orifice with a drain hole as shown in Fig. 2. The layout shows a 4-in. pipe trapped between 1½-in. extended inlets and outlets. The author has probably noted the statement in the Fluid Meter Committee report that a jet issuing from an orifice into an enlarged section extends to the walls of the pipe at 4 or 4½ diameters distance from the orifice. This property, however, does not apply to the case of a jet issuing from a long tube. In that case the restricted area of the jet may carry far beyond that distance, and it may have an effect on the differential pressure even at a distance of 10 pipe diameters, which the author allowed in his layout.

The orifice plate had a 9/32-in. drain hole at the bottom. The area of this hole in some cases formed 4½ per cent of the area of the orifice. The author allowed for that area, assuming that it will pass the steam in the same proportion as the opening of the orifice. He could not be certain of that, however, because the condensate lodging in the lower part of the 4-in. pipe in front of the orifice may at times prevent the full discharge through that opening, and thereby affect the coefficient of discharge. This opening is so close to the wall of the pipe that it may at times be partially closed by the packing.

In Table 1, of the thirty-eight tests shown, the only points that could be of value are the first twelve, which were made on the No. 1 downstream pressure tap. If the author had referred to Fig. 12 of the Fluid Meter report, he would have seen beforehand the results of locating the pressure tap farther away from the

[5] Mechanical Engineer and Vice-President, Republic Flow Meters Co., Chicago, Ill. Mem. A.S.M.E.

vena contracta. The region between the vena contracta and the point of restoration is uncertain at best and is never recommended for practical use in connection with an orifice plate.

Figs. 3 and 4 are intended to indicate that the coefficient of the orifice was reduced at low velocities. If we restrict ourselves to the data on tap No. 1 and if we plot the curves more accurately, this variation with velocity will be less apparent. At the top of Fig. 4 there was one point omitted on the first velocity of the smallest orifice. The result would show three almost identical points on the first three velocities and three identical points on the second three velocities of the small orifice.

In referring to the Fluid Meter Committee, the author is wondering why his results do not agree with the Fluid Meter Committee coefficients. The writer believes that the author's tests have demonstrated the value of the orifice as a measuring device in that it agreed so closely (within a few per cent) even though the installation was not what it should be. It may be added that recent experiments on orifices have proved beyond doubt that the orifice coefficient varies with velocity only when approaching the region of laminar flow, and in that region the coefficient is considerably increased, which is contrary to the author's indications.

Sanford A. Moss.[6] The paper shows evidence of a great deal of careful work, and the author presents very interesting data showing variation of orifice coefficient with different velocities, with different positions of the pressure holes with the different area ratios. The paper is a very valuable contribution to our knowledge of flow measuring apparatus. However, instead of assisting in the use of thin-plate orifices, as the author intends, the paper should have exactly the opposite effect and should discourage the use of thin-plate orifices. The author starts out by saying that "The value of the thin-plate orifice as a fluid meter has been established beyond all question," and he then goes on to demonstrate by a great many carefully conducted experiments that the thin-plate orifice is not a good fluid meter. The reason is of course that the coefficient of a thin-plate orifice is very uncertain and depends on all of the variables which the author takes into account. As the writer understands the paper, the author takes full theoretical account of all the theoretical differences, such as variations in density, moisture content, initial velocity head, and properties of steam. Therefore, the variations in the final coefficient of discharge c are purely empirical differences which cannot be taken account of by theory and which can be found only by experiments, such as those given in the paper. Table 1 shows that c has a minimum value of 0.552 and a maximum value of 0.761. This gives an extreme variation of 38 per cent. Of course, a large part of the differences are given by the different downstream taps. However, the author shows that the position of the venturi contraction varies with the different circumstances, so that there is no theoretically sound way for deciding just which downstream tap to use.

The author's work covers a great deal of territory, but nevertheless there is a vast amount of additional territory to be covered for different pressures, different velocities, different sizes of orifice, and different area ratios. A number of other papers have been published giving data for some of this other territory, and many systems for using thin-plate orifices have been proposed.

The author implies that the manufacturers of meters for thin-plate orifices have exact data which they are retaining. The possession by manufacturers of exact data covering all the variables is to be questioned.

There is to be contrasted with the thin-plate orifice, with such an uncertainty in the coefficient discharge, the nozzle with well-rounded approach with a very definite coefficient. This has been used for many years either as a venturi meter or with insertion in a pipe line in the same way as a thin-plate orifice. A detailed discussion of the use of a nozzle with well-rounded approach was given by the writer in a paper presented at the December, 1927, meeting, and its advantages as compared with the thin-plate orifice were pointed out. The data given in the paper confirm all of the statements made in the paper regarding difficulties of use of a thin-plate orifice.

The author has presented a very valuable paper as a result of a great deal of careful work, but his paper demonstrates the exact opposite of the point he intended to make.

Author's Closure

The author is very grateful to those who have discussed the paper and offered criticism that will be helpful in future work. It is a matter of regret that lack of time and opportunity prevented more extensive work, but it is hoped that the research will be continued.

Criticism of the use of taps 2, 3, and 4 is not justified, as these points may be used quite as well as No. 1, provided the coefficient is known. The desirable point of connection is one which gives a good differential and where the coefficient varies little for a slight change in location of the point. Tap No. 4 is a place where the jet in all probability fills the pipe, being four diameters downstream, and is therefore a good point; one meter builder places the downstream tap eight diameters below the orifice. Information about taps 2 and 3 is also very desirable if for no other purpose than helping to locate the vena contracta.

Objection to the thickness of the plate by Mr. Sprenkle is interesting in view of the fact that orifice B was an exact duplicate in dimensions, including the $^{9}/_{32}$ in. hole, of that supplied by the meter maker on the 100-hp. plant referred to except that orifice B was 0.016 in. thick, while that of the meter maker was 0.015 in. The small hole was presumably for drainage, and care was taken that it was not closed up by the packing. There seemed to be no alternative to including the area of the small hole in that of the orifice, although it had little effect in the case of the larger orifices. The $^{3}/_{8}$-in. drain pipes were closed during each test.

Both Professor Judd and Mr. Spitzglass criticize the distance between the $1^{1}/_{2}$ in. pipe and the orifice, but as no definite suggestion is offered it only proves that more information is needed as to the setting of orifices and the effect of changes in pipe section on them. In the tests the $^{1}/_{2}$-in. calorimeter pipe, which extended across the 4-in. pipe, must have largely broken up the jet.

There is considerable force in Mr. Moss' contention that meters with nearly constant coefficients, especially when these are close to unity, as in the nozzle and venturi tube, have much to commend them, but the orifice has very much to its credit also. The paper does not try to establish a case for the orifice, but it most clearly shows that where it is used great care must be exercised in the setting and in the coefficients used, and I have seen some unfortunate troubles due to neglect of these precautions. More information is needed about the device, and it is to be hoped that it will be forthcoming.

There was no intention in the paper to reflect on the meter manufacturers, and it may have been an error to assume that they had obtained actual coefficients for the meters they sold, but a very careful and fruitless search for coefficients for orifice B was the cause of the investigation being started, and its scope was afterward enlarged.

The question of the variation of the coefficient with the velocity has been raised by Mr. Northam, Mr. Sprenkle, and Mr. Spitzglass and is a most important one. Recently when in Berlin the author discussed this paper with a well-known authority, who then showed some curves which he had obtained with the

same general characteristics, and it is to be hoped that he will soon make these public so that a comparison may be made. It is a point that should be definitely settled, although a similar condition is well known to exist in the case of the venturi meter.

Unfortunately the author is unable to furnish further details regarding the work, as he is at this time abroad and cannot refer to his notes or to any details of the tests or papers mentioned in the discussion.

The Peak-Load Problems in Steam Power Stations

By A. G. CHRISTIE,[1] BALTIMORE, MD.

This paper deals with the problem of the annual peak load in steam power plants. The use of the load-duration curve for the purpose of studying annual peak loads is analyzed and the conclusions are drawn that (1) plant intended for annual-peak-load service should only be installed at the lowest possible first cost, and that (2) economy of peak-load equipment can be sacrificed to secure low initial cost.

Various schemes that have been proposed to provide equipment for carrying the annual peak loads are analyzed. The three plans that appear most promising are those involving the use of steam accumulators, of peak-load units, and of present plant after new base-load equipment has been added.

In order to indicate the possible annual savings through the application of these three methods, the author assumes an electric system with a maximum annual peak load of 200,000 kw., together with certain data for annual load factors of 65, 45, and 25 per cent on this system. With certain assumed plant costs, fuel costs, and operating performances, an analysis is made of the annual operating costs of the various methods, and the possible annual savings through the use of steam-accumulator plant or peak-load units are shown in the form of a series of curves. These savings in some cases may be of a large order.

MUCH thought has been devoted to methods of improving the daily load factors of steam-electric power stations. Night loads have been added, power demands for morning and early afternoon hours have been developed, and attention has been given to reducing peak demands which usually occur at about six o'clock in the afternoon. This paper will discuss the problem of carrying the maximum peak loads of the year.

The Load-Duration Curve

The load-duration curve represents the cumulative duration of all loads throughout the year as shown in Fig. 1. Each point on the curve indicates the hours per year in which the load has not been less than the kilowatts represented by the point. To plot this curve, the daily load curves are first taken and the average output for each hour of the twenty-four is noted. A record is made of the duration in hours of each load throughout the year. These loads are then plotted in decreasing order from the peak load with cumulative time as a base, until the loads for the whole 8760 hours of the year have been recorded. A smooth curve, or a stepped curve as preferred, drawn through the plotted points, represents the load-duration curve of the particular system.

The area under the curve represents kilowatt-hours output to a given scale, and may be used to check the yearly output computed by other means.

The annual load factor as used in this paper is the ratio of the kilowatt-hours generated to the maximum demand during the year multiplied by 8760, the total hours per year. This ratio is thus the area under the load-duration curve divided by the area represented by the product of the maximum load of the year and 8760. The annual load factor of that portion of the demand above any given load may be found by taking the ratio of the area under the curve above the given load, to the product of 8760 and the difference between the given load and the maximum peak load. The annual load factor of that portion of the load below any given load is the ratio of the area under the curve between zero load and the given load, to the product of 8760 and the given load. The steeper the load-duration curve, the lower will be the annual load factor, as is indicated by Fig. 1, which has an annual load factor of 30.4 per cent. On the other hand, the flatter the load-duration curve and the less it diverges from the flat curve at maximum and minimum load, the higher will be the annual load factor, as shown in Fig. 2, which has an annual load factor of 51.4 per cent.

Loads in excess of 50 per cent of the maximum peak in Fig. 1 occur for only 1050 total hours during the year, while loads in excess of 75 per cent of the maximum peak exist for only 200 hours in the year. The kilowatt-hours generated by the equipment employed to carry load in excess of 50 per cent of the maximum peak and shown by the cross-hatched area on the diagram represent only 4.8 per cent of the total annual output. The equipment carrying load above 75 per cent of the maximum peak in Fig. 1 produced only about 0.5 per cent of the total kilowatt-hours generated. Load in excess of 80 per cent of the maximum peak in Fig. 2 lasts for 320 total hours and develops about 0.62 per cent of the total annual output.

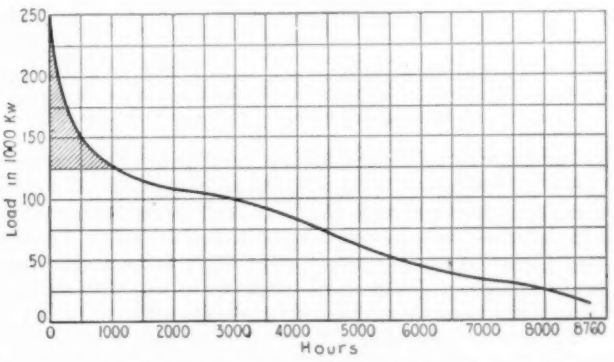

Fig. 1 Load-Duration Curve for System With 30.4 Per Cent Annual Load Factor

The annual load factor has been plotted in Fig. 2 for that portion of the load above each load. For instance, the annual load factor for that portion of the load in excess of 75 per cent of the maximum peak is 2 per cent, as shown on the upper scale. Also, the annual load factor for that portion of the load in excess of 50 per cent of the maximum peak is 18.6 per cent. This method of drawing the annual load factor for various portions of the maximum peak assists in analyzing the peak-load problem.

A study of load-duration curves leads to the formulation of two statements regarding peak-load equipment in a generating system: (*a*) Plant intended for peak-load service only should be installed at the lowest possible first cost; (*b*) Economy of peak-load equipment can be sacrificed to secure low initial cost. The first statement is evident from a consideration of the few hours of service of this portion of the system during the year.

---

[1] Professor of Mechanical Engineering, Johns Hopkins University. Mem. A.S.M.E.

Contributed by the Power Division and presented at the Annual Meeting, New York, December 3 to 7, 1928, of The American Society of Mechanical Engineers.

Only equipment with a low first cost can be justified. The second follows from a consideration of the small amount of power generated by such peak-load equipment. The cost of each kilowatt-hour thus generated consists predominantly of fixed charges, with relatively smaller charges for fuel, labor and maintenance.

Proposed Schemes to Carry Peak Load

Electrical systems have had such rapid growth that additional generating capacity is needed every few years. The design of

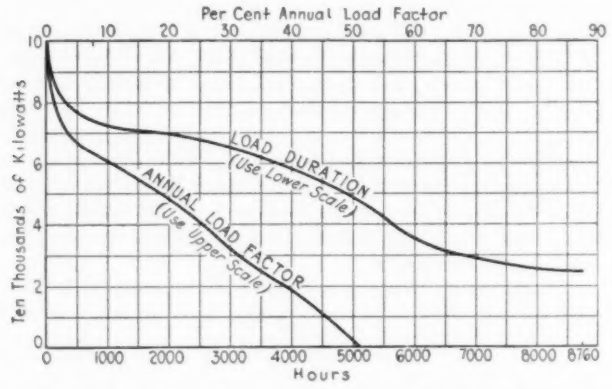

Fig. 2 Load-Duration Curve for System With 51.4 Per Cent Annual Load Factor and Annual-Load-Factor Curve for That Portion of Output Above Given Loads

power plant and equipment has also developed so that fuel economies are available by the addition of new units. Each new installation has been made the "base-load" plant of the system, although there have been exceptions to this practice. The high load factors of many systems which have well-sustained high loads throughout the greater portion of the day with no short, sharp peaks favor the addition of base-load units.

Methods of carrying peak loads were discussed at the convention of the Verband Deutscher Electrotechniker at Kiel, Germany, in June, 1927, and reported in *Elektrotechnische Zeitschrift*, June 30, 1927. High-level water storage, Diesel engines, electric storage batteries, and Ruths steam accumulators were considered in this connection.

Few sites are available in this country where the combination of lack of pondage on the river, low load factor, and nearby available natural storage basins at high head would make an economic possibility of hydraulic storage during off-peak hours for use on peak load.

Electric storage batteries for peak-load service are usually limited to those systems which still have Edison direct-current distribution. Few large batteries will be installed except for emergency reserve in order to preserve continuity of the direct-current service. Storage batteries are still of great value for such service in important districts of many large cities. They are costly and are not generally considered economical equipment to carry system peak loads.

Large Diesel engines are being installed in some European systems for peak-load service. Much can be said in favor of Diesel engines for this purpose on account of their quick availability and low stand-by and operating costs. Their future development should be closely watched by power engineers with this possible use in mind. The development of large Diesel engines for central-station service has been slow in America due to high first cost, and on this account it is not likely that Diesels will be widely used for peak-load service in the immediate future.

Steam Accumulators

The steam accumulator has been used for many years both here and abroad for service with exhaust steam from reciprocating engines, and its operation is well understood by engineers. A Swedish engineer, Dr. J. Ruths, applied the principle of steam storage to accumulators for large quantities of steam by making the pressure vary between wide limits—for instance, from 250 to 50 lb. per sq. in. gage. In the following discussion the use of the term "steam accumulator" will refer to one of this high-pressure type.

The steam accumulator finds economic justification in power plants to take violent load fluctuation of short duration, to enable the plant to carry sharp daily peak loads economically, and to carry a portion of the annual peak load.

The application of steam accumulators in industrial power plants with wide, frequent, and rapid fluctuations in steam demand has been described in R. A. Langworthy's paper "The Ruths Steam Accumulator."[2] Central stations which serve street railways, underground railways, and electrified trunk lines have power demands which vary quite as rapidly and between as great extremes of boiler capacity as in many industrial plants, and to which steam accumulators would seem desirable additions.

The cost of an accumulator will depend upon the extent and nature of the fluctuations in steam demand that it will have to meet. If the fluctuations are of short duration, the accumulator installation need not be large. If the fluctuations are of long

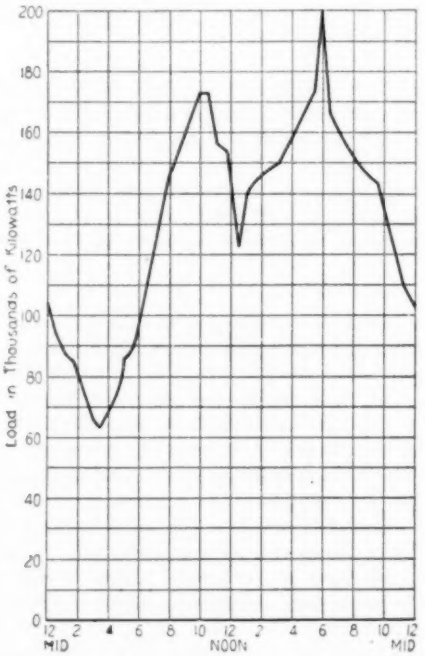

Fig. 3 Average Daily Load Curve for System With 65 Per Cent Annual Load Factor

duration and very irregular, more accumulator capacity will be required and the cost will increase. Where no increase in total station output is anticipated subsequent to the accumulator installation, the fixed charges on the new equipment, including costs of changes on turbines and piping, must be balanced against the savings resulting from better operation of the boiler plant.

A point is soon reached in electrical systems with growing loads when additional generating capacity must be installed.

[2] Trans. A.S.M.E., vol. 50, no. 15, 1928, paper FSP-50-33.

The choice may lie between additional boiler-house equipment and another standard high-pressure turbo-generator; steam accumulators and a special turbo-generator to carry fluctuations and peak loads; or a special peak-load turbine and boilers. A boiler plant which has been subject to wide fluctuations in load can generally carry a steady load of much higher average capacity with less difficulty and at better efficiency. Hence the addition of steam accumulators would improve the performance of older boilers, and would also save the cost of additional boilers, boiler house, and coal handling and other equipment. Accumulators are generally placed out in the open with no housing or any construction other than the supporting concrete foundations and the necessary piping and valves.

Steam turbines for accumulators are usually operated on saturated steam at moderate pressures, which permits the use of cast-iron casings. The low annual load factors for peak-load service will not warrant refinements in the design of turbine or condenser plant, and these for use with accumulators should be little, if any, more expensive than similar plant for peak-load service at standard pressures. Some operating advantages may be secured at slight additional cost by making the accumulator turbine a mixed-pressure turbine capable of operating steadily in emergencies on steam direct from the boilers, or desuperheated.

Steam accumulators are suitable for peak-load service when the peaks are sharp and of short duration. The Siemens-Schuckert Werke of Berlin, Germany, have recently received an order from B.E.W.A.G., the electricity works of that city, to install 16 Ruths accumulators in connection with the Charlottenburg Station, one of the older plants of the system. Vertical accumulators each 69 ft. high, 14 ft. 9 in. in diameter, and with a capacity of about 11,000 cu. ft. will be added. These will stand in the open with no housing, and in appearance will resemble a group of

FIG. 4 LOAD-DURATION CURVE AND ANNUAL-LOAD-FACTOR CURVE FOR SYSTEM WITH 65 PER CENT ANNUAL LOAD FACTOR

Cowper stoves. They will have a steam capacity sufficient to carry a 40,000-kw. peak with a three-hour base on two turbines each of 20,000-kw. capacity, and to generate 67,000 kw-hr. during this period. The boilers of the plant will supply steam to these accumulators at night and during drops in the day demand. This service will increase not only the load factors on the boilers, but also, as the accumulators float on the line, the rate of driving the boilers will become more constant, resulting in an increase in boiler-plant efficiency. The accumulator equipment will take the top portion of the Berlin daily peak, which has become very sharp, and thus permit other stations to operate on higher load factors with improved performance.

OTHER STEAM PLANT FOR PEAK LOAD

Old stations on a power system often offer possibilities of increased capacity for peak-load service. Many have stokers with low settings and old equipment. Some of these may be changed to powdered-coal firing with unit mills, water-cooled furnace walls, evaporators, air preheaters, and radiant-type superheaters, and the output of the boiler plant can thus be greatly increased during peak loads. If adequate cooling water is available, the old turbines may be rebuilt for greater steam capacity at peak load.

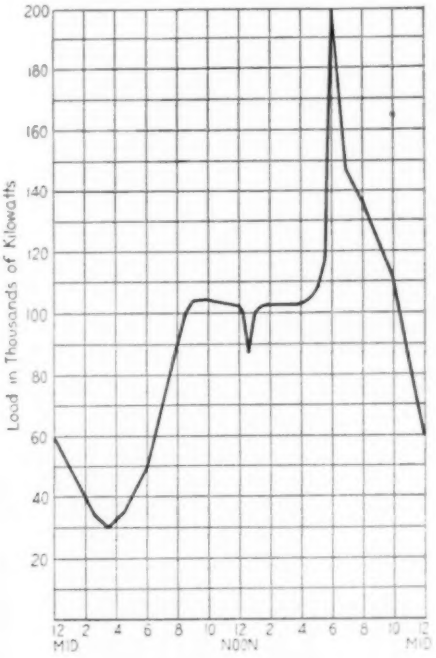

FIG. 5 AVERAGE DAILY LOAD CURVE FOR SYSTEM WITH 45 PER CENT ANNUAL LOAD FACTOR

Small turbines may be replaced by new, larger, peak-load units. Generators may also be rewound for added capacity, or may be replaced by units of larger output. Such changes will materially increase the capacity of an old plant as a peak-load station, and the resultant gain in system capacity may be secured at a lower total cost than by any other plant which will provide the same additional capacity.

When new and highly economical boilers and turbines are added to a power system and are operated as base-load units during the early years of their use, the capacity factors of the older equipment are decreased. The question now arises, whether the installation of cheap, rugged units of large capacity for peak-load service only, in place of highly efficient base-load units, would be economically justified. It is also desirable to determine whether such peak-load units would provide lower costs than steam-accumulator plant.

These peak-load turbines are of simple design and moderate efficiency so that as great an output as possible may be secured from a given frame, thus lowering the first cost per kilowatt of capacity. Condenser equipment for moderate vacuum may be installed. Peak-load boilers could be either oil fired or provided with water-cooled walls, large furnaces, and unit pulverizers for quick starting, low stand-by costs, and maximum ratings during their short daily periods of operation.

ECONOMICS OF METHODS OF CARRYING PEAK LOADS

In order to make some concrete comparisons of the relative economy of steam accumulators, base-load units, and peak-load units, the average daily load curves for a year (for 65 per cent

annual load factor and for 45 per cent annual load factor) of a plant with a total capacity of 200,000 kw. have been assumed from data in A. H. Markwart's paper "Power in California."[3] The corresponding load-duration and annual-load-factor curves

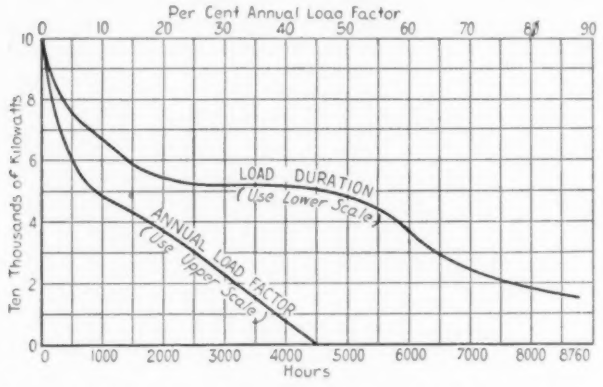

FIG. 6 LOAD-DURATION CURVE AND ANNUAL-LOAD-FACTOR CURVE FOR SYSTEM WITH 45 PER CENT ANNUAL LOAD FACTOR

lator was taken as $55 per kw. of capacity. Accumulators with their foundations and piping were assumed to cost $17 per kw-hr. of maximum charging capacity. The cost of accumulator plant in the following calculation was based on an arbitrary assumption that the maximum daily peaks of the year to be carried by the accumulators would have a time base twice as great as that shown by Figs. 3 and 5, which are average daily load curves. Hence for a given portion of the peak load, the daily storage capacity of the accumulator was assumed to be twice the kilowatt-hours shown by that portion of the average daily load curve. Similar assumptions were made in the calculations for 25 per cent load factor. These assumptions were made for the purpose of this paper only. In an actual case the daily load curve for that day on which the maximum yearly peak occurs should be used to calculate the necessary kilowatt-hour capacity of the accumulator.

The influence of variations in these prices will be discussed later. Fixed charges were assumed for all systems to be as follows: interest, 6 per cent; taxes, insurance, etc., 3 per cent; depreciation, 6 per cent; total, 15 per cent. Coal of 12,500 B.t.u. per lb. as fired was assumed at a cost of $5 per ton of 2000 lb.

The standard plant equipment to which additions are to be

are shown in Figs. 4 and 6. The data on load factors and kilowatt-hours output above and below given loads as shown in Table 1 were taken directly from Mr. Markwart's paper. The second and third columns in the table indicate the annual load factor and the percentage of the total kilowatt-hours output, respectively, for those portions of the load curves in Figs. 3 and 4 below the given load shown in the first column. The fourth and fifth columns show similar data for those portions of the load curves above the given load. The sixth to ninth columns show the corresponding data for Figs. 5 and 6. A load-duration curve, Fig. 7, was drawn for 25 per cent annual load factor from other available data. Table 1 also gives data on this load-duration curve in the tenth to thirteenth colums.

The following plant costs were assumed for the purposes of this discussion:

Peak-load plant complete.....$85 per kw. capacity
Standard plant complete.....$100 per kw. capacity
Base-load plant complete with latest heat-saving equipment.....$115 per kw. capacity

The steam-accumulator plant can be as simple in the turbine room as the peak-load plant. Its cost exclusive of the accumu-

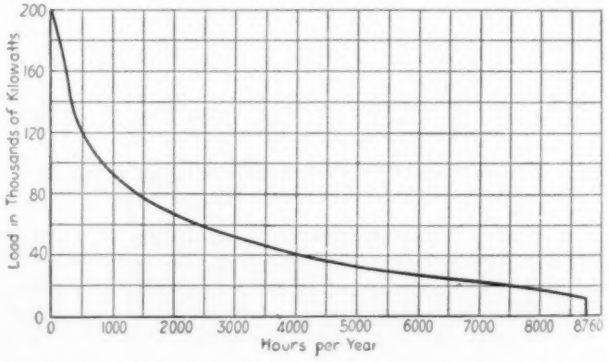

FIG. 7 LOAD-DURATION CURVE FOR 25 PER CENT ANNUAL LOAD FACTOR

made was assumed to approximate recent practice. The variation in heat rate with load factor of such standard plant, as expressed in B.t.u. per kw-hr., is given by curve A, Fig. 8, and is expressed by the formula

$$\text{B.t.u. per kw-hr.} = 13{,}600 + \frac{100{,}000}{\text{Annual load factor in per cent}}$$

[3] *Jl. Franklin Inst.*, Aug., 1927.

The steam leaving the accumulator will not be superheated. For the purpose of this paper, gage-pressure limits of 200 lb. to 20 lb. will be assumed on the accumulators, and an average steam consumption of 20 lb. per kw-hr. on the turbine. An allowance of 12.5 per cent will be added to take care of auxiliary power, radiation losses from the accumulators, and steam required to start up the turbine. The accumulator plant would therefore require 22.5 lb. of steam per kw-hr. net output. Assume that at night the boilers add 1000 B.t.u. per lb. to generate this steam at an efficiency of only 75 per cent. The average heat requirements of the accumulator plant will be $(22.5 \times 1000)/0.75 = 30{,}000$ B.t.u. per net kw-hr., which seems a liberal figure.

A special turbine and boiler plant, for peak-load service only, would be added to the standard plant where the steam conditions may be assumed as 400 lb. gage, 700 deg. fahr. The condenser could be designed for 28 in. of vacuum. The average steam consumption under these conditions was assumed to be 11 lb. per kw-hr. An allowance of 12.5 per cent additional steam at average load was made for auxiliaries and for losses in starting up. If 1200 B.t.u. are added per pound of steam in a boiler built for large capacity rather than for economy, and which operates at an average efficiency of only 65 per cent, the average B.t.u. per net kw-hr. output will be $11 \times 1.125 \times (1200/0.65) = 22{,}850$ B.t.u.

The base-load units will be assumed to operate with high pressure, high superheat, bleeders, low vacuum, and air preheaters or economizers to insure high plant economy. The performance of such a base-load unit is given in curve B, Fig. 8, and is expressed by the formula:

$$\text{B.t.u. per kw-hr.} = 12{,}900 + \frac{100{,}000}{\text{Annual load factor in per cent}}$$

Additional plant operators for steam-accumulator, peak-load, and base-load units are provided at the rate of 60 cents per hour. The steam accumulator is entirely automatic and requires little

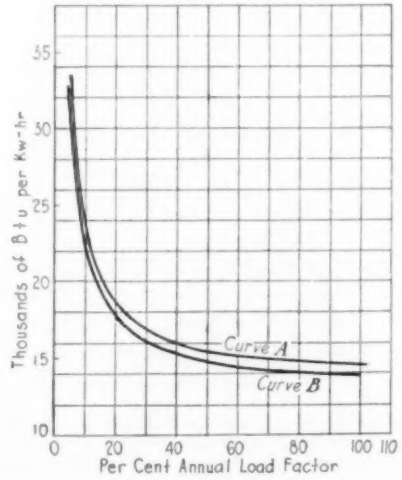

FIG. 8 RELATION OF B.T.U. PER KW-HR. TO ANNUAL LOAD FACTOR

attention. Its turbine will require an operator for a single shift of 8 hours per day during the peak load. If used for annual peak only, this operator need not be employed for the whole year. The peak-load plant is assumed to operate only during a single 8-hour shift with two additional operators, one in the boiler room and one in the turbine room. The base-load unit operates the full 24 hours and two additional operators per 8-hour shift are provided, one for the boilers and one for the turbine. When the added unit exceeds 40,000 kw., it has been assumed that adjustments will be made in the labor force of the original station so that no additional operators other than those just mentioned will be required in any new plant.

The assumption has also been made that no plant operates at a higher annual load factor than 80 per cent. This provision

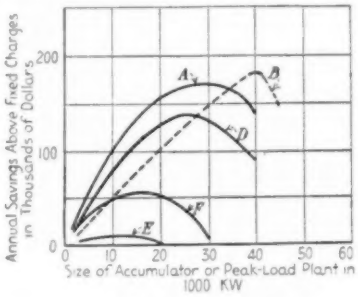

FIG. 9 ANNUAL SAVINGS ABOVE FIXED CHARGES THROUGH THE USE OF STEAM-ACCUMULATOR PLANT OR PEAK-LOAD UNIT ON A 200,000-KW. SYSTEM WITH 65 PER CENT ANNUAL LOAD FACTOR AND WITH COAL COSTING $5 PER TON

Curve A—Annual savings, steam accumulator over addition of base-load plant to standard plant.
Curve B—Annual savings, peak-load unit over addition of base-load plant to standard plant.
Curve C—Annual savings, combined accumulator and peak-load plant over addition of base-load plant to standard plant.
Curve D—Annual savings, steam accumulator over addition of standard unit to standard plant.
Curve E—Annual savings, steam accumulator over addition of base-load unit to system with standard plant and old low-efficiency plant.
Curve F—Annual savings, steam accumulator over addition of base-load unit to system with standard plant together with older plant of moderate efficiency and still older plant of low efficiency.
Curve G—Annual savings, steam accumulator over addition of base-load unit to system with a series of units with efficiencies decreasing from the standard plant to the very old plant.

NOTE: The differential between curves A and B at any size of accumulator or peak-load unit remains constant for that particular size. Curves have not been drawn for annual savings with peak-load units for conditions represented by curves D, E, F, and G, as this would confuse the diagrams. The savings by the use of peak-load units with these combinations can be found by deducting the differential between curves A and B from the curve of accumulator savings for the particular system in question.

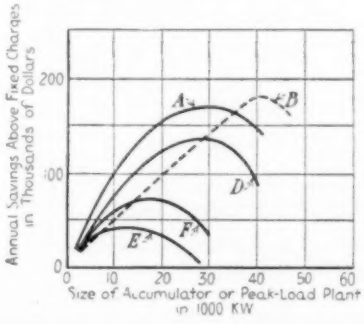

FIG. 10 ANNUAL SAVINGS THROUGH THE USE OF STEAM-ACCUMULATOR PLANT OR PEAK-LOAD UNIT ON A 200,000-KW. SYSTEM WITH 65 PER CENT ANNUAL LOAD FACTOR WITH COAL COSTING $4 PER TON
(See Fig. 9 for definition of curves.)

allows ample time for condenser cleaning, boiler and turbine maintenance, general inspection, and overhauling.

The following comparisons will be based only on fixed charges and fuel costs with the additional labor. It is assumed that repairs and maintenance, attendance, supervision, and other charges will remain substantially constant in all cases, and they are therefore not included in the comparisons, although it would appear that these charges should be less for accumulators than for boilers.

STEAM ACCUMULATORS VS. BASE-LOAD UNITS

To show the method by which the following analyses were made, a 20,000-kw. accumulator plant is assumed in Case 1 to

take the top 20,000 kw. of the maximum peak of 200,000 kw. of the 65 per cent annual-load-factor curve shown in Figs. 3 and 4. This will be compared with a base-load unit of 20,000 kw. capacity also applied to the load curves of Figs. 3 and 4 which will operate with an 80 per cent annual load factor. The standard plant is assumed to carry the remaining portion of the load in each case. The comparison of yearly costs is as follows:

CASE 1—STEAM ACCUMULATORS VS. BASE-LOAD UNITS, COMPARISON OF YEARLY COSTS

Steam Accumulator Plant (20,000 kw., cost $67 per kw.):		
Fixed charges, $0.15 \times 20{,}000 \times \$67$	=	$201,000
Fuel at 1.5 per cent annual load factor (30,000 B.t.u. per kw-hr.) $= 0.015 \times 8760 \times 20{,}000 \times \frac{30{,}000}{12{,}500} \times \frac{\$5.00}{2000}$	=	15,768
Standard Plant (180,000 kw.):		
Fixed charges, $0.15 \times 180{,}000 \times \$100$	=	2,700,000
Fuel at 72.2 per cent annual load factor (14,985 B.t.u. per kw-hr.) $= 0.722 \times 8760 \times 180{,}000 \times \frac{14{,}985}{12{,}500} \times \frac{\$5.00}{2000}$	=	3,411,933
1 extra operator, $\$0.60 \times 2920$	=	1,752
Total annual cost		$6,330,453
Base-Load Unit (20,000 kw.):		
Fixed charges, $0.15 \times 20{,}000 \times \$115$	=	$345,000
Fuel at 80 per cent annual load factor (14,150 B.t.u. per kw-hr.) $= 0.80 \times 8760 \times 20{,}000 \times \frac{14{,}150}{12{,}500} \times \frac{\$5.00}{2000}$	=	396,653
Total kw-hr. generated $(a) = 0.65 \times 8760 \times 200{,}000 = 1{,}138{,}800{,}000$		
Total kw-hr. on base-load unit $(b) = 0.80 \times 8760 \times 20{,}000 = 140{,}160{,}000$		
Total kw-hr. on standard plant $= (a) - (b) = 998{,}640{,}000$		
Annual load factor, standard plant $= \frac{998{,}640{,}000}{180{,}000 \times 8760} = 63.33$ per cent		
Standard Plant (180,000 kw.):		
Fixed charges, $0.15 \times 180{,}000 \times \$100$	=	2,700,000
Fuel at 63.33 per cent annual load factor (15,180 B.t.u. per kw-hr.) $= 0.6333 \times 8760 \times 180{,}000 \times \frac{15{,}180}{12{,}500} \times \frac{\$5.00}{2000}$	=	3,031,711
6 extra operators, $6 \times \$0.60 \times 2920$	=	10,512
Total annual cost with base-load unit		$6,483,876
Total annual cost, using steam accumulator		6,330,453
Annual saving by the use of steam-accumulator plant above fixed charges		$153,423

Table 2 presents Case 1 in tabular form together with Cases 2 and 3 for sizes of accumulator plants and base-load plants up to 40,000 kw. calculated for 65 per cent annual load factor as per Figs. 3 and 4. Two operators are provided for the accumulator plants in Cases 2 and 3, since these would have to operate for a portion of two shifts during the annual peak loads. The annual savings above fixed charges with coal at $5 per ton as shown in Table 2 are shown graphically by curve A, Fig. 9. The annual savings with coal at $4 per ton are shown by curve A, Fig. 10. Calculations were made in the same manner for the addition of steam accumulators or base-load plant to standard plant in systems with annual load factors of 45 and 25 per cent as shown by Figs. 6 and 7. The annual savings under these conditions with both $5 and $4 coal are shown by curves A in Figs. 11, 12, 13, and 14.

The annual savings above fixed charges that appear possible by the use of steam-accumulator plant, as shown by these tables and curves, are of such magnitude that an analysis will be made of the effect on the final results of changes in the assumptions on which the calculations are based.

In Case 1, if the first cost of the complete accumulator plant were increased as much as 25 per cent, the annual saving would still be $103,173. Doubling the fuel consumption for the steam

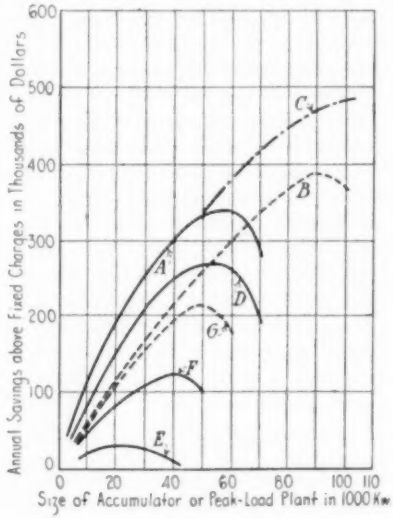

FIG. 11 ANNUAL SAVINGS THROUGH THE USE OF STEAM-ACCUMULATOR PLANT OR PEAK-LOAD UNIT ON A 200,000-KW. SYSTEM WITH 45 PER CENT ANNUAL LOAD FACTOR AND WITH COAL COSTING $5 PER TON
(See Fig. 9 for definition of curves.)

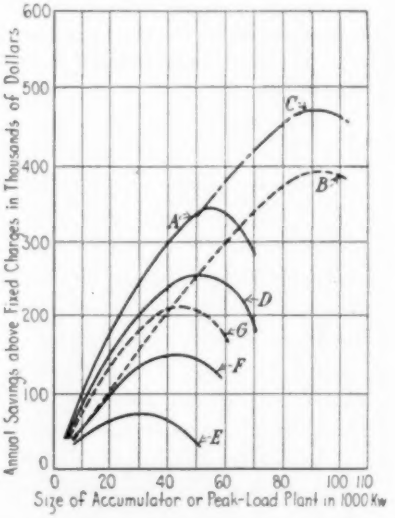

FIG. 12 ANNUAL SAVINGS THROUGH THE USE OF STEAM-ACCUMULATOR PLANT OR PEAK-LOAD UNIT ON A 200,000-KW. SYSTEM WITH 45 PER CENT ANNUAL LOAD FACTOR AND WITH COAL COSTING $4 PER TON
(See Fig. 9 for definition of curves.)

accumulator would decrease the saving only $15,768. Hence considerable variations in the initial cost and fuel costs of the accumulator plant will not wipe out its net savings. The effect of a change in the price of coal is variable, as can be seen by comparing points on curves A in Figs. 9, 11, and 13 for $5-per-ton coal with similar points on curves A in Figs. 10, 12, and 14 for $4-per-ton coal. An increase in coal price of $1 per ton will cause similar variations in savings in the opposite direction. It is interesting to note that in the case of standard plants the

effect of variations in coal cost is small over the ranges of size of accumulator plant that would probably be installed.

Considering the base-load unit in Case 1, a decrease in first cost to $100 per kw. will reduce its total costs $45,000. Even a 10 per cent reduction in heat consumption, resulting from higher boiler pressure and reheating, would only lessen total costs by $39,665. Normal variations in the costs of the base-load unit will not lower these costs to those of the accumulator.

Another factor is the variable element in the assumed heat rates. In the case of the base-load plant it is obvious that if the variable element is reduced, the coal cost of the base-load plant will also be reduced and the annual savings by accumulator or peak-load plant would be correspondingly reduced. For instance, if the variable factor is changed so that the heat rate of the base-load plant becomes

$$\text{B.t.u. per kw-hr.} = \frac{12{,}900 + }{\text{Annual load factor in per cent}}$$

$$\frac{80{,}000}{}$$

the base-load station's performance with 80 per cent annual load factor becomes 13,900 B.t.u. per kw-hr., a saving of (14,150 — 13,900)/14,150 = 1.77 per cent of its fuel cost. Except for the larger base-load plants this will have little effect on the final results shown by curve A in the various figures. If the variable factor of the heat rate of the standard plant is changed to

$$\text{B.t.u. per kw-hr.} = \frac{13{,}600 + }{\text{Annual load factor in per cent}}$$

$$\frac{80{,}000}{}$$

the annual saving in Case 1 would decrease $267. Calcu-

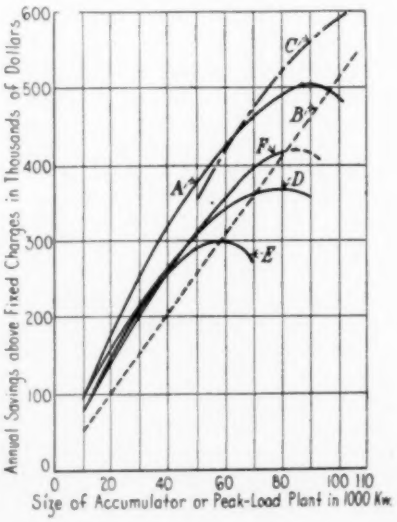

FIG. 13 ANNUAL SAVINGS THROUGH THE USE OF STEAM-ACCUMULATOR PLANT OR PEAK-LOAD UNIT ON A 200,000-KW. SYSTEM WITH 25 PER CENT ANNUAL LOAD FACTOR AND WITH COAL COSTING $5 PER TON

(See Fig. 9 for definition of curves.)

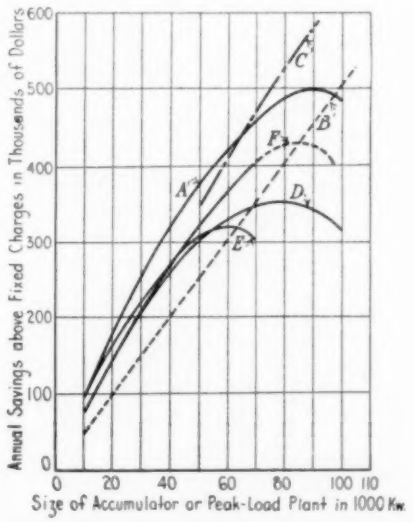

FIG. 14 ANNUAL SAVINGS THROUGH THE USE OF STEAM-ACCUMULATOR PLANT OR PEAK-LOAD UNIT ON A 200,000-KW. SYSTEM WITH 25 PER CENT ANNUAL LOAD FACTOR AND WITH COAL COSTING $4 PER TON

(See Fig. 9 for definition of curves.)

lations on the assumed plants indicate that reasonable changes in the assumed variable factor of the heat-rate equations for the standard plant, have no important effect on the annual savings of steam-accumulator plants.

PEAK-LOAD UNITS VS. BASE-LOAD UNITS

Calculations were made to determine the annual savings above fixed charges resulting from the addition of various sizes of peak-load plant in place of base-load plants. These savings are shown by the dotted curves B in Figs. 9 to 14. The difference between curve A and curve B in each case represents the difference in annual savings between the accumulator plant and the peak-load plant. This difference remains constant for a given size of accumulator and peak-load plant at a given load factor.

Curves A and B indicate the possibility of further savings with

25 and 45 per cent annual load factors from a combination of accumulator and peak-load plants. The annual savings from a few of these combinations are indicated by curves C in Figs. 11 to 14. These data indicate that the addition of peak-load plant effects no additional saving until the economic capacity of the accumulator plant is exceeded by the combined capacity of accumulator and peak-load equipment.

Steam Accumulators vs. Additional Standard Plant

Instead of adding a base-load unit to the system another unit may be added at the same cost and efficiency as those of the assumed standard plant. The annual savings that may be effected by the installation of a similar capacity of steam-accumulator plant to carry peak loads over the new standard unit are shown by curves D in Figs. 9 to 14.

Steam Accumulators on Systems With Standard and Old Plants

The figures having the greatest influence on the savings are the differences in the fixed charges of the accumulator or peak-load plant and the equivalent capacity of base-load plant. These differences will vary with the assumed plant costs. The next important influence is the saving in coal costs when load is transferred from one plant to another after the installation of the base-load plant. In the plants assumed in curves A, B, C, and D the differences in B.t.u. per kw-hr. between base-load plant and standard plant are not very great. Many electrical systems, however, are supplied from both modern and older stations which may have wide differences in heat rates. Consequently the shifts of loads between such stations when a base-load unit is added may result in a large saving in coal. If the relative sizes of old and modern standard plants in relation to the load-duration curve are such that this shift of load represents a large number of kilowatt-hours, the saving in coal costs by the installation of a base-load unit may offset, in a large measure, the savings in fixed charges that so greatly favor accumulator and peak-load plants.

An assumption was made that a system consisted of a certain capacity of standard plant whose station heat rate as before was represented by the formula:

$$\text{B.t.u. per kw-hr.} = 13{,}600 + \frac{100{,}000}{\text{Annual load factor in per cent}}$$

together with certain capacity of old plant with a heat rate as follows:

$$\text{B.t.u. per kw-hr.} = 19{,}000 + \frac{105{,}000}{\text{Annual load factor in per cent}}$$

A transfer of a kilowatt-hour of load from the old station to the standard plant, resulting from the installation of base-load plant, produces a coal saving of at least 0.4 lb. The annual savings that would result from the installation of an accumulator plant in place of a base-load plant, in a system with various combinations of standard and old plant with heat rates as above, are shown by curves E in Figs. 9 to 14. The value of the fuel saved by the shifts of load resulting from the installation of a base-load plant in such systems with high load factors offsets the advantage of lower fixed charges with accumulator plant, and leads to little or no net saving. With low load factors, however, this fuel saving is of less value, for fewer kilowatt-hours are involved in the shift of load, and the annual savings above fixed charges by the use of accumulator plant in place of base-load plant are large, as shown by curves E in Figs. 13 and 14.

Steam Accumulators on Systems With Mixed Plants

Many electrical systems do not have such wide variations between the heat rates of the old and the standard plant as in the preceding paragraph. Others may contain some plant with a heat rate intermediate between that assumed for the old and standard plant. Calculations were made to show the effect of the introduction of such plant, known as "medium plant," with a heat rate as follows:

$$\text{B.t.u. per kw-hr.} = 16{,}300 + \frac{100{,}000}{\text{Annual load factor in per cent}}$$

The annual savings above fixed charges resulting from the installation of accumulator plant in place of base-load plant in such a system are plotted in curves F, Figs. 9 to 14, and show a substantial increase over the savings shown in curves E. If the variations in heat rate were less extreme than those assumed and more intermediate plants employed, calculations indicate that the savings by the use of accumulator or peak-load plant in place of base-load plant will exceed those shown by curves F. This condition is approximated in many electrical systems where the operating equipment ranges from small, low-efficiency turbines and boilers, progressively up to the most modern highly efficient units. There are so many possible combinations of such plant with varying heat rates that many different costs may be obtained. Annual savings by the accumulator plant in one of these combinations are shown by curves G, Figs. 11 and 12. Calculations indicated that there could be a considerable variation in the proportions of the standard and older equipment for a given size of accumulator or base-load plant, without appreciably affecting the savings shown by curves E, F, and G, Figs. 9 to 14.

Attention has already been called to the differential between the annual savings of the accumulator and peak-load plant of a given capacity, which for given load factors, coal costs, and capacities of units is shown by the distance between the curves A and B. This differential at the same accumulator or peak-load unit capacity can be applied to curves D, E, F, and G in the respective figures if the annual savings by the use of peak-load units with these various combinations are desired.

Conclusions

With the assumed cost data and a triangular peak, the steam accumulator loses its advantage if the base of the peak that it is to carry exceeds four hours. These studies have been made on load curves with sharp annual peak loads such as occur in some cities with large lighting loads. Calculations indicate that peak-load units are less economical than an accumulator plant except in the large sizes. On the other hand, the availability of peak-load units for emergency service, particularly in the case of long-sustained peak loads on dark days, is greater than that of the accumulator. The same degree of availability may be secured on the accumulator turbine by making it a mixed-pressure unit.

The load-duration curves of systems with broad, flat daily peaks may show a certain portion of the annual peak which has a low annual load factor. The long duration of such daily peaks will favor the installation of a peak-load plant in preference to steam accumulators.

A steam-accumulator plant could carry peak loads other than during the annual peak, and this would lead to station economies due to the operation of fewer boilers and standard turbines. The charged accumulator is also available for emergencies during off-peak hours such as thunderstorm peaks, fog, etc. The charging of the accumulator with steam during the night would improve the load on the boilers, and this should lead to more efficient boiler-house operation during that period. Accumulators require little maintenance and repairs, and this cost will be less than for the equivalent capacity of the boiler plant.

Accumulators are subject to little wear and tear, hence their rate of depreciation should be less than that of a similar capacity of boiler plant. No financial credit has been given in this paper to the accumulator plant for any of these savings, although it is reasonable to expect that these may be of a substantial size. The annual savings shown by the various curves refer only to the annual peak load of the system.

The accumulator, with its lower first costs, saves in fixed charges. The base-load plant saves fuel. The net savings depend on the relative values of these two savings, and as shown by the various curves given in the paper, may amount to a large sum of money.

An important point shown by curves A, B, C, and D in the various figures is that steam accumulators and peak-load units effect their largest savings when added to a system consisting of standard plant with modern equipment only. Accumulators have usually been considered for addition to systems with older plants, whereas this study indicates that they can effect the largest savings when applied to systems with the most modern plants, provided these carry sharp peak loads.

A second striking fact is the large margin of saving that may be secured by the use of accumulators in place of base-load plant to carry annual peaks with any plant combination when the annual load factors are low.

A third point of interest is that the lower the price of coal, the larger the accumulator savings in systems with old and mixed plants, as shown by comparing the curves for different coal prices. This results from the fact that the value of the fuel saving effected by the addition of base-load units is less with low-priced coal than with expensive coal.

It is well to bear in mind in studying the figures presented in this paper that the results refer specifically to the assumed data. In conclusion, although these studies do not consider all possible cases of annual peak loads, they will direct attention to the importance of considering methods of carrying such peak loads and the possible place of steam accumulators and peak-load units in modern central stations. Since each system is a problem in itself, and should be considered separately, this paper may suggest ways of studying the peak-load problems of various power systems.

Discussion

GEORGE C. USHER.[4] It will probably be conceded that the peak-load problem in British power stations will undergo a very considerable change as the Electricity Act comes into operation and the linking up of selected stations takes place. It is reasonable to suppose that the larger selected stations will operate as base-load stations, while smaller stations in each area will be used as peak-load stations and brought into operation only to take the peak loads in each group. In the immediate future, however, each station will have its own particular peak-load problem to deal with, and whatever method is adopted there are two main considerations which must be generally satisfied. These are, first, that the response of the plant to peak-load demand shall be immediate and, second, that the response shall be capable of indefinite prolongation.

In the boiler house both of these important points can be met with pulverized fuel. Pulverized-fuel-fired boilers are capable of wide and immediate variation of load, together with a high standard of generating efficiency at all ratings. The steam generator, which is the logical development of such boilers, fitted with water screens and walls, has enabled a plant of high evaporative capacity to be installed at comparatively low first cost.

[4] General Manager, Director, International Combustion Engineering, Ltd., Kingsway, London, England. Assoc. A.S.M.E.

For a station where the peak loads are frequent and of short duration, it is possible to take these peaks by driving the generators beyond their normal continuous rating. It is not possible to advocate this practice with stoker-fired boilers, however modern the design, since the maximum rating is definitely limited by the grate performance. It may seem an exaggeration to say that the evaporation from a steam generator is limited only by the rate by which it can be fed with water; but, provided intense circulation can be maintained and the burners are designed for short turbulent-flame production, the evaporation per square foot can be brought to exceedingly high figures, and in emergency can be pushed well above the normal maximum running.

Stations having a well-defined peak of several hours' duration are best served by the installation of peak-load generators. These can be brought up to pressure in the minimum of time and at minimum cost, and can with perfect ease be banked ready to go on the line; they are available, therefore, not only for peak-load service but for emergency service.

By far the greater part of the paper is taken up with a cost analysis of various methods of carrying peak load on a 200,000-kw. system with varying peak load and varying load factor. The disadvantage of such a method is that the results of such an investigation are only of special application, and for other reasonable cases could be assumed to give entirely dissimilar results, such as a station having high annual load factor with a fairly high percentage peak of steady duration. Further, the basic figures of plant cost compare very unfavorably with such as can be obtained in this country for a station of such large capacity. The coal cost figure also seems extremely high.

(1) A large increase in size is necessary with increasing duration of demand
(2) The heat consumption rate per kilowatt hour is extremely high, and often more than twice that of an efficient generating plant
(3) The accumulators are not necessarily available in sudden emergency such as the breakdown of plant.

M. D. ENGLE[5] AND G. R. DAVISON.[6] The paper is timely, and it brings up for discussion the question of the most economical equipment for generating the low-load-factor portion of the system load, or, in other words, those kilowatts which result in the sale of very few kilowatt-hours of electrical energy. To supplement the paper we would like to point out several factors which have not been brought out and which have a very important bearing on the subject.

The first of these is the factor of turbine-generator inspection and maintenance. This factor is not very important on systems which have a summer load that is very small compared with the peak load of the previous winter, but let us consider a system with a lighting and power load such as shown by Fig. 3 in this paper.

Fig. 15 shows the daily load curves of the Edison Electric Illuminating Company of Boston expressed, for the convenience of the discussion, as a percentage of the 1927 annual peak. The load factor of this system has been increasing year by year and is approximately 40 per cent at present. The peak load is growing at the rate of approximately 9 per cent per year, and so we believe can be taken as representative of many systems in this country. The peak load during the summer of 1928 was approximately 80 per cent of the peak load of the previous winter,

[5] Station Engineering Department, The Edison Electric Illuminating Company of Boston, Boston, Mass. Jun. A.S.M.E.

[6] Generating Department, The Edison Electric Illuminating Company of Boston, Boston, Mass.

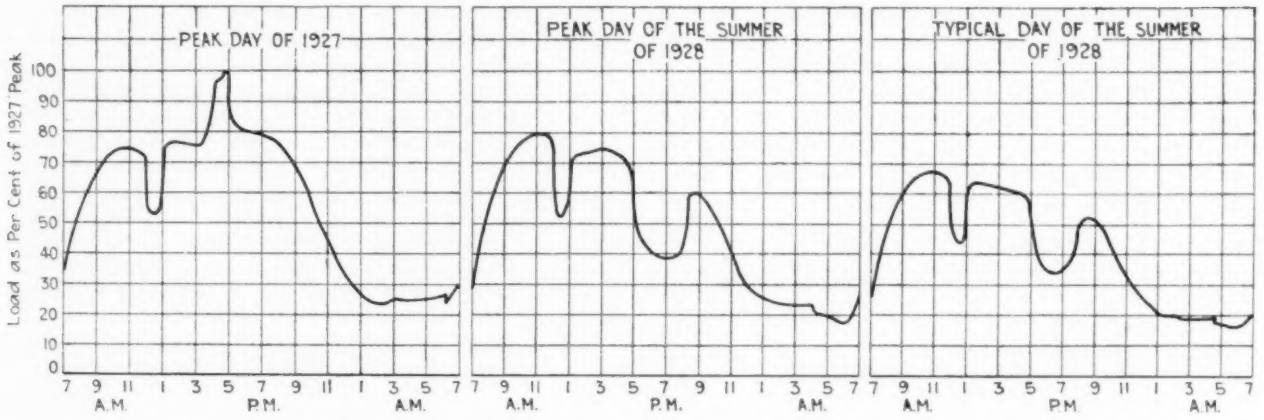

FIG. 15 DAILY LOAD CURVES OF THE EDISON ELECTRIC ILLUMINATING COMPANY OF BOSTON

and the peak load on a typical week day during the summer of 1928 was approximately 67 per cent of the peak load of 1927.

Let us consider a system which has daily load curves such as shown by this chart and the annual peak of which is 200,000 kw., as was assumed in the studies given in the paper. From this chart it is seen that such a system would have a peak load of 160,000 kw. during the summer following the 200,000-kw. annual peak. The peak load on a typical day of the same summer would be approximately 135,000 kw.

It is good operating practice to open up all turbine generators once a year for inspection and maintenance. If the number of machines on the system is large and the inspection and maintenance work is carried on during the whole year, to serve the system load will require an installed generating capacity between

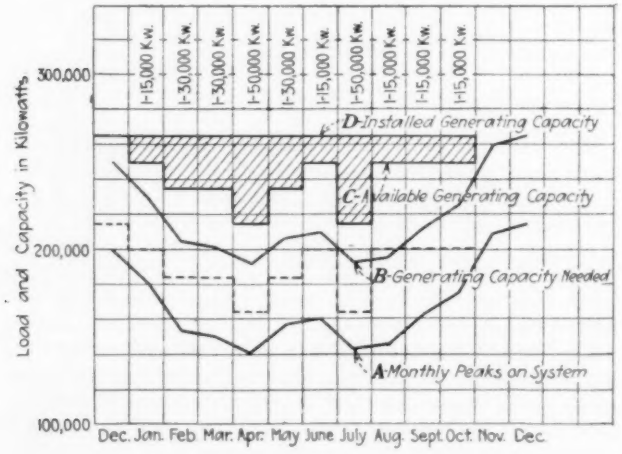

FIG. 16 MONTHLY PEAKS OF SYSTEM

20 and 30 per cent greater than would be required if all machines were available for carrying load during the few months of the year when the annual peak load might be expected to occur. We believe that all will agree that the economical method is to arrange the maintenance schedule so that all machines are available during the peak period.

The 200,000-kw. system that we are considering might be served by five 55,000-kw. turbine-generator units. In actual practice, however, such a system would probably be served by units varying in size from 15,000 kw. to 50,000 kw. Let us assume that there are five 15,000-kw. units, three 30,000-kw. and two 50,000-kw. units, having a total capacity of 265,000 kw.

Fig. 16 shows the monthly peaks on the system for the spring and summer following the 200,000-kw. annual peak and also the generating capacity needed and the generating capacity available.

The maintenance schedule for this system would require that ten turbine-generator units be opened up during the year. It has been our experience that this inspection and maintenance require an average of one month per machine. This time would probably be less for the smaller and longer for the larger machines, but for simplicity we have shown each unit out for one month.

Curve *A* shows the monthly peak loads on the system for the year following the peak load of 200,000 kw. in December. Curve *B* shows the generating capacity needed on the line to supply the load and protect the continuity of the service by having at all times sufficient capacity on the line so that the load can be carried if the largest unit trips out for any reason. Curve *D* shows the installed generating capacity of 265,000 kw., and the cross-hatched area shows the capacity of the units out of service for inspection and maintenance. The curve *C* at the bottom of the cross-hatched area shows the generating capacity available during the time when the various units are out of service.

The dotted curve shows that at no time during this period would there be sufficient generating capacity if a 50,000-kw. unit was unexpectedly lost. These curves show that in this setup we are not attempting to protect against the contingency of having a unit out of service for maintenance when a 50,000-kw. unit fails; and yet with the number of units involved that is really a possibility.

There are no units on such a system that are standing idle all year waiting for the annual peak. In fact, practically all of the available units will be operating for a considerable number of hours, practically every month of the year. This same general statement is true for steam-generating equipment.

We therefore do not see where the strictly peak-load equipment is justified unless for some special reason the system has an abnormal peak during a very short period of the year.

H. HOBSON.[7] The paper resolves itself into a comparison of the merits of installing Ruths steam accumulators together with suitable generating plant for dealing with the peak load with the benefits from installing new and efficient boilers and generating plant for dealing with a corresponding amount of base load. It is assumed, in either case, that the load on the balance of the system would be dealt with by plant referred to as "standard plant."

The argument in favor of the installation of steam accumulators

[7] Supply Engineer, Central Electricity Board, Charing Cross, London, England.

and equipment is really based on the claim that the increased heat consumption per unit generated by the steam-accumulator plant is more than offset by the reduced capital charges as compared with new and efficient boiler and turbine equipment assumed to be installed for dealing with the base load.

On the basic data assumed in the paper, it would, however, appear to be impossible to make a case for the installation of base-load plant at all. This is due to the fact that, as compared with the standard plant, the reduced heat consumption of the base-load plant would not effect a sufficient saving in coal cost to cover the increased capital charges incurred.

Even if the base-load plant were operated at 100 per cent load factor, the saving in coal cost would be less than one-half of the extra capital charges incurred. Having regard to both capital charges and efficiency, the base-load plant is thus very much worse than the standard plant, and in no circumstances, therefore, could a case be made for its installation.

The foregoing anomaly has a direct bearing on Table 2, which gives the annual costs incurred by the installation of a steam-accumulator plant for dealing with the peak load as compared with the installation of a corresponding amount of base-load plant. It will be seen that the case for the installation of a steam-accumulator plant is seriously impaired, if the comparison is made with the costs which would be incurred by the installation of further standard plant instead of by the installation of base-load plant.

Apart from these considerations it is doubtful whether it is sound economics under present-day conditions to install plant for peak-load operation. If no further improvements in power station design could be foreseen, it would certainly pay to construct cheaper and less efficient plant for dealing with the peak load. Under present conditions, however, the improvements in power station design are so rapid as to warrant, in many cases, the scrapping of existing plant before it is actually worn out. In these circumstances, it is evident that the tendency should be toward running the older existing plant at peak load, and not toward spending capital on new plant to deal with this load.

So far as the conditions in Great Britain are concerned, a further aspect presents itself as a result of the transmission system which is now being constructed by the Central Electricity Board.

This transmission system, commonly known as the "grid," will interconnect all the stations required for generating the electricity supply of the country. The base load will be generated by efficient stations which will be in continuous operation, but the peak load will be generated by the less efficient stations which will be brought into operation when required.

From this point of view, it does not appear that the steam-accumulator plant would have any advantages to offer, as it necessarily involves the boilers generating steam for the purpose of charging the accumulators at times of light load on the station. In general, however, when the "grid" system is complete, it is not proposed to operate stations under these conditions. The peak-load stations will be brought into operation when required, during which time they will be generating nearly their full output. After the peak load has been dealt with, the stations will be closed down, thus enabling substantial savings in standby coal and labor costs to be effected, and this clearly would not be possible if the boilers had to be kept under steam for the purpose of charging steam accumulators.

LEE J. LEVERT.[8] The paper outlines an ideal system—a system where there are no troubles; a system where all machines, boilers, and feeders stay in; a system where all the overhauling is done on schedule time; a system where the customers are drilled to turn on and turn off the lights on certain schedules assigned to them by the public utility management.

The system outlined is a dream, however—a dream of every public utility executive; it is a dream of every operator. Our friends from Boston sound the first pessimistic note. You know the tea party which started the Revolution took place in Boston. They tell their brethren in Maryland that it is quite possible that the machine might trip out while under load. They also say that sometimes it is impossible or inadvisable to overhaul the machines on the off-peak time and there is a likelihood of the necessity of taking the machine out when the load is very heavy.

I am still more pessimistic than our friends from Boston, and I say that not only turbines but boilers and feeders are quite likely to have their tantrums. There is no relationship between the turbine outage and that of the boilers and feeders. It is quite likely that we lose turbines in one place, feeders in another, and boilers in a third. It reminds me of the case of a person having a blue coat and gray vest in one place and a gray coat and blue vest in the other; similarly, it is quite possible that we might have an excess boiler capacity due to turbine outage at a station in one place and an excess generator capacity in another. It does not do any good for the East River superintendent to know that Hell Gate has an excess steam capacity to run East River turbines, because that steam is just as unavailable as if Hell Gate station was in Shanghai, China. I take pleasure in paraphrasing Lincoln's saying as "You can run some of the equipment all of the time, and you can run all of the equipment some of the time, but you cannot run all of the equipment all of the time."

We can obtain the base load to be carried by the system from the load-duration curve. The economical capacity required, however, to carry the base load must be at least 30 per cent greater than the base load itself, because we must provide for an outage for repairs and an outage on the load at any point of the system. Inasmuch as the turbine represents the greatest concentration of capacity, which might not be true a few years from now when some of the 80,000-kw. boilers will be in operation, only turbines need to be considered. We have to assume that any station might have one of its largest units out for repairs and another unit in the same station might trip out during the peak load of the system.

I believe that all the peak capacity can be taken care of by the overload valves of the turbogenerators, forcing the boilers, and old generating stations. Why in the world should we spend more money for peak-load capacity when we have all generating capacity which can take care of the extreme peaks and be used as standbys for emergency?

Of course, there are cases when the dismantling of old equipment might be dictated by economical situations such as land values or change of the nature of the locality, or the advance of the art might be so great as to make it economical to replace this equipment by more efficient machines. I would suggest adding another curve to the multitude of curves which are already used for power-plant work. The curve I suggest is a curve which would show the capacity required to carry the loads shown by the load-duration curve, and for the want of a better name I would call this curve the "capacity duration curve." This capacity duration curve would give us the capacity which the system must have available in order to maintain certain reliability standards at all times when handling the load indicated by the load-duration curve.

I. E. MOULTROP.[9] There is no such thing as a base load station. Any station may be operated on base load for the first few

[8] Assistant Engineer of Power Plants, The United Electric Light and Power Company, New York, N. Y. Jun. A.S.M.E.

[9] Chief Engineer and Assistant Superintendent, Construction Bureau, Edison Electric Illuminating Company of Boston, Boston, Mass. Mem. A.S.M.E.

years of its life or any station may be operated on the base load during certain parts of the year, but there is no such thing as a 100 per cent load factor station, and we should stop talking about such dreams.

From some of the discussions presented, the writer is inclined to believe that some of the discussors have read this paper very casually. If they have, they have made a mistake. Assuming the conditions that the author has set up, his figures are approximately correct. The only problem is to find a situation where those assumptions apply.

The power industry is growing so fast that the electric utilities find they have a large amount of obsolete generating equipment on their hands. This obsolete equipment generally proves to be the cheapest peak equipment that they can use.

There are a number of fields where the steam accumulator may be justified. The central steam-heating business is growing rapidly. It may be that the steam accumulator will play an important part in the development of this industry. It also appears logical that the steam accumulator may be economically justified in industrial installations which have rapidly fluctuating demands for hot water and steam.

Warren Viessman.[10] The author has presented a very interesting paper on the present practice of applying and using the steam accumulator, principally on the Continent. The manner in which he has covered the procedure for analyzing and selecting an accumulator is very useful. It is the kind of analysis that we need to consider in our problems, and although, as a number of speakers have said, there are certain cases where we would not want to consider an accumulator, there are also many others where it might be advisable.

My experience with large central stations has been in accord with that of the previous speakers; that is, there are many factors which enter into such a determination, and in order to be certain that the plant can carry the load when machines are out for repair, an accumulator or even a peak-load installation is not usually advisable, base-load machines being much preferred.

However, on central-station systems which have a peak load similar to that of the city of Berlin it is doubtless advisable to have a steam-accumulator installation to take care of the highest peak load, after standby equipment has been put on the line. In the small isolated central stations the peak loads are rather severe at times and of short duration, and in a central station of this type an accumulator unit might be most desirable.

I appreciate what the previous speaker said in regard to the use of an accumulator on a central district heating system. On such a system when heat is put on on cold mornings, the peak is very heavy, and for half an hour or perhaps an hour the use of an accumulator would be most beneficial.

One of the broadest fields for the application of such equipment is the industrial field. In that field there are many opportunities of application in industries where the steam consumption for process work is short but heavy, and application in industries of this type does not require a special turbine, but merely the accumulator installation itself to meet the process steam requirements, relieving the boilers which are usually operated nearly to capacity all the time. With an accumulator the process steam could be generated in the boilers and stored in the accumulator during the periods of light power loads and withdrawn from storage during the periods when the power and process loads are very heavy.

A. E. R. de Jonge.[11] The very able paper has interested me very much. There is one point which has not been brought out by any of the previous speakers, and this is that the steam accumulator can have application only in power systems where conditions are fairly stable; i.e., where large increases in capacity are not expected. In any rapidly growing system I do not think that the steam accumulator will stand any chance whatsoever.

I have been associated for over nine years with one of the most rapidly growing plants in the world, the power station of the Shanghai Municipal Electricity Department in China. You may picture to yourself power stations in China as some small and unimportant affairs, not very modern, erected in some out-of-the-way place, and probably kept up badly. But that is one of the most modern plants in the world.

The Shanghai station is only one plant, not a system of interconnected plants such as in this country, and yet the load factor is as high as 60 per cent (see *Engineering*, June 1, 1928, pages 685 and 805); and I believe that this is one of the highest, if not the highest, load factor for any single station. These remarks refer to conditions as they were in February, 1928.

This system has had a most remarkable growth, having grown during the nine years of my association with it from a capacity of 39,000 kw. to 161,000 kw. From my intimate experience with that system, the steam accumulator has no chance whatsoever in such a rapidly growing system.

R. A. Langworthy.[12] The author has emphasized a phase of power-plant development that is well worth the attention of those interested in the design, construction, and financing of such plants.

In the last ten years great strides have been made in the matter of increased efficiency, and the performance of the large modern power plant is remarkable when the results of ten or fifteen years ago are considered.

It seems to the writer, however, that in the endeavor to gain the last fraction of a per cent in efficiency some of our engineers and designers perhaps have lost sight of the very important factor of fixed charges on the investment. The fixed charges are an important part of the cost of electric power, and when the station is finished they are a permanent burden and cannot be affected in any way by the future operation of the plant, no matter how well organized it may be.

It is a matter of serious question sometimes whether, in our effort to reach the last notch in efficiency, our investment has not been increased by an amount which would actually show a net loss on the overall cost of the power, when both fixed charges and operating expenses are considered.

The modern power plant is a complex institution and contains a great deal of apparatus upon which the designers have expended their best thought. They have, undoubtedly, produced very efficient machinery, but as is often the case efficiency beyond a certain point is attained at the expense of a proportionately larger increased cost of the equipment involved.

In stations having an average load factor, much of this expensive equipment, representing a considerable part of the investment, is installed to meet the peak loads and is idle for a great part of the time, although the fixed charges continue 365 days in the year.

It is manifest that any design which will reduce the investment necessary to carry the peak load and thereby reduce the fixed charges should have most serious consideration.

The author has pointed out a method of meeting the situation of peak loads by means of the steam accumulator. So far as the writer knows, this piece of equipment has never been seriously considered in the United States in conjunction with the central power stations. Its application, however, to large power stations

[10] Director, Bureau of Mechanical and Electric Service, Baltimore, Md. Jun. A.S.M.E.

[11] Designer, New York Edison Company, New York, N. Y. Mem. A.S.M.E.

[12] United Engineers and Constructors, Inc., New York, N. Y. Mem. A.S.M.E.

for the purpose of carrying the peak loads might be termed unique in the history of such plants on this side of the water. It would seem that in the future design of large central stations this piece of equipment should be considered on its merits, the same as any other part of the power plant, and a decision on whether to install it should be based upon its effect on the total overall cost of generating electric power.

LOUIS ELLIOTT.[13] The author has done the profession and the utility industry a service by presenting in clear fashion a specific problem in providing for peak loads on a power system, with a solution comparing alternative schemes. In this country it has been the usual procedure, in building up a steam-power system, to install a plant unit to carry base load— at least for the first portion of its life. Such units have almost always been designed to give an efficiency at least equal to that of the best existing facilities, with the assumption that the low-load-factor portion of the annual requirements could be carried advantageously by the less economical equipment already in service.

Although this course of action has in general been wise, especially considering the radical improvement in the art, the rapid growth of power systems, and the frequent consolidations during the past decade, it is timely that attention should now be drawn to other methods of system extension. Basic conditions in not a few regions are becoming more nearly stabilized, load growth is going on at a lower rate, and station economies may not improve as fast as heretofore. In some cases the base load can be taken care of economically by existing capacity, and it is the increasing peak that must be provided for.

Whereas in the past steam accumulators have appeared to American utility engineers to be suitable chiefly for industrial work, Diesel engines have been used in relatively small sizes only, and plant units designed specifically to carry peak loads have been rare, a careful comparison of different methods for carrying peaks should now be made, with no prepossession in favor of past practice. As has not infrequently been the case in other developments, European engineers have led the way in the adoption of certain of the newer methods of handling peaks on steam-power systems—such as the aforementioned use of steam accumulators and the installation of Diesel engines. Although European conditions are frequently quite different from those obtaining in this country, and although solutions of problems on a moderate scale cannot always be applied on a large scale, certain combinations of circumstances may justify the adoption of methods heretofore little used by utilities in this country.

It is evident that a great deal of careful analysis was required in the preparation of the paper, and the resulting curves and conclusions, based on the assumed conditions, are most interesting. As is stated in the paper, however, it would be unwise to apply to any new problem the principles laid down, without a careful collection and analysis of pertinent data; a moderate variation in sharpness or duration of peak may change entirely the economics of the case.

ALPHONSE A. ADLER.[14] The writer sees a great many applications of steam accumulators in industrial plant work. He has in mind dyehouse work in particular. Here the peak loads come twice and sometimes three times a day, depending upon the type of goods in process. There are additional advantages in plants of that character because they can not only use the steam for process work but can also use the hot water to start the tubs at a higher temperature so as to release some of the boiler capacity required in warming up the water beforehand. That is an excellent application for steam accumulators. However, a great many local plants are not sufficiently large to warrant the installation of complicated equipment. Engineers are compelled to design these small plants for operators who know just enough to run a plant like a great many plants they have seen. If you give them a new machine, you sometimes have to train a new man for the job.

N. E. FUNK.[15] The author has presented in a clear manner the thought of the possibility of installing peak-load rather than base-load plants, and in his conclusions has pointed out the fact that suggestions in this paper are not a cure-all for every power problem.

The writer believes it may be well to emphasize some of the factors involved in this problem. If steam accumulators are installed instead of base-load units, there is a decrease in installation costs, but the old plant must produce much more energy than would be the case were base-load units installed. Therefore, basically, the savings in annual charges, due to lesser installation costs, are reduced by an amount equal to the product of the energy that would have been produced by the base-load plant had it been installed and the difference in the increment operating costs of the old plant and base-load plant. Decreases in the difference between the cost of installing the steam accumulators and the base-load units, or increases in the increment difference, reduce the net saving. These changes may even produce a negative result in respect to saving, in which case it would be more economical to install the base-load units.

A very rough comparison is given in Table 3, using some of the figures in the author's Case 1, but changing the increment energy cost difference between the old plant and the new base-load plant.

TABLE 3

Difference in mills per kw-hr. between increment energy cost of old plant and base-load plant	Annual savings by installing accumulators	
	With 15% annual carrying charges	With 12% annual carrying charges
1.50	−$ 35,000	−$ 64,000
1.30	− 7,000	− 36,000
1.00	+ 34,000	+ 5,000
0.7	+ 75,000	+ 46,000
0.3	+ 130,000	+ 101,000
0.1	+ 158,000	+ 129,000

The table distinctly shows that with large differences between the increment energy costs of the new base-load plant and the old plant the installation of steam accumulators would result in a loss as compared with the installation of new base-load units. The same situation would hold as the difference in cost between the installation of base-load units and steam accumulators decreases.

In combination hydroelectric and steam-electric generating systems, where a variable river flow occurs, the hydroelectric plant must be utilized during the high-flow period as a base-load plant and during the low-flow period as a peak-load plant. To obtain the maximum capacity value from the hydroelectric plant at extreme low flows it is necessary to utilize it on the extreme peak of the load. This would force the steam-accumulator section of the steam plant into a section of the load where the duration would be considerably longer than four hours and would immediately put it beyond practical consideration from the point of direct increased carrying capacity, although it still might have a use as an emergency reserve.

The steam accumulator has been used in the past for smoothing out very rapid power fluctuations such as in rolling-mill engines

[13] Mechanical Engineer, Electric Bond and Share Company, New York, N. Y. Mem. A.S.M.E.

[14] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

[15] Assistant General Manager, Philadelphia Electric Company, Philadelphia, Pa. Mem. A.S.M.E.

and for like services. An installation of this kind might be feasible and show a considerable economic advantage in a station supplying railway service only, with extremely high peaks of very short duration, in which case the accumulator would alternately store and release energy without very great change in pressure. It would thus permit the boilers to operate at a much better efficiency.

The steam accumulator has an additional disadvantage in its application in a large power system in that it is an inflexible tool and is incapable of as wide use in the load curve as a standard plant.

In determining the usefulness of this type of plant it is therefore necessary to predict the type of system load over the useful life of the projected accumulator plant, the projected base-load plant, or the projected peak-load plant in order to decide which would give the maximum economy for the entire life of each type of installation.

The author in his conclusions has definitely pointed out that the results presented in his paper do not indicate that steam accumulators should be applied to all systems having very sharp load curves, and distinctly warns against this assumption. Even though it is a repetition, the writer desires again to call attention to the fact that this application of steam accumulators must never be considered as a sure economic possibility and that each case must be carefully considered, giving due weight to all the variable factors in each specific problem, before a sound decision can be made.

H. L. H. Smith.[16] It seems to the writer that one of the most fundamental aspects of the whole question is whether a power company should spend money on handling its peak load or whether it should spend money only on handling the base load. It seems that the question can be considered from two sharply divergent aspects, one of which has a basis in reality and the other has not, although it has significance in clearing our ideas on the matter. If, for instance, any electric power company were confronted by the extremely unreal situation of building up a large power system in a community which had only started, but which it was known in a matter of half a dozen years would attain a large size, the electric company might reflect that in half a dozen years it would have to handle a peak load of a certain high value and a base load of much lower value, and it hence might consider actively whether it should scheme to handle the peak load by the use of accumulators. Actually, of course, no such situation ever confronts any company.

What we always have is a growing system, so that in considering the illustrations of the paper, the horizontal axis always remains the same, whereas the vertical axis is always expanding, so that if a company installed an accumulator system at any stage of its growth, as the years went on that accumulator system would be able to operate a lower and lower number of hours each year. Of course, the answer of American systems as to whether they should spend money to handle peak loads has unmistakably been in the negative. It is an open question as to whether the answer will always remain so. The writer thinks that all will agree that considerable light has been shed on the question by the paper.

Among the somewhat radical schemes that have been suggested to handle the peak load of a constantly enlarging system is one that occurred to an executive of this company, which is situated on the Atlantic Coast. He said that he would like to have a study made which would consider if there would be anything in the idea of constructing a steam station on a barge and hauling it up and down the coast line from one year to another in order to handle the peak load in the most efficient manner, as it might be acute in one season in one locality and more acute in another season in another locality; the idea being that the turbine and boiler plant constituting the floating peak-load station should be especially designed to represent low cost of installation, economics of operation of course working the other way. Such an investigation has been started, but no answer as yet has been obtained.

F. T. Leilich.[17] The author has presented a very interesting set-up of the economics of accumulators for hypothetical plants, but it is not possible to draw other than very general conclusions from it.

His assumed B.t.u. per kilowatt-hour and unit costs are somewhat better than for the average modern plant. Taking Case 1 as being representative, the saving of $153,000 for the accumulator is less than 12 per cent on the investment. This saving would be reduced to about $100,000, or 8 per cent net, if the slightly improved annual load factor was not credited with 1.3 per cent economy betterment. Estimating on the very elusive duration curve for future years does not provide a very secure basis upon which to make large expenditures. With the growth of power systems and interconnection the whole becomes more elastic for the load dispatcher, and as the most economic point of operation is generally less than full load, the reserve capacity in machines operating on the line is large, and short-duration peaks may be easily handled. In a small system an accumulator and special turbine installation must be backed up by reserve capacity; and for a large network the elasticity of the system will enable it to absorb swings and peaks. The accumulator and its turbine are not readily adaptable as a universal reserve.

The annual load factor is of little use in preparing an operating and cost schedule, because service outage, and the base, peak, and hydro power available must be considered in preparing load schedules during the year.

The study seems to overlook certain important practical considerations essential to insuring continuity of service. To fulfil its mission of carrying load over the peak hours as shown by the load-duration curve, the accumulator and its machine would have to be charged and on the line for more than the entire period over which the peaks extend because the amount and time of these are not exactly known nor can they be predicted much in advance. To carry the accumulator equipment as capacity reserve during times of reduction of available capacity for overhaul and inspection would involve operation of the equipment over greater periods, with resultant increase in the kilowatt-hour output. Based on total operating and fixed costs of the plants as assumed, the savings are less than $2^1/_2$ per cent and the fuel costs are roughly 50 per cent of the total; therefore the margin is only 5 per cent to cover unforeseen conditions of load, coal costs, etc.

The accumulator undoubtedly has a place in power generation, but each system must be considered as a special case and detailed studies must be made accordingly. Considering the uncertainties of future load and interconnections, it seems reasonable to insist that an installation of special equipment should clearly show a net return sufficient to cover a reasonable divergence from estimated conditions and at the same time assure the investors a substantial profit.

Author's Closure

We have heard most of the objections that may be raised to the use of steam accumulators in electrical power plants. These have been presented principally by men who are primarily interested in the operation of such plants. Their opinions have quite evidently been based on operating rather than financial considera-

[16] Research Engineer, New England Power Company, Boston, Mass. Mem. A.S.M.E.

[17] Research Engineer, Consolidated Gas, Electric Light and Power Company, Baltimore, Md. Mem. A.S.M.E.

tions. Operators wish to have only standardized equipment in their plants in order to simplify operating problems, although, as the paper itself emphasizes, this may not result in the production of power at the lowest total cost for a given set of load conditions.

It has been pointed out repeatedly in other discussions that whereas the production cost of power has decreased through the use of large high efficiency units, the fixed charges per unit of output have changed but little for several years. Public-utility executives are asking engineers to consider first cost more carefully, and will soon demand plants of lower first cost in order to further reduce total power costs. This will mean a reconsideration of plant design, of unit sizes, and of means for carrying peak loads in the cheapest possible manner. When engineers study the problem from this viewpoint, the advantages of steam storage will be obvious where high peak loads of short duration must be carried. The author believes with Mr. Moultrop that many engineers have only read this paper in a casual way.

Several speakers referred to the advantages of steam accumulators in industrial plants and on heating systems. It is now quite generally recognized that steam storage has distinct advantages in these services and that such uses will be extended very rapidly as opportunities are presented to add such new equipment. In view of the unanimous agreement in regard to this use of steam accumulators discussion of these applications was omitted from the paper, which is confined solely to demonstrating the economics of adding accumulator plant to steam power stations to carry peak loads.

The possible use of older equipment for stand-by and peak-load service is fully recognized and discussed in the paper. There is little question concerning the suitability of this equipment for such service. The question raised in the paper is whether it may not be cheaper to add low-cost accumulator plant to carry peak loads and to maintain the present plant in continuous service carrying regular loads for more years, than to buy further new standard equipment and to relegate present equipment to peak-load service only. This is a financial as well as an operating problem, and as shown in the paper, there are conditions where the addition of accumulator plant may save large sums of money annually.

There is another point in regard to the growth of load in this country that must not be overlooked. Power salesmen have been very active in our utilities until almost all the present available power loads have been added to the utility's service. These additions have materially improved load factors and have lessened the sharpness of peak loads. Are we assured that the power demands will continue to grow at an equal rate as lighting peak demands? This is questionable, and in some cases there are indications of the reappearance of sharp lighting peaks. As one of the discussors pointed out, some customers have already been notified to limit their peak loads. The author knows of a large system which can force certain consumers to discontinue their demands at the time of peak load and furthermore pays them rebates for so doing. Are such policies right? Would it be better economics to utilize steam-accumulator plant to carry these peak loads and to allow the customers to continue manufacturing at their maximum output? After all, it is the extra marginal production over a certain definite output that fixes profit in an industrial plant. The necessity to curtail this extra production must diminish the manufacturer's profits to a greater extent than he is recompensed by any possible rebate that the utility may pay. The utility should therefore be prepared to meet any possible peak demands that may occur in serving the consumer.

Referring specifically to some of the points raised in the discussion, Mr. de Jonge objects to the use of steam accumulators on a rapidly growing load. That is exactly the type of load in the city of Berlin on which the German engineers decided that the accumulator had its best possible field of application. Why should one set aside, only for peak service, large units that have been installed only a few years, when they are still serviceable and economical and when the peak load can be carried by cheaper accumulator sets? Dr. F. Munzinger has stated that the large Klingenberg Station in Berlin, with its 80,000-kw. units, cost $60 per kilowatt to build, while the accumulator plant now being installed by the same company at its Charlottenburg station cost only $45 per kilowatt. Character of load, cost of coal, and first costs of equipment must determine whether steam accumulators should be added to any system regardless of rate of growth.

Mr. Smith's interesting discussion indicates that utility executives are already giving consideration to the economics of handling peak loads. He calls attention to the difficulty of predicting the character of future loads, which difficulty is quite generally recognized.

Mr. Langworthy has emphasized the importance of watching investment costs in striving for high efficiency, and particularly when plant equipment has few hours use per year.

The discussion by Messrs. Engle and Davison attempts to show that the outage schedule of turbines for overhaul and maintenance necessitates the operation of every unit for a considerable number of hours each month and that steam-accumulator plant would not be suitable for this service. An analysis of their data indicates that this condition is largely due to their local combination of unit sizes and that quite other conditions might prevail had other turbines been used. Fig. 15 indicates that 20 per cent of the maximum peak, or about 40,000 kw., is of the type best handled by accumulators. The writers state that load growth is 9 per cent per year, or about 20,000 kw. If 30,000-kw. units had been added in place of 50,000-kw. sets, the flexibility for reserve and maintenance would have been increased, and a possible further addition of two 20,000-kw. accumulator units for the peak might have resulted in a cheaper and more economical system from a financial standpoint than the present one. Also their outage requirements would have been less pressing if new equipment for the next winter's peak had been available in the preceding fall. Furthermore, the use of an accumulator set would lessen the peak demands on the boilers and furnaces and would lower stoker maintenance.

Mr. Usher calls attention to the need of immediate response at the time of peak load. Steam-accumulator plant fills this need. As the accumulator turbines operate on saturated steam, they can be started easily and in less time than when superheated steam is used. Once on the line they can take full load immediately. These turbogenerators could spin on the line as synchronous condensers, when their response to load demands would be instantaneous. For instance, a steam-accumulator plant at Malmo, Sweden, in a demonstration in 1927 picked up the complete load of a hydroelectric system when the line breakers were tripped, with not more than a momentary fluctuation in voltage. Peak-load units do not need to be capable of carrying load indefinitely, for other reserve is available for use at all loads under the peak. Attention is called in the paper to the use of special peak-load units for long-sustained peaks due to fog, etc., as Mr. Usher urges. The accumulator is best fitted for short, sharp peaks. Regarding the heat-consumption rate of the accumulator set, it can be shown easily that this is an insignificant item in total costs for peak-load units and can be virtually neglected. Contrary to Mr. Usher's opinion, accumulators are available for sudden breakdown emergencies and can carry load until other boilers or turbines can be put into service.

Mr. Funk's table showing the effect of the difference in cost between energy from base load and old plant, on savings, illustrates very effectively the influence of this factor on possible

savings. It is apparent that steam-accumulator plant is not particularly fitted to serve with hydroelectric developments on rivers with variable flow, as indicated by Mr. Funk.

Mr. Levert insists that the system with which he is associated has all the generating capacity needed to take care of extreme peaks and to serve as stand-by. He asks why they should find more money for peak-load capacity. It is quite possible that a careful analysis of the total cost of providing and maintaining this excess capacity is greater than would have been the case if cheap steam-accumulator plant had been installed to carry peak loads and to serve as emergency reserve at other times. Too little regard has been paid to the total investment in certain cases.

Mr. Hobson has called attention to the unfortunate choice of figures giving the B.t.u. per kilowatt-hour on standard and base-load plants. These figures were chosen as representative of what one might expect by adding fuel-saving improvements to a plan without changing pressure and temperature conditions. Mr. Leilich believes these assumed performances are better than could be obtained in practice. The paper, in discussing Case 1, shows that even if a heat consumption were taken 10 per cent below that assumed for the base-load plant, the gain through the use of the accumulator would still be significant. This also applies to the other cases shown. A curve for a plant of such remarkable efficiency would fall somewhat below curve D in the various figures.

The situation in Great Britain as influenced by the "grid" is an exceptional one, as Mr. Hobson points out. The large number of less efficient stations made available through the grid interconnection can provide for peak-load demands for several years, particularly since this equipment is already bought and paid for. This excessive capacity is partly due to the large stand-by reserve capacity carried in most British stations.

One speaker criticized the use of a heat rate of 22,850 B.t.u. per kw-hr. for the peak-load turbine. A triangular peak load was assumed, and the average heat consumption over the whole of such a peak was figured as 22,850 B.t.u. per kw-hr., based on some turbine guarantees. The performance of the accumulator turbine at its point of highest economy should be considerably less than this figure.

Mr. Leilich has calculated net savings in per cent of first cost. It must be remembered that these net savings are over and above fixed charges. In effect they represent possible dividends and as such provide liberal marginal earnings on the investment. Accumulator charging can generally be done during off-peak hours at night, when the increase in boiler load is welcomed, and also during the noon-hour dip.

No claim has been made in the paper that the proposed accumulator plant can be universally applied. As many discussors have pointed out, its field is special, and each case of possible application must be studied as a separate problem. There may be places where base-load and special peak-load units should be installed, just as there are other places where the installation of accumulators would result in the lowest total power costs.

As pointed out in the paper, savings of several hundred thousand dollars a year may be possible through the use of steam accumulators in certain plants. In such cases, both operating and designing engineers will have difficulty in convincing their utility executives that steam storage should not be used. The steam accumulator is not a cure-all for all peak-load problems, but it may find a useful place in American central stations for the reduction of the total cost of power.

Condition Curves and Reheat Factors for Steam Turbines

By CLARENCE C. FRANCK,[1] PHILADELPHIA, PA.

This paper offers a theory for "condition curves and reheat factors" developed by a study of the basic thermodynamic principles involved. A method is developed which makes possible the construction of "condition curves" for any turbine, when certain operating or guarantee characteristics are known. The question of "condition curves" immediately presents the closely related "reheat factor," and the theory developed for the "condition curve" has been applied to determine values for "reheat factors."

I—CONDITION CURVES

A CONDITION curve may be defined as a line on a Mollier diagram which connects points representing the condition of the steam at the entrance of each successive stage, the end point of the curve representing the condition of the steam leaving the last row of blades. This curve is of assistance to engineers in the design of turbines, and particularly in heat-balance calculations involving bled steam. A method that will facilitate the drawing of correct condition curves should prove helpful and useful to engineers. The construction of condition curves has been much discussed, and this work will be briefly reviewed.

Previous Data

Brown and Drewry[2] assume that the internal efficiency of the turbine is 10 per cent greater in the superheated than in the saturated region. This assumption gives a means for estimating the division of Rankine heat drop in the two regions, and by a cut-and-try method, the point at which the condition curve crosses the saturation line may be approximated.

Baumann in a recent paper[3] states that the stage efficiency in the saturated region is a function of the moisture content of the steam and that this stage efficiency decreases 1.0 per cent for every 1.0 per cent increase in the moisture content of the steam.

Warren and Blowney, in a paper[4] based on more recent test data, find that the stage efficiency in the saturated region should be decreased 1.15 per cent for every 1 per cent increase in the moisture content of the steam.

Goudie[5] gives a method of locating the condition curve by solving for the pressure at which the condition curve crosses the saturation line. This is done by combining an assumed equation of the condition curve with an equation of the saturation line to find their point of intersection.

The condition curve is assumed to be capable of expression by the relation

$$p_1 v_1^{\,n} = p_s v_s^{\,n}$$

and that of the saturation line by

$$v_s = \left(\frac{\text{Constant}}{p_s}\right)^{\frac{1}{\lambda}}$$

which may also be written in the form

$$p_s v_s^{\,\lambda} = 490$$

where p_1 = pressure, lb. per sq. in. abs., at initial condition
p_s = pressure, lb. per sq. in. abs., at saturation condition
v_1 = volume, cu. ft. per lb., at initial condition
v_s = volume, cu. ft. per lb., at saturation condition
n = coefficient of expansion and is a function of the stage efficiency
λ = 1.067.

Combining the equations of these two curves we have

$$p_s^{\,1-\frac{n}{\lambda}} = \frac{p_1 v_1^{\,n}}{490^{\lambda}}$$

Substituting for λ

$$p_s = \left(\frac{333.4}{p_1^{\,y} v_1}\right)^{z} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where $z = \dfrac{n\lambda}{n-\lambda}$, and $y = \dfrac{1}{n}$.

If proper values are substituted in Equation [1], p_s, the pressure at which the condition curve crosses the saturation line, may be calculated.

Equation [1] is based on the assumption that

$$v_s = \left(\frac{\text{Constant}}{p_s}\right)^{\frac{1}{\lambda}}$$

is the equation of the saturation line.

Goodenough[6] gives the following equation to express the conditions at the saturation line:

$$\log p = A - B/T - c \log T - DT + ET^2 - \Delta \quad \ldots. [2]$$

$$v - c = BT/p - (1 - 3ap^{1/2}) \times m/Tn \quad \ldots\ldots\ldots\ldots [3]$$

These equations might be combined to give an equation for the saturation line. It is seen, however, that such an equation would be complicated and would not take the simple form of the Goudie equation.

Callendar[7] gives the following equations to express the conditions at the saturation line:

$$\log p = 22.2787 - \frac{5226.1}{T} - 4.71734 \log T + 0.7302\,(c-b)\,\frac{p}{T} \quad \ldots\ldots\ldots [4]$$

$$v = \frac{RT}{Ap} - c + b$$

These equations might also be solved to find an equation for the saturation line, but again it would be in a complicated form. Goudie[8] also states that his simple equation for the saturation

line, $pv^{\lambda} = 490$ is approximate, although the error involved by its use is small.

Goudie's method of considering the equation of the condition curve to be of the form pv^n = constant, where n is a function of the stage efficiency, appears to be rational. In fact, all of the condition curves which have been drawn in this investigation appear to follow this exponential law in the superheated region. Goudie's values of n are calculated by the following expression:

$$n = \frac{1}{1 - \eta_s\left(1 - \frac{1}{\gamma}\right)}$$

where n = coefficient of expansion for a given stage efficiency
η_s = stage efficiency, and
γ = adiabatic coefficient of expansion.

The results are based on the assumption that γ is a constant equal to 1.3. Callendar[9] and Mollier give the value of γ as 1.3. Zeuner assumes γ as 1.33. Schüle[10] finds γ equal to 1.33 but states that the value may vary between the limits of 1.3 and 1.35. Prof. G. A. Goodenough, in a personal communication, stated that there is no particular virtue in the value 1.3 or 1.33, and that different tables of superheated steam would probably give different values of γ.

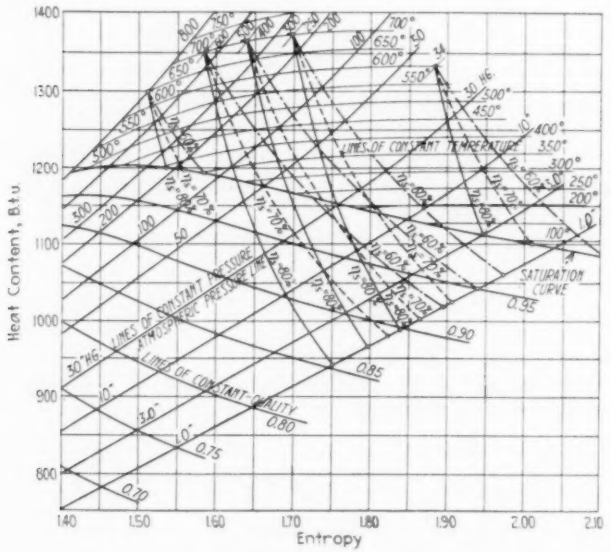

FIG. 1 CONDITION CURVES FOR STEAM TURBINES
(Goodenough Mollier diagram.)

The value of γ was found to vary slightly over any one Mollier diagram. Goodenough's Mollier diagram was used to plot the condition curves in this paper. It was found that γ for superheated steam varies from 1.32 in the high-pressure region of low entropy to 1.31 in the low-pressure region of high entropy. The value of γ may be calculated by taking an adiabatic pressure drop from a given initial pressure in the superheat region to some lower pressure above the saturation line, and by applying the characteristic equation pv^{γ} = constant, to these initial and final conditions. The average value of γ between the low and high entropy limits of the Goodenough Mollier chart was found to be approximately 1.315.

The value of γ was also calculated for the Ellenwood chart[11] which is based on the Marks and Davis.[12] It was found that values of γ over the entire superheated region varied from 1.34 to 1.30.

A slight difference in the value of γ shifts the position of the condition curve to the right or left of its true position. For example, consider that the true value of γ for a particular section of the Mollier diagram is 1.31, and the assumed value of γ used in calculating the coefficient of expansion n for a certain stage efficiency is 1.30. Then the value of n resulting from the use of the incorrect γ is approximately 0.5 per cent less than the true value. The overall effect of the use of 1.3 instead of the true value, 1.31, would be to decrease the stage efficiency approximately 2 per cent for the entire expansion in the superheated region.

Reference has already been made to the fact that an increase in the moisture content of the steam in the saturated region is accompanied by a decrease in the stage efficiency. This assumption was used in this investigation of the saturated portion of the condition curves. Warren and Blowney's figure of 1.15 per cent decrease in stage efficiency for every 1 per cent increase in the moisture content of the steam, which appears to be the latest available data on the subject, was assumed.

Condition curves may be accurately drawn by the step-by-step method when the stage efficiency is known. This method is very tedious, and considerable time is required to draw the complete condition curve in this manner.

Many designers approximate the condition curve by plotting the three controlling points, viz., the initial condition, the point where the condition curve crosses the saturation line, and the end point at exhaust. These fixed points may be connected by straight lines which have been assumed to be sufficiently accurate to serve for ordinary bleeder calculations. A smooth curve may also be drawn through the points, with a steeper slope in the superheated than in the saturated regions, to provide for the difference in stage efficiencies in the two regions. While either of these two methods may be satisfactory for ordinary purposes, careful bleeder calculations make greater accuracy in plotting the condition curve desirable as the condition of the bled steam is figured directly from the pressure given at the bleeder points on this curve.

There have been recent cases in which the predicted bleeder conditions were considerably different from those actually obtained later on completed turbines. This deviation from the expected conditions frequently has esulted in a decrease in the overall station economy and was therefore undesirable. The increases in heat consumption may have been small in certain cases, but these persist throughout the whole useful life of the machine. Such losses might have been prevented by a more accurate knowledge of the turbine stage efficiencies and by the use of a more carefully drawn condition curve to represent the true steam conditions at all points during expansion in the turbine.

Our increasing knowledge of steam-turbine design and power-plant heat balance will in the future require more accurate data on the conditions of all steam bled from the turbines. This can only be predicted with assurance when correct condition curves have been drawn on the basis of known stage efficiencies.

INVESTIGATION

SUPERHEATED REGION

The first step was to investigate whether condition curves in the superheated region could be expressed by an equation in the

[9] "Properties of Steam," Callendar.
[10] "Technische Thermodynamik," W. Schüle, 3rd edition, art. 9, p. 48.
[11] "Steam Charts," F. O. Ellenwood.
[12] "Thermal Properties of Superheated and Saturated Steam," Marks and Davis.

form pv^n = constant. Curves for different stage efficiencies were plotted by the step-by-step method for this purpose.

A second object was to determine whether there was any fixed relation between the value of the coefficient n in this equation for the condition curve, pv^n = constant, and the stage efficiency η_s.

Initial points for the condition curves were taken at 800 lb. per sq. in. abs., 650 deg. fahr.; 600 lb., 400 lb., and 250 lb. per sq. in. abs., 700 deg. fahr.; and 34 lb. per sq. in. abs., 600 deg. fahr. This choice gave the full range of conditions on the Goodenough Mollier diagram. Other initial conditions could be selected at intermediate points on the plotted curves.

The step-by-step method was used in plotting the condition curves for stage efficiencies of 80 per cent, 70 per cent, and 60 per cent, respectively, as shown in Fig. 1, giving a group of three condition curves from each initial point.

Each curve was plotted by assuming a small constant value of Rankine heat drop for each step, so that the number of steps between the initial conditions and the saturation line was in no case less than twenty. This was done in order that the curves obtained would approach expansion with an infinite number of stages. However, it was found on replotting that the form of the curve did not change substantially when half the number of steps was used. A smooth curve is drawn through the loci of the points representing the conditions of the steam at the entrance of each step, and this is taken as the condition curve for the given stage efficiency.

The corresponding pressures and volumes at different points along the condition curves were plotted on logarithmic-coordinate paper. These are shown in Fig. 2. The various points fell along the same straight line for the same stage efficiency and indicated that the equation of the condition curves was of the form, pv^n = constant.

The values of n can be taken as the slope of the lines from Fig. 2 or calculated by the following formula:

$$n = \frac{\log p_1 - \log p_2}{\log v_2 - \log v_1}$$

where p_1, v_1 = pressure and volume, respectively, at initial point
p_2, v_2 = pressure and volume, respectively, at any point on the condition curve down to the saturation line.

The values of n thus obtained are given in Table 1.

TABLE 1 VALUES OF n

η_s, per cent	800 lb., 650 deg.	600 lb., 700 deg.	400 lb., 700 deg.	250 lb., 700 deg.	34 lb., 600 deg.	Average
60	1.170	1.169	1.169	1.169	1.169	1.169
70	1.203	1.205	1.203	1.204	1.204	1.204
80	1.241	1.241	1.239	1.240	1.239	1.240

As the average of these values shows a maximum error of $\pm$ $^1/_{1200}$ or $\pm$ 0.08 per cent when compared to the individual values and as these are within the limits of accuracy of the chart and personal errors, it is reasonably safe to assume that the average values may be used.

The values of n were plotted against corresponding values of η_s taken from Table 1, and it was observed that the resulting curve was of parabolic form. In order to determine the values of n at intermediate-stage efficiencies the equation of the curve must be set up with n as a function of η_s.

Representing $n = f(\eta_s)$ by a general equation of the parabola,

$$(n - b)^2 = 4p(\eta_s - a)$$

where n corresponds to the abscissa and η_s to the ordinate.

The values of the constants a, b, and p may be determined by substituting the average values of η_s and n from Table 1 in the general equation. This gives a set of three equations and three unknowns, from which the following values of the constants were found:

$$a = 2.47428$$
$$b = 2.469$$
$$p = -0.22385$$

Substituting these in the general equation, we have

$$n = 2.469 - \sqrt{2.22536 - 0.8954\,\eta_s}$$

The values of n for any assumed stage efficiency calculated by this general equation are as shown in Table 2.

TABLE 2 VALUES OF n

η_s	n	η_s	n	η_s	n	η_s	n
60	1.169	68	1.198	76	1.224	84	1.256
61	1.174	69	1.201	77	1.229	85	1.259
62	1.176	70	1.204	78	1.232	86	1.263
63	1.179	71	1.208	79	1.236	87	1.267
64	1.183	72	1.211	80	1.240	88	1.271
65	1.186	73	1.214	81	1.244	89	1.275
66	1.190	74	1.218	82	1.248	90	1.278
67	1.194	75	1.221	83	1.252		

These values of n enable one to readily plot a condition curve

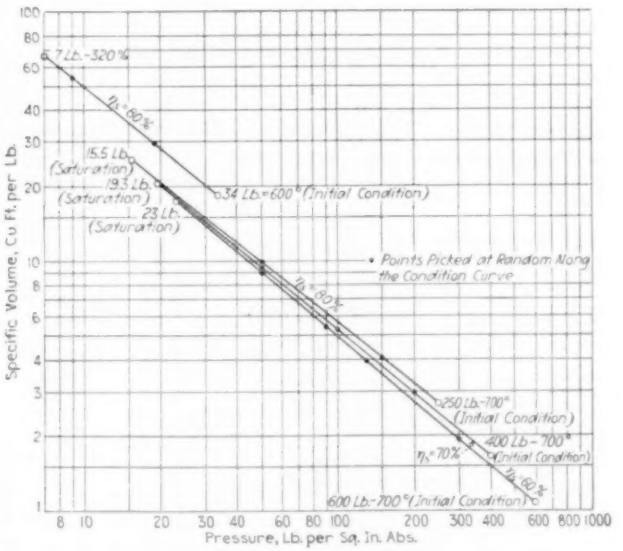

FIG. 2 LOGARITHMIC PLOT OF CONDITION CURVES IN THE SUPERHEATED REGION

in the superheated region for any assumed value of the stage efficiency on the Goodenough Mollier diagram.

SATURATED REGION

The saturated portion of the condition curve extends from the point where this curve crosses the saturation line to the exhaust pressure.

This portion of the condition curve is more difficult to draw by the step-by-step method as the stage efficiency is decreasing with increasing moisture contents of the steam. However, a cut-and-try method of assuming such a Rankine heat drop that the end point of the step is at a given quality eliminates intermediate calculations. For example, the first step will be the continuation of the condition curve of the superheated region from the saturation line to the 99 per cent quality line. The average stage efficiency for this step is:

$$\eta_a = \eta_{s1} - \left[\frac{1.15\,(1 - x)}{2}\right]$$

where η_a = average stage efficiency for the step, in per cent (from 100 per cent to 99 per cent quality)

η_{s1} = stage efficiency of the beginning of the step, in per cent (i.e., at 100 per cent quality)

x = quality of steam at the end point of the step, in per cent (i.e., 99 per cent quality).

Then

$$\eta_a = \eta_{s1} - 0.575$$

Assume some value of h_r, a Rankine heat drop to a pressure p_x (Fig. 3). The corresponding value of the actual heat drop converted to work per stage is $h_s = \eta_a h_r$.

Next scale from the point a the value h_s. The end point b of the step is where this constant-total-heat line intersects the pressure line p_x. If the point b does not fall on the assumed quality line of 99 per cent, a new value of h_r should be assumed giving a new value of p_x, and the end point recalculated. The point b on the 99 per cent quality line is the beginning of another step which can be calculated and plotted in the same manner. The condition curve can be completed in this way to any desired final back pressure, the stage efficiency decreasing in proportion to the progressive increase in the moisture content of the steam. In this investigation the condition curves were carried to the absolute-pressure line for one inch of mercury (see Fig. 1).

The same procedure as in the superheated section was used to determine whether the portion of the condition curves in the saturated region was of the form pv^n = constant. It was found, however, that the curves when plotted on logarithmic-coordinate paper had decided curvatures as shown, for example, in Fig. 4. This indicated that the condition curve in the saturated region

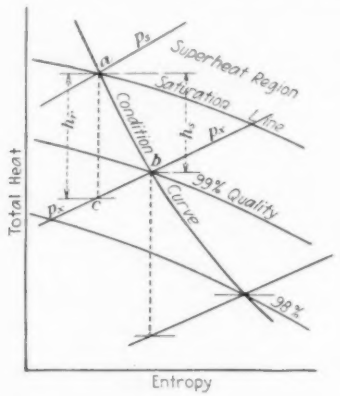

FIG. 3 CONSTRUCTION OF CONDITION CURVE
(Section from Goodenough Mollier diagram.)

did not follow the law pv^n = constant, probably owing to the use of decreasing stage efficiencies with added moisture in the steam.

However, upon examination it was found that the ratio H_s/H_r in the saturated region gave a constant coefficient C for each of the condition curves, where H_r = Rankine heat drop from the point where the given condition curve crosses the saturation line to the 1-in. of mercury pressure line; and H_s = heat available for work between the saturation line and the end point of the condition curve on the 1-in. of mercury absolute-pressure line.

The values of C found in this investigation for various values of η_s where the condition curves cross the saturation line are given in Table 3.

TABLE 3 VALUES OF C

η_s per cent	600 lb., 700 deg.	400 lb., 700 deg.	250 lb., 700 deg.	Average
80	0.780	0.782	0.781	0.781
70	0.689	0.692	0.690	0.690
60	0.594	0.597	0.597	0.596

The product of C for a given value of η_s at the saturation line, and H_r, the total Rankine heat drop from the point where the given condition curve crosses the saturation line to the exhaust pressure, gives the value of H_s which fixes the end point of this condition curve on the exhaust-pressure line. Also when the coefficient C is multiplied by the Rankine heat drop from the

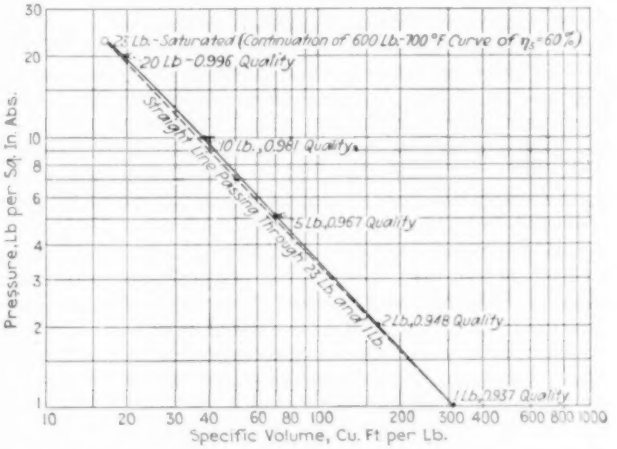

FIG. 4 LOGARITHMIC PLOT OF CONDITION CURVES IN THE SATURATED REGION

saturation line to any intermediate pressure above the final exhaust pressure, the corresponding value of H_{s1} to that pressure is found and the point at which the condition curve intersects this intermediate pressure line is determined. The point where the condition curve crosses the saturation line is fixed by the condition curve of the superheat region, and the remainder of the condition curve may be drawn by plotting points at various intermediate pressures between the saturation line and exhaust pressure by means of this coefficient C. The values of C for intermediate stage efficiencies are given in Table 4.

TABLE 4 VALUES OF C

η_s per cent	C	η_s per cent	C	η_s per cent	C	η_s per cent	C
60	0.596	68	0.671	76	0.746	84	0.816
61	0.605	69	0.680	77	0.755	85	0.825
62	0.614	70	0.690	78	0.764	86	0.833
63	0.624	71	0.700	79	0.773	87	0.842
64	0.633	72	0.709	80	0.781	88	0.851
65	0.642	73	0.718	81	0.789	89	0.859
66	0.653	74	0.727	82	0.798	90	0.868
67	0.661	75	0.737	83	0.807		

DISCUSSION OF PRECEDING METHODS

Trials were made to determine whether the data obtained by the preceding methods would hold for other cases.

A curve with initial conditions of 400 lb. abs., 600 deg. fahr., η_s = 70 per cent, was drawn by the step-by-step method.

Intermediate points on the condition curve between the initial conditions and exhaust pressure were computed by the methods developed in the preceding paragraphs. These points did not show any appreciable variation from the curve plotted by the step-by-step method. Another trial with initial conditions of 250 lb. abs., 600 deg. fahr., η_s = 70 per cent, gave the same comparative results by the two methods. Another condition curve was drawn with initial conditions of 800 lb. abs., 750 deg. fahr., η_s = 80 per cent, and again the points were substantially the same by both methods.

To test the flexibility of the tables a curve with initial conditions of 400 lb. abs., 700 deg. fahr., η_s = 85 per cent, was drawn by the step-by-step method. It was found that the predicted condition curve cut the exhaust line at 0.6 B.t.u. below the end point of the curve drawn by the step-by-step method. This was

the greatest deviation between the two values throughout the entire length of the curve, and may have been partly due to personal errors in reading small heat drops.

Checks were also made between the two methods with initial conditions picked at random as follows:

(1) 160 lb. abs., 520 deg. fahr., and η_s = 70 per cent
(2) 240 lb. abs., 490 deg. fahr., and η_s = 80 per cent
(3) 220 lb. abs., 530 deg. fahr., and η_s = 60 per cent
(4) 260 lb. abs., 600 deg. fahr., and η_s = 85 per cent
(5) 350 lb. abs., 700 deg. fahr., and η_s = 67.4 per cent.

Substantial agreement was found in all cases.

In the preceding investigation no consideration was given to the effect of supersaturation. If this had been considered, the condition curve would have continued beyond the saturation line according to the law pv^n = constant, for the supersaturated region, until a point was reached representing the limit of supersaturation. Beyond this point it would probably be necessary to use a larger moisture correction than 1.15 per cent decrease in the stage efficiency for an increase of 1 per cent in the moisture content of the steam.

Methods of Drawing Condition Curves

Condition curves used for practical purposes are drawn by assuming that the stage efficiency throughout the expansion is either constant or variable. Some designers assume that the stage efficiency increases down to the saturation line and decreases in the saturated region. Constant stage efficiency is sometimes assumed for the whole expansion.

In all cases the stage efficiency should be corrected for the moisture contents of the steam. As the data given in Table 4 take this into account, no further mention wil be made to the effect that *the stage efficiency decreases 1.15 per cent for every average 1 per cent increase in the moisture content of the steam.*

Constant Stage Efficiency

The following example shows the steps that must be taken to construct the condition curve on the assumption that the stage efficiency is constant.

Assume a turbine with a constant stage efficiency of 80 per cent operating under the initial conditions of 400 lb. abs., 700 deg. fahr. at the first-stage nozzles and exhausting at an absolute pressure of 1 in. of mercury.

(1) Locate the initial point on the Mollier diagram.
400 lb. absolute
700 deg. fahr.
1.6387 = E = entropy
1.669 = v_1 = specific volume, cu. ft. per lb.
1362.4 B.t.u. per lb. heat content.
(2) Table 5 shows the method of tabulating and computation for the superheated portion of the condition curve.

TABLE 5 COMPUTATIONS FOR SUPERHEATED PORTION OF CONDITION CURVE

(The value of n for η_s = 80 per cent is 1.240.)

Points	Pressures, lb. per sq. in. Initial p_a	Final p_b	Ratio of pressures, i.e., $\left(\frac{p_a}{p_b}\right)^{\frac{1}{1.24}}$	Specific volumes — Initial v_a	Final $v_b = \left(\frac{p_a}{p_b}\right)^{\frac{1}{1.24}} \times v_a$	B.t.u. per lb. at p_b and v_b[1]

[1] Exhaust condition, 1 in. mercury absolute.

Variable Stage Efficiency

The condition curve for variable stage efficiency may be computed as in the previous case, with the exception that different values of n and C must be taken for every change in stage efficiency as shown in the following example.

Assume a turbine of ten stages, five in the superheated region and five in the saturated region. The stage efficiencies of the five stages in the superheated region will be assumed as 76, 77, 78, 79, and 80 per cent, respectively. The stage efficiencies, not corrected for moisture contents, of the five stages in the saturated region will be assumed as 80, 78, 76, 74, and 72 per cent, respectively. The operating conditions of the turbine will be 500 lb. abs., 700 deg. fahr., at the nozzles of the first stage and exhausting at 1 in. mercury absolute pressure.

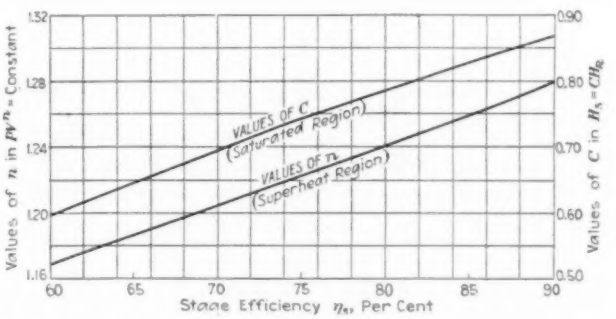

Fig. 5 Values of Constants Used in Construction of Condition Curves

Superheated Region.

(1) Let the first stage operate between the pressure limits of 500 lb. and 300 lb. From Fig. 5 or Table 2 the value of n at η_s = 76 per cent is 1.224. The initial steam volume, v_{s1-1}, at 500 lb. abs., and 700 deg. fahr. is 1.32 cu. ft. per lb.

The end point of stage No. 1 will be fixed by the relation

$$v_{s1-2} = v_{1-1}\left(\frac{p_1}{p_2}\right)^{\frac{1}{n}}$$

or

$$v_{s1-2} = 1.32\left(\frac{500}{300}\right)^{\frac{1}{1.224}}$$

$$= 2.003 \text{ cu. ft. per lb.}$$

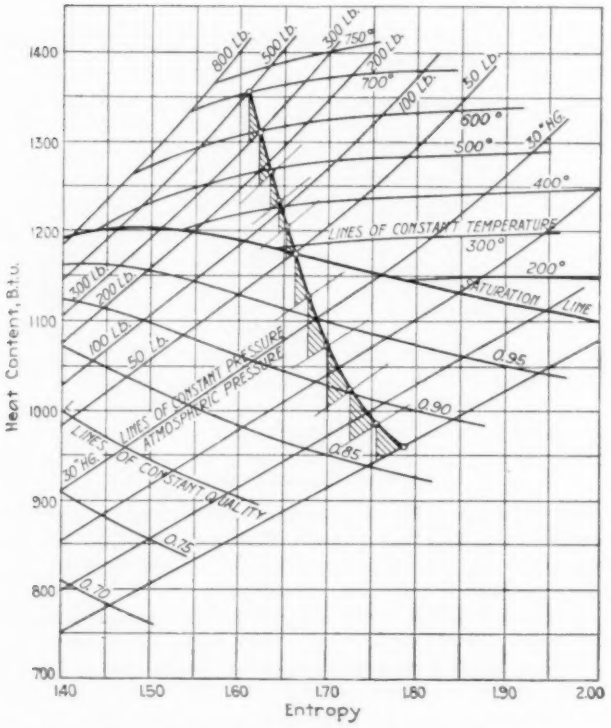

FIG. 6 CONDITION CURVE FOR A TEN-STAGE TURBINE OF VARIABLE STAGE EFFICIENCY
(Goodenough Mollier diagram.)

Therefore the end point of stage No. 1 is located at 300 lb. and 2.003 cu. ft. specific volume or 1310.0 B.t.u.

In the case of the first stage as well as in the succeeding ones, a point could be located at some intermediate pressure between the stage limits in order to fix three points through which to draw the condition curve for each separate stage.

(2) Let the second stage operate between 300 lb. and 180 lb.

n at η_s = 77 per cent is 1.229.

$$v_{s2-2} = 2.003\left(\frac{300}{180}\right)^{\frac{1}{1.229}}$$

$$= 3.035 \text{ cu. ft. per lb.}$$

Therefore the end point of stage No. 2 is located at 180 lb. and 3.035 cu. ft. specific volume or 1266.5 B.t.u.

(3) Let the third stage operate between 180 lb. and 120 lb.

n at η_s = 78 per cent is 1.232.

$$v_{s3-2} = 3.035\left(\frac{180}{120}\right)^{\frac{1}{1.232}}$$

$$= 4.218 \text{ cu. ft. per lb.}$$

Therefore the end point of stage No. 3 is located at 120 lb. and 4.218 cu. ft. specific volume or 1236.1 B.t.u.

(4) Let the fourth stage operate between 120 lb. and 75 lb.

n at η_s = 79 per cent is 1.236.

$$v_{s4-2} = 4.218\left(\frac{120}{75}\right)^{\frac{1}{1.236}}$$

$$= 6.1705 \text{ cu. ft. per lb.}$$

Therefore the end point of stage No. 4 is located at 75 lb. and 6.1705 cu. ft. specific volume or 1203.3 B.t.u.

(5) Let the fifth stage operate between 75 lb. and 49 lb.

n at η_s = 80 per cent is 1.240

$$v_{s5-2} = 6.1705\left(\frac{75}{49}\right)^{\frac{1}{1.24}}$$

$$= 8.696 \text{ cu. ft. per lb.}$$

Therefore the end point of stage No. 5 is located at 49 lb. and 8.696 cu. ft. specific volume or at the saturation line.

In the above computations for stage No. 5 the end point fell exactly on the saturation line. In case the point does not fall on the saturation line, another trial with a different lower pressure limit may be carried out. However, in most cases it is not necessary to terminate a stage directly at the saturation line.

Saturated Region.

(6) Let the sixth stage operate between 49 lb. and 22 lb.

C from Fig. 5 or Table 4 at η_s = 80 per cent is 0.781.

This figure allows for the correction to stage efficiency caused by the moisture content.

$$\begin{aligned} H_{6-1} &= 1159.6 \\ H_{6-1R} &= 1114.6 \\ H_{R_6} &= 45.0 \times 0.781 = H_{S_6} = 35.1 \end{aligned} \qquad \begin{aligned} H_{6-1} &= 1159.6 \\ H_{6-2} &= 1124.5 \text{ B.t.u.} \end{aligned}$$

Therefore the end point of stage No. 6 is located at 22 lb. and 1124.5 B.t.u.

(7) Let the seventh stage operate between 22 lb. abs., and 17 in. of mercury.

C at η_s = 78 per cent is 0.764

$$\begin{aligned} H_{7-1} &= 1124.5 \\ H_{7-R} &= 1058.4 \\ H_{R7} &= 66.1 \times 0.764 = H_{S7} = 50.5 \end{aligned} \qquad \begin{aligned} H_{7-1} &= 1124.5 \\ H_{7-2} &= 1074.0 \text{ B.t.u.} \end{aligned}$$

Therefore the end point of No. 7 stage is located at 17 in. of mercury and 1074 B.t.u.

(8) Let the eighth stage operate between 17 in. of mercury and 6 in. of mercury.

C at η_s = 76 per cent is 0.746

$$\begin{aligned} H_{8-1} &= 1074.0 \\ H_{8-1R} &= 1010.2 \\ H_{R8} &= 63.8 \times 0.746 = H_{S8} = 47.5 \end{aligned} \qquad \begin{aligned} H_{8-1} &= 1074.0 \\ H_{8-2} &= 1026.5 \text{ B.t.u.} \end{aligned}$$

Therefore the end point of No. 8 stage is located at 6 in. of mercury and 1026.5 B.t.u.

(9) Let the ninth stage operate between 6 in. of mercury and 2.5 in. of mercury.

C at η_s = 74 per cent is 0.727

$H_{9-1} = 1026.5$

$H_{9-1R} = 976.5$

$H_{R9} = 50.0 \times 0.727 = 36.3$

$H_{9-1} = 1026.5$

$H_{S9} = 36.3$

$H_{9-2} = 990.2$ B.t.u.

(10) Let the tenth and final stage operate between 2.5 in. of mercury and 1.0 in. of mercury.

C at $\eta_s = 72$ per cent is 0.709

$H_{10-1} = 990.2$

$H_{10-1R} = 941.5$

$H_{R10} = 48.7 \times 0.709 = 34.5$

$H_{10-1} = 990.2$

$H_{S10} = 34.5$

$H_e = 955.7$ B.t.u.

The end point of the expansion is 955.7 B.t.u. at 1 in. of mercury. This figure does not contain the leaving loss, and the true condition of the steam entering the condenser is found by adding that loss.

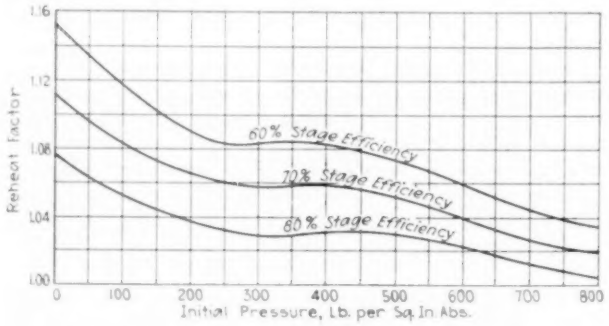

FIG. 7 REHEAT FACTORS, SUPERHEATED REGION
(Based on an initial temperature of 600 deg. fahr. Expansion from initial condition to saturation line.)

The condition curve is formed by passing a smooth curve through the points. The completed curve is shown in Fig. 6.

II—REHEAT FACTORS

Reheat factors are of great importance to the turbine designer, as they are indications of the ratio of the actual heat energy available for work in the stages to the total Rankine heat drop. Reheat occurs when a portion of the stage losses are reconverted into heat energy, some of which is available for work in succeeding stages. The reheat factor is always greater than unity and depends upon stage efficiency and steam conditions.

PREVIOUS WORK

The value of the reheat factor R for any definite expansion is expressed by the ratio of the summation of Rankine heat drops Σhr for the various stages to the total Rankine heat drop Hr from initial conditions to final pressure, i.e.,

$$R = \frac{\Sigma h_r}{H_r}$$

Also the ratio of the heat H_s converted to work to the total Rankine heat drop H_r is a measure of the energy conversion in the turbine, and is known as the *Internal Efficiency*, η_i; i.e.,

$$\eta_i = \frac{H_s}{H_r}$$

The total heat converted to work, H_s, is equal to the summation of the heat converted to work, h_s, in each stage of the turbines, i.e., $H_s = \Sigma h_s$. The values of h_r and h_s denote, respectively, the Rankine heat drop and the heat actually converted into work per stage, and the ratio h_s/h_r expresses the stage efficiency, η_s; i.e.,

$$\eta_s = \frac{h_s}{h_r}$$

If the stage efficiency is assumed to be constant for all stages of the expansion considered, then

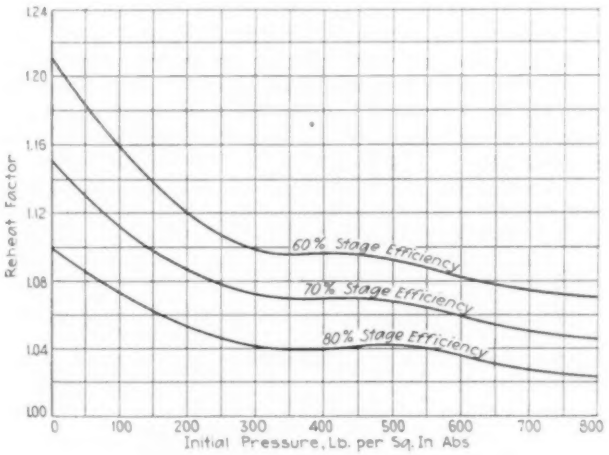

FIG. 8 REHEAT FACTORS, SUPERHEATED REGION
(Based on an initial temperature of 650 deg. fahr. Expansion from initial condition to saturation line.)

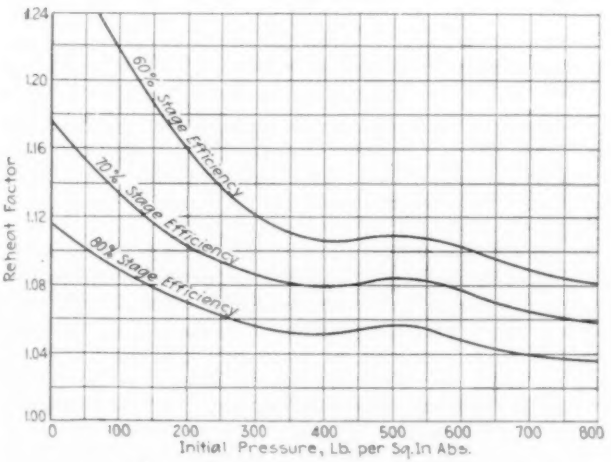

FIG. 9 REHEAT FACTORS, SUPERHEATED REGION
(Based on an initial temperature of 700 deg. fahr. Expansion from initial condition to saturation line.)

$$H_s = \eta_s \Sigma h_r$$

and $$\eta_i = \frac{\eta_s \Sigma h_r}{H_r}$$

or $$\eta_i = \eta_s R$$

Hence $$R = \frac{\eta_i}{\eta_s}$$

Several mathematical expressions have been derived to calculate reheat factors, but these derivations depend upon a constant value of the coefficient of adiabatic expansion γ for superheated steam. However, as shown in the preceding discussion of condition curves, γ varies for various steam tables and even for different steam conditions on the same Mollier diagram.

It is therefore apparent that these theoretically derived reheat factors may not truly represent actual values.

Investigation

The value of the reheat factor for the complete expansion from initial condition to final pressure as determined by the relation $R = \eta_i/\eta_s$ holds true when the value of the stage efficiency η_s is constant. The construction of the condition curves explained in previous paragraphs has been based on expansion with constant stage efficiency in the superheated region, and uniformly decreasing stage efficiency in the saturated region. This fact suggested that the investigation of reheat factors be separated into two parts: namely, the superheated region with constant stage efficiency, and the saturated region with variable stage efficiency.

Superheated Region. In plotting the condition curves shown in Fig. 1 the step-by-step Rankine heat drops h_r were determined. The relation $R = \eta_i/\eta_s$ can be checked by means of

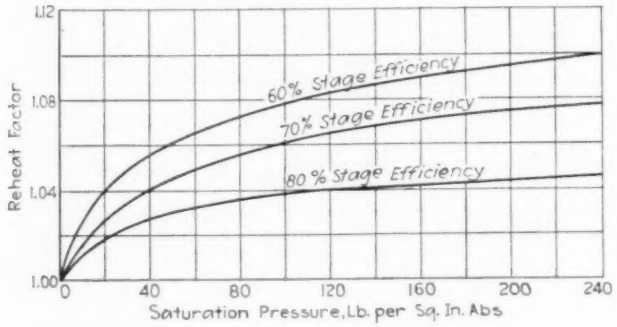

Fig. 10 Reheat Factors, Saturated Region
(Expansion from saturation line to 1 in. Hg absolute back pressure.)

the equation $R = \Sigma h_r/H_r$, as the summation of the individual heat drops Σh_r may be made from the initial conditions. This procedure gave exact checks of reheat factors in all cases. These calculations provided reheat factors for fifteen different initial conditions.

In order to determine values of reheat factors for the entire superheated region, the previously outlined method of constructing condition curves for the superheated region was applied for other steam ranges. Initial conditions were selected and different stage efficiencies assumed, so as to give a number of points through which curves showing the variation of reheat factors with initial conditions could be constructed. In these determinations of η_i for use in the relation $R = \eta_i/\eta_s$ it was only necessary to locate the point at which the condition curve crossed the saturation line, so that the values of H_r and H_s could be calculated.

Figs. 7, 8, and 9 show values of reheat factors in the superheated region. These values are for expansion with constant stage efficiency, with an infinite number of stages, from the initial superheat conditions to the saturation line.

Saturated Region. The problem is decidedly different in the case of the saturated region. The effect of the decreasing stage efficiency on the construction of the saturated portion of the condition curves was shown in the previous discussion of condition curves. This variable stage efficiency, combined with certain properties of steam, make it difficult to determine a true average stage efficiency for the entire expansion in the saturated region. Hence for the saturated region the relation $R = \eta_i/\eta_s$ cannot be used, and the laborious method of summing up the individual Rankine heat drops Σh_r must be followed.

The previous work on condition curves gave data to calculate reheat factors for nine different conditions in the saturated region. The method previously outlined was used to construct condition curves of different stage efficiencies from various saturation pressures to the 1 in. of mercury back-pressure line. The summation of the individual Rankine heat drops h_r was obtained from the plotted condition curves by stepping off along the curve with a pair of dividers.

Fig. 10 shows values of reheat factors in the saturated region. The stage efficiencies shown on the curves of Fig. 10 are the values assumed for the beginning of expansion at the saturation line. These stage efficiencies are decreased with increasing wetness of the steam as explained in the earlier section. The values of the reheat factors are for expansion with decreasing stage efficiency for an infinite number of stages, from a given saturation pressure to the 1 in. of mercury absolute exhaust pressure.

Discussion. Knowing the initial condition and the stage efficiency, the reheat factor in the superheated region may be found from Figs. 7, 8, and 9 without previous knowledge of the shape or location of the condition curve. However, to determine the reheat factors in the saturated region, the pressure where the condition curve crosses the saturation line must be predetermined, which can easily be done by the methods developed in this study.

III—CONCLUSIONS

This investigation has been made by the use of Goodenough's Mollier diagram, and the constants used in constructing the condition curves and the reheat factors can only be used in connection with that diagram.

The author has applied the constants determined by this investigation to plot condition curves on different Mollier diagrams. It was found that these condition curves did not check with similar ones drawn by the step-by-step method. This showed quite conclusively that different diagrams based on various steam tables have different characteristics. To plot the condition curves correctly on such different diagrams, it is only necessary to determine the characteristics of the particular steam tables that are used.

The author considered investigations of the characteristics of different steam tables. However, it was felt that the research on the properties of steam, sponsored by the A.S.M.E., and carried on jointly at the Bureau of Standards, Harvard University, and the Massachusetts Institute of Technology, will fix certain relations from which standard properties of steam can be calculated. With these properties thus permanently established, the basic principles of this investigation can be applied to determine values for the constants, and to calculate reheat factors which could be universally used.

The author wishes to acknowledge his indebtedness to Prof. A. G. Christie, of the Johns Hopkins University; Prof. G. A. Goodenough, of the University of Illinois; W. B. Flanders, of the Westinghouse Company; Prof. J. H. Keenan, of Stevens Institute of Technology; and G. B. Warren of the General Electric Company for valuable information and suggestions.

Power Supply for New England Industry

By F. M. GUNBY,[1] BOSTON, MASS.

IN CONSIDERING the broad subject of the power supply for New England industry, it should be of interest to know how much power is required, whether or not the amount is increasing, the sources from which power is obtained, and its cost compared to that in other parts of the country. One of our largest industries is composed of the electric power and lighting companies, referred to generally as the central stations. It is of interest to know how much of the total energy used is supplied by these central stations, and how much is supplied and used by the manufacturing plants, referred to as the industries.

The principal objects of this paper are therefore:

a To show how much power New England is using and the rate of increase, including power generated by the industries and by the central stations.

b To analyze the growth and sources of power in the industries to see if any definite trend is indicated as to procurement of power.

c To compare figures for the approximate cost of power in various sections of the country.

The facts brought out in attempting to attain these objects will show what is going on in connection with our power supply, and may give the answer to some of the points on which there has been much discussion in the past.

New England attained her industrial development through the inventive and industrial capacity of her people, and because Nature had helped her in some respects although handicapping her in others. One of her many advantages in the early days of manufacturing was that there was an abundant supply of water power which could be easily harnessed.

As the manufacturing units grew larger, the water powers were supplemented by steam, and later by purchased electricity.

Throughout this development we can see the abandonment of small factories and water powers as being no longer able to meet the increasing competition, first, from more efficient plants, and, later, from plants located where some conditions made production costs lower. It appears that we must always keep the element of comparative cost clearly before us. We can see today examples of small water powers, or ones which would be excessively expensive to redevelop, being abandoned when worn out.

From these small beginnings the power requirements have developed until it was estimated by the Power Investigating Committee of the Associated Industries of Massachusetts that the energy required for all of New England in 1928 would be in excess of 8¾ billion kilowatt-hours, not including railroad locomotives.

This Power Investigating Committee was appointed in 1923 by the Associated Industries of Massachusetts to "ascertain the facts with reference to the power situation in New England." The members were Charles T. Main, Chairman, Henry I. Harriman, Dugald C. Jackson, George L. Finch, and B. Preston Clark. It served without pay, but the work of its staff cost several thousand dollars, and it spent about a year in preparing its report, which was published in April, 1924.

The report of this committee is a most comprehensive study of the power situation in New England, and has been used in this paper as the basis for much of the data as to power requirements, and the author wishes to make suitable acknowledgments here for use of the data contained therein.

It has been possible to get figures in regard to Massachusetts industries for 1925, and for her public utilities for 1927, with which to test the accuracy of the estimates made in that report. The results of these checks indicate that the actual rate of increase in the amount of power required has closely approximated the rates predicted by the Committee. It is probable that what is true of Massachusetts will hold for the rest of New England, so that the data given in the Committee's report may be used with confidence today.

These statements refer to the total power, which shows a consistent increase. Individual elements, of course, vary from the average. The textile industry, and particularly the cotton portion of it, shows a decrease in power used. Some other industries have grown to offset this. Some large public-utility systems, partly by absorbing the load of others, have grown at rates far above the average, five of the larger ones showing, in the five-year period from 1922 to 1927, an average increase of about 75 per cent. The interchange of energy between companies shows a large increase for this five-year period.

Amount of Power Required

Fig. 1 shows the total energy requirements for New England, not including railroad locomotives, from 1915 to 1923, and the Committee's estimated rate of increase. The power shown here includes that for the industries, for public and domestic lighting, power for homes, and for all of the miscellaneous purposes for which public-utility energy is used. It shows that for 1928 about 8¾ billion kilowatt-hours will be required, of which about 5¾ billion would be generated by central stations and about 3 billion by the industries. The Power Investigating Committee predicted an annual increase of total energy, after eliminating duplication, etc., of from 1.5 to 2 per cent of the 1923 output. It also estimated that the central-station output would increase faster than this, or at the rate of about 9 per cent of the 1922 total. The actual average rate of increase from 1922 through 1927 was just over 9 per cent.

It was further shown that about two-thirds of this power is used in an area of Massachusetts, Rhode Island, and New Hampshire centering about Eastern Massachusetts. Massachusetts uses approximately one-half the energy required for all the New England industries.

In 1922 about 70 per cent of the total energy was generated by fuel and 30 per cent by water, and the same proportions held for the energy generated by central stations and industrial plants. In 1927 about 75 per cent of the energy generated by the central stations was from fuel, and it is probable that the same figure would hold for the industries.

Taking the six public-service electric companies reporting over 100 million kilowatt-hours generated in 1927 and adding certain other companies closely associated with them, we find that in 1922 they accounted for about 85 per cent of the total energy generated by all the electric companies, and in 1927 for about 89 per cent.

Another important point is that in 1927 all the public utilities and municipal plants, excluding street railways, reported a total of about 3,500,000,000 kw-hr. on their switchboards. Of this, however, only about 2,400,000,000 kw-hr. was generated or purchased from sources which would not be duplicated in the re-

---

Contributed by the Power Division and presented at the New England Industries Meeting, Boston, Mass., October 1 to 3, 1928, of The American Society of Mechanical Engineers.

ports, showing that about 1,100,000,000 kw-hr. was sold or interchanged between public utilities. This was about 2½ times the amount of energy so interchanged in 1922.

This shows that the companies did a large volume of business on interchange of power, and undoubtedly a great conservation of fuel and other costs resulted. During this year there was purchased from plants not a part of the public-service companies, about 40 million kilowatt-hours. This was purchased mostly from a few industrial plants having surplus water power, and from the Metropolitan District Commission, generated by its water-supply works.

Another interesting feature is that in Massachusetts the increase of load from 1922 to 1927 for the industries only, was about 130,000,000 kw-hr., while the increase in load of the central stations was about 930,000,000 kw-hr. for the same period, showing that the industries used only about one-seventh of the increase in the central-station loads, the remainder probably being used for public and domestic purposes, including lighting, washing, ironing, cooking, and other domestic purposes, and "sitting up to listen in."

TABLE 1

Industry	1909	1914	1919	1922	1925
Cotton goods (incl. smallwares)	362,000	438,100	526,400	536,500	572,200
Woolen and worsted goods (incl. felts)	127,200	154,100	190,100	199,000	230,000
Paper and wood pulp	115,800	133,900	145,300	139,100	153,200
Iron and steel works, foundry and machine-shop products	.....	.....	.....	100,000[a]	133,000[a]
Dyeing and finishing textiles	.....	30,900	39,100	53,000	72,300
Boots and shoes (incl. cut stock and findings)	.....	39,700	48,400	50,700	43,700
Rubber goods	.....	17,500	34,400	43,000	62,000
Electric machinery, apparatus and supplies	.....	29,900	36,400	40,000	57,500
Leather, tanned, curried, and finished	.....	26,500	34,200	37,900	40,500
Cordage, twine and jute goods	.....	28,600	32,400	33,000	.....
Wire and wire working	.....	15,100	24,800	23,900	31,400
Gas	.....	11,500	18,800	22,200	25,700
Printing and publishing	.....	.....	21,100	20,500	24,200
Cutlery and misc. tools	.....	.....	20,900	19,900	.....
		925,800	1,172,300	1,318,700	1,445,700
Misc. other industries	?	471,000	557,200	471,400	567,300
Total	1,175,100	1,396,800	1,729,500	1,790,100	2,013,000

[a] These figures are probably not strictly comparable.
NOTE.—The total for 1926 was 2,016,000 hp.

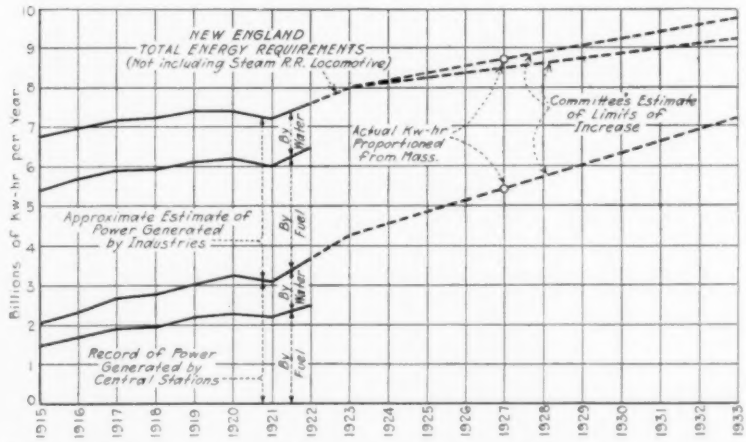

FIG. 1 GROWTH OF NEW ENGLAND POWER REQUIREMENTS IN EQUIVALENT KILOWATT-HOURS
(Taken from report of Power Investigating Committee of Associated Industries of Massachusetts, January, 1924.)

From 1922 to 1927 the generation by street-railway plants decreased by about 38,000,000 kw-hr., or about 10 per cent.

POWER REQUIRED IN VARIOUS INDUSTRIES

Table 1 shows the installed horsepower in the principal power-using industries in Massachusetts for the past several years. (All figures given to nearest 100.) These are arranged in order of size for 1922.

The figures given are for the installed capacities as reported to the Massachusetts Department of Labor and Industries. The actual load requirements will be less, and have been estimated.

The boot and shoe industry is the only important one in Massachusetts which shows less installed horsepower capacity in 1925 than it had in 1922, the decrease being from 50,700 to 43,700 hp.

Fig. 2 shows the growth of power capacity in all the industries in Massachusetts, both in installed capacity and in probable actual load.

This chart shows that there has been practically no change in the amount of installed water-power capacity, a slight decrease in the installed fuel-burning power-generating equipment, and a rapid increase in the amount and proportion of purchased power.

In 1922 the purchased power for all industries was about 38 per cent of the total, and in 1925 it was 43 per cent of the total, showing that purchased power accounted for much of the growth of the total power in the industries. In fact, the increase in purchased power accounted for about 90 per cent of the total increase in the installed horsepower in the industries.

The fuel-burning capacity installed in the generating plants of the industries in 1925 was almost exactly the same as it was in 1914, while the water-power capacity was the same as it was in 1900. This indicates clearly the trend toward the purchase rather than the generation of power in the industries, at least as far as growth is concerned. It also means that as some generating plants wear out, their places are taken by purchased current.

Some industries require large amounts of steam for their process work, and for which fuel must be burned, whether power is generated or not. Among these are the woolen, paper, dyeing and finishing, rubber, soap making, sugar refining, laundry, and similar industries. The installed capacity in these industries in Massachusetts in 1925 was about 570,000 hp., or about 28 per cent of the total of the state's industries. The purchased current represents about 28 per cent of the power uses of these industries, and this ratio has not changed much in recent years.

The remainder of the industries have about 1,440,000 hp. installed, and of this about 50 per cent in 1925 was for purchased current. The industries in this group have relatively little use for steam in their processes, the principal uses being for warming the buildings.

The proportion of purchased power in all the industries of the state has increased from 16 per cent in 1914 to 43 per cent in 1925, and it will probably increase materially in the future.

PRINCIPAL POWER-USING INDUSTRIES

The three largest users of power among the industries of Massachusetts, and probably of New England as a whole, are the cotton manufacturing, woolen and worsted manufacturing with their several subdivisions, and the paper and wood-pulp industries.

Table 2 shows the installed horsepower in 1922 and 1925 as reported to the Massachusetts Department of Labor and Industries.

These figures represent installed generating capacity and motor capacity for purchased current, and surplus water-power capacity.

TABLE 2

Industry	Hp. installed, including secondary water and other surplus capacity 1922	1925	Increase, Per cent
Cotton manufacturing	536,500	572,200	7
Manufacturing of wool, including felts	199,000	230,000	15
Paper and wood pulp	139,100	153,200	10
All other industries	915,500	1,057,600	15½
Total	1,790,100	2,013,000	12½

In the textile industry there has been a considerable increase in the installed motor capacity for the same machinery, due to the use of individual drives, etc.

For this and other reasons it is felt that the Bureau of the Census data as to the number of spindle-hours operated during the year are a better guide to the total power used by the cotton textile industry than is given by the installed horsepower capacity. In 1922 the cotton mills of Massachusetts operated 25,233,000,000 spindle-hours. In 1927 they operated 19,662,000,000 spindle-hours, or 78 per cent as much as in 1922. Assuming that a kilowatt-hour will operate an average of 37 spindles for an hour, the power required in 1922 was 682,000,000 kw-hr., and in 1927 it was 530,000,000 kw-hr., showing a decrease of 152,000,000 kw-hr. per year in the power actually used by the cotton mills in Massachusetts. The decrease for all New England cotton mills was 227,000,000 kw-hr.

This loss is accounted for by plants running at part capacity, or that have liquidated, or have moved to locations where manufacturing costs would be lower, or by plants that have scrapped some of their older equipment. This shrinkage is still going on.

The statistics for the woolen and worsted mills and allied plants do not give the spindle- or loom-hours operated except for the country as a whole. It seems probable that the New England mills may have run fewer hours in 1927 than in 1922. However, the installed horsepower capacity in Massachusetts mills increased about 15 per cent between 1922 and 1925 and the use of power probably increased in about the same ratio. The same figures may be assumed to hold for all of New England. The actual load for this industry was estimated at 125,000 hp. for 1922, and it was probably 145,000 hp. in 1927.

The installed horsepower in the paper and wood-pulp industry of the state increased from about 139,100 to 153,200 hp. or in the neighborhood of 10 per cent. It is probable that the actual load increased in about the same proportion.

From the above it appears that between 1922 and 1925 the textile industry's actual power load decreased by about 11 per cent while in the same period the actual load of the remainder of the industries in Massachusetts increased about 15 per cent. The total actual load increased from 1,250,000 to 1,302,000 hp., which is just about the increase predicted by the Power Investigating Committee.

Data for the textile mills for 1927 show only a small decrease from 1925. The figures as to installed capacity in the other industries are not yet available.

These checks show that the estimates for the future requirements for power for New England industries as given by the Power Investigating Committeee of the Associated Industries of Massachusetts have proved accurate.

The figures also give a clear indication that while New England's largest power-using industry has suffered severely in recent years so that the amount of power used by it has shown a substantial decrease, the growth of the other industries has been sufficient to more than offset this loss.

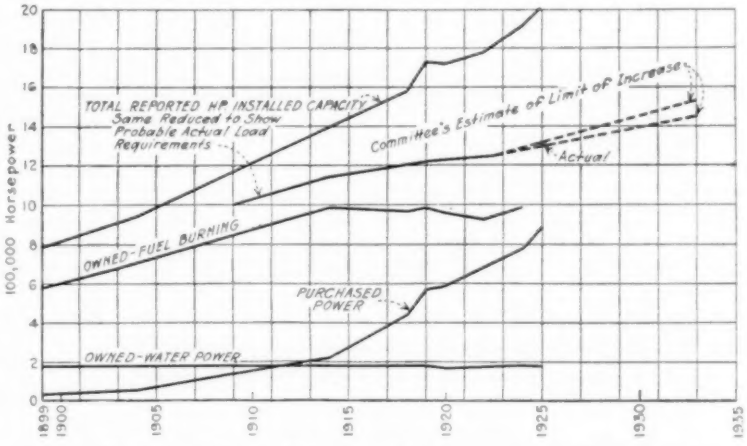

FIG. 2 GROWTH OF POWER CAPACITY—ALL INDUSTRIES IN MASSACHUSETTS
(Taken from report of Power Investigating Committee of Associated Industries of Massachusetts, January, 1924.)

COMPARATIVE COSTS OF PURCHASED POWER IN VARIOUS SECTIONS OF THE COUNTRY

Since the products of our industries must compete with those from other sections of the country, a comparison of the cost of production in various sections is of interest. A comparison of the costs of purchased power in various parts of the country has been made. It may be assumed that the same features which affect the cost and price of power of the public utilities will have a similar effect on the cost of power if made by the industries, so the relative cost of purchased current should give a reliable picture of power costs in those sections.

The cost per kilowatt-hour delivered at the mill voltage has been estimated from the rates of large power companies in the Central West, Middle Atlantic, and some of the Southeastern states. In calculating these costs, the same loads and hours of use were assumed in all cases, so that the results would be as fairly comparable as possible, and for each locality the rate applying which would result in the lowest cost has been used.

These figures must not be taken too literally as applying to any particular load because, with the various companies, the form of the rate, the method of determining the demand, power-factor clauses, etc., may apply in actual practice differently from the assumptions made in calculating the cost from the published rates.

In Fig. 3, the upper curves show the cost per kilowatt-hour for various loads or demands when the plant runs 200 hours per month, and assuming that the average load is 80 per cent of the demand, or, in other words, that the demand is used 160 hours per month. This would correspond to a fairly steady load, like a textile plant running one shift.

The lower curves show the cost based on using the demand 368 hours per month, corresponding to a steady load running two 55-hour shifts. The prices for all current were reduced to the basis of low tension delivery at the industry's plant.

The graphs for the cost in New England were made up by averaging the rates charged by the

Central Maine Power Company
Edison Electric Illuminating Company of Boston
Hartford Electric Light Company
Narragansett Electric Company of Providence
England Power Company, and the
Turners Falls Power & Electric Company.

Similarly, that marked "Central West" was made up from the rates of the

Cleveland Electric Illuminating Company
Commonwealth Edison Company of Chicago
Union Gas and Electric Company of Cincinnati, and the
Union Light and Power Company of St. Louis;

that marked "Middle Atlantic" was made up from the rates of the

Consolidated Gas, Electric Light & Power Co. of Baltimore
Philadelphia Electric Company, and the
Public Service Company of New Jersey;

and that marked "Southeast" was from the rates of the

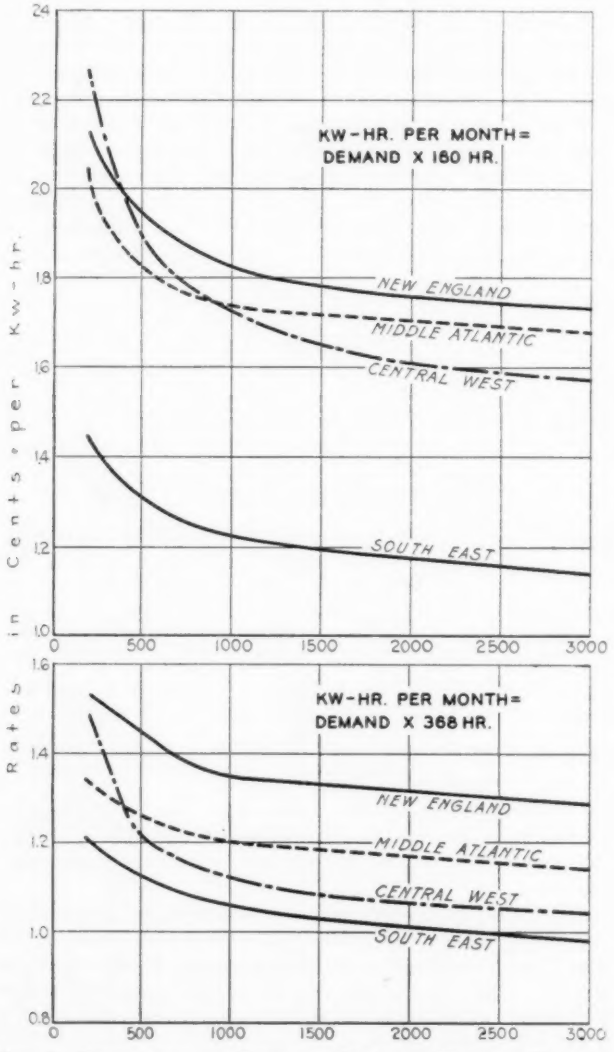

FIG. 3 COMPARISON OF COST PER KILOWATT-HOUR IN VARIOUS SECTIONS OF THE UNITED STATES

(Rates shown are averages of prices for purchases current from several important companies in each section of the country. Rates are reduced to low-tension basis.)

Alabama Power Company
Georgia Power Company, and the
Southern Power Company.

DIVERSITY FACTOR AND INTERCONNECTIONS

The power required to drive a single machine will follow all the variations in the cycle of operation of that machine, showing the maximum and the minimum requirements at the appropriate periods. The power to operate 100 such machines will not show 100 times the maximum, nor 100 times the minimum, but will show variations much less than these, and only the average power will increase in even approximate proportion to the number of machines making up the load.

In a similar way, the load characteristics for different factories and of different industries are different, and if many of these are supplied from the same power source, its capacity does not need to be so great as the sums of the peak loads of each unit connected. In the same way, the lighting of homes and streets would not usually reach its peak during the period of the industrial day shift.

An individual plant or a small utility will get little benefit from these conditions, while a large power system will be able to realize great savings in capacity required and from improvement in load factor from being able to combine the loads of many plants and industries with one power system. The result has been larger and more efficient generating stations and the shutting down or holding in reserve of the less efficient fuel-using stations. Most of the large companies are now interconnected so that they may exchange power with each other. Such arrangements make it possible to use the generating equipment to the best advantage, to make use, at times, of water power which would otherwise be wasted, and to give greater assurance of reliable service.

With these modern arrangements, a considerable portion of the energy required in New England is bought and sold between power companies from day to day almost on a commodity basis. What one has available but has no immediate use for, another may be able to use—at a price. One example of this, in which several large companies in Massachusetts and Connecticut are interested, is the Connecticut Valley Power Exchange.

Another of our large water-power companies has for years had interchange arrangements with companies having large steam power plants, and also with industries and others having steam and water powers, and with large water-power companies operating in other states.

INDUSTRIES REQUIRING PROCESS STEAM

There are certain industries which must burn large quantities of fuel to get steam for use in their processes regardless of how their power is obtained. In this group are the wool manufacturing, dyeing and finishing of textiles, paper manufacturing, rubber industry, sugar refining, soap manufacturing, and a good deal of the chemical industry.

Where this steam can be used in the processes at low pressure, as much of it usually can be, it is simple and efficient to put high-pressure steam through a prime mover and generate power with a small portion of its heat and use the exhaust in the processes. This is common practice in most of these industries. Much has been written on the subject, including a paper by W. F. Ryan[2] on the use of unusual high pressures for this work, and by M. K. Bryan on the importance of selecting the proper apparatus for the conditions, and of guarding against losses due to fluctuating conditions of power and steam loads.

One important matter in the use of non-condensing turbines in connection with process steam is to avoid waste where the requirements for steam and power do not coincide. Where the steam requirements are far in excess of the amount produced in making power, there will be no waste.

There are many cases, however, where there is an excess of power requirement at one time of day and an excess of steam requirement at another. In cases where warm water is used in the process in large quantity, it has been possible to balance these conditions by making and storing warm water.

It would seem that these cases should give grounds for the

[2] Trans. A.S.M.E., vol. 47 (1925), p. 779.

power companies to come in and act as the balance wheel and sell all the kilowatt-hours the industry did not make from its steam needs. Special rates would generally be desirable, probably working on a buy-and-sell arrangement. There is about a half-million horsepower in industries having these conditions, and in this field the rate of growth of purchased current is small and may be expected to remain so unless some such arrangement as indicated can be worked out.

There are now cases of waste where, because an industry cannot afford not to generate some of its power with process steam, it is forced to generate it all, and at times to waste steam. It would seem that there should be some solution which would meet these cases and permit the power companies and the industries to share what must now be wasted. In the case of industries using, say, less than 500 kw., there will probably not be sufficient savings possible to justify doing anything special.

Each of these cases would require individual consideration, but if the problem is approached by both sides in the same spirit which has led to the great interchange of power between the utility companies, a constructive solution should be found. Something may be accomplished in localities where manufacturing is concentrated by the use of central stations using very high initial pressures and exhausting at a pressure high enough to permit the economical transmission of steam for considerable distances.

General Summary

In a paper of this kind it is possible to draw only conclusions applying to the situation as a whole. Such conclusions cannot be applied to particular cases, as each case may have special features which would materially affect the answer.

There is no hard and fast formula by which we may say that all users of a given amount of power should purchase it or should not purchase it, and there will not be so long as the rates of power companies differ and conditions in plants vary, and the individual retains his independence.

The total amount of power used by the industries is increasing, and part of this increase has been provided for by an increase in the generating capacities in the industries, while a greater part has been provided in the form of purchased current. This condition demonstrates that the users have found that, for some conditions, it is better to generate the power required, and, for other conditions, to purchase it, and, for still others, to generate some and purchase some. That the proportion of power purchased is increasing shows that there are more conditions which make that course advisable than there are which make generation advisable.

There are probably cases where it would have been better to adopt a different solution than the one chosen, due to lack of sufficient engineering information or data, or to financial conditions, or salesmanship, or prejudice; but these cases form only a small portion in what the industry has done as a whole.

The investment in plant will nearly always be less when power is purchased than when it is generated by the industry. The cost of power is a matter which must be determined when considering how to obtain it, and will play an important part in arriving at the decision.

The power supply where the installations are well made has been satisfactory, whether generated by the industry or purchased. Poor installations have given unsatisfactory results in both cases.

In general, plants served by long transmission lines are subject to more frequent interruptions and annoyance than those with good installations of their own. On the other hand, there is less likelihood of a long shutdown, due to accident, when served by a modern, well-managed utility than where the industry has its own plant and does not have sufficient spare capacity.

The following points are of particular interest. In these, 1922 is used as a base.

1 The total power load of New England, excluding railroad locomotives, is increasing at an average rate of about 3 per cent per year.

2 The load of the industrial plants of Massachusetts is increasing at the rate of about $1^1/_2$ per cent per year, and this figure probably holds for all New England.

3 The load on the central stations is increasing at an average rate of about 9 per cent per year.

4 The increase of load in the industrial plants accounts for only about one-seventh of the increase in load on the central stations, the balance being used for public lighting, domestic purposes, and the many new uses which are constantly developing.

5 The bulk (about 90 per cent) of the increase of installed power capacity in the industries is in the form of purchased-power facilities. This is not true to the same extent for those industries which use large amounts of steam in their manufacturing processes.

6 As gaged by the relative rates for purchased current, the cost of power in New England, while considerably higher than in the Southeast, is, on the average, only about 5 to 10 per cent higher for single-shift work than in the Central West and Middle Atlantic states. For two-shift work the excess cost in New England is more marked. This is natural in view of the distance from the coal supply.

7 There are some who hesitate to face the fact that our textile industry is in a deplorable condition, and there are others who seem convinced that all New England industrial development is on the decline. Such attitudes do not change facts, and the facts are that what we have lost and are losing in some lines, notably textiles and shoes, we have made up for by growth in other lines; so that the total use of power, and the prosperity which goes hand in hand with it, has maintained its normal rate of increase. As long as this is so, it seems that New England must be fundamentally sound.

Discussion

Charles L. Ware.[3] In the woolen industry the trend has been toward increased use of heat in processing, particularly in the finishing process. As this is almost wholly at comparatively low temperatures the opportunity for using the heat rejected from power units is especially favorable. It would therefore seem that the use of purchased power in this industry should properly show a downward trend if full advantage is taken of the possibilities.

In certain branches of the woolen industry it is found that as much as two-thirds of all steam generated is used directly in process work besides utilization of the waste heat from power units. In other branches a very satisfactory balance is had when nearly all steam first goes through the engine or turbine. It is only in cases where the dyeing and finishing processes are not incorporated with the preparation and weaving plants that any excess of waste heat is to be anticipated, provided that a proper selection and application of driving units is made.

In one large plant a change from hydroelectric to steam power has been made in which normally all steam generated goes to the power units and all process steam is bled at suitable pressures and the remainder passed to a condenser which furnishes the requisite warm water. By means of a suitable control system the temperature is kept constant and the fluctuation in quantity equalized to process by storage tanks. In this instance the fuel consumption

[3] Engineer, Steam and Water Power, American Woolen Co., Andover, Mass. Mem. A.S.M.E.

was not increased by the addition of the power units, as experience developed that there had previously been a material waste in the use of steam when the supply was taken direct from the boilers and that the interposition of turbines as reducing valves aided in checking this waste.

There are notable examples in this industry of private plants which could supply to the central station considerable power for a part of the time at a low cost by reason of their need of the process heat obtainable by steam extraction or from condenser water and which would also be benefited by having a supply of cheap power available for small overtime uses or when process requirements were smaller than the supply available when generating all of the power demand. Under such an arrangement the individual plant could depend on the central station for breakdown service, thus avoiding the cost of spare units.

Such arrangements would be more feasible when the connection was with a large power system so that a single plant either supplying or drawing its rated capacity would have no serious effect on the system as a whole.

A plan of cooperative connections of this sort would probably require the formulation of special rates, methods of protection, and rules and regulations of a comprehensive nature if the practice were to become at all general among this class of power users.

Study and suggestion along these lines would seem to be quite within the province of this organization.

S. L. Elden.[4] Mr. Gunby's paper has utilized statistics which give a complete review of the existing situation as it has been developed in actual practice in New England and elsewhere.

In pointing out the increasing tendency toward the utilization of purchased power for industry in general, it is of course apparent that favorable results follow from such a course, otherwise it would not continue to develop in an ever-increasing ratio.

Observation of industrial operations utilizing purchased power from the larger companies has always brought into view the relief which the power user seems to have secured from having an inexhaustible source of power at his command as compared with the anxieties which frequently exist where the operation of a private plant is not all that could be desired.

It is undoubtedly true that the cost of power in most processes is today a very small element in the total cost of any finished product, hence the choice between purchased and privately made power must usually be made from a consideration of other points of view than the relative cost of power from different sources.

We have found in many situations that the ease with which power requirements can be extended to meet a growing business may overcome any unfavorable cost factors which under various methods of computation may possibly appear to make private operation more economical.

As to comparative costs for purchased energy in various portions of the country, there would undoubtedly have been different results obtained by Mr. Gunby by the selection of other companies in obtaining the average costs in various locations.

In the New England group where the highest costs were shown it would have seemed more reasonable to include only strictly hydroelectric companies when comparing costs with that group designated as "Southeast" where only hydroelectric companies are involved. By readjustment to provide a comparable basis, it appears upon a rough check that New England might well be placed in a more favorable position than appears from the computations as shown in the paper.

There appears to have been no recognition taken of the rate schedules in existence in New England whereby the central stations supply large blocks of service to industrial customers under so-called "off-peak" rates. These rates average lower than any rate shown in the graphs up to approximately 2500 hours of use.

Some large power users have effected substantial savings in power costs through the purchase of energy under these rates whereby energy which they are required to develop from their own plants is but a small fraction of their yearly requirements.

In referring to New England conditions and costs for purchased energy, it seems important to consider the entire rate question and to give credit to New England ingenuity in the development of rate schedules which result in an actual economy to the user and at the same time are productive of a large amount of business to the utilities.

In the conclusions which Mr. Gunby has drawn, the old contention of unreliable service derived from long transmission lines is again brought to the front, and it is desirable to point out that under conditions existing in New England most long transmission lines are parts of systems that are backed up by both hydroelectric and heavy steam reserves; where the steam reserves are not actually a part of the system owning the transmission lines other companies supply the necessary steam reserves through the extensive interconnections which now exist.

In the largest system in New England the multiplicity of sources of power and the subdivision of the generating plants and transmission lines into units limiting the capacity involved in the case of the failure of a single line or unit have gone far toward relieving the system as a whole of the troubles which were long considered inherent in systems employing long transmission lines.

It is believed that this factor will shortly become of even less importance, when duplications of lines, both over the same and different routes, are completely developed from all important sources of power as is now contemplated in a number of important systems. Further, the development of protective equipment capable of contending with lightning, now the greatest source of trouble, will undoubtedly be such in the future that even less trouble will result from lightning than occurs at present.

With respect to the future power supply for New England, there is no evidence to show that any of our public utilities are neglecting to provide for the future in an ample and careful manner. Extensions to steam generating plants are contemplated to meet forecasted requirements where dependence is placed upon steam generation. Hydroelectric developments of the first magnitude are either under way or in contemplation, to utilize important sites which can be properly developed and coordinated into a single operating system, thus combining the output of both hydroelectric and steam sources of supply throughout New England.

The extensive interconnections which have been and are being developed will unify practically the entire power sources throughout New England with the exception of the state of Maine. New England can rest assured of continuous power developments adequate in every respect to meet the requirements of its industries in the future as in the past.

An important innovation in the operation of private power installations appears to rest on the possibility of some of our utilities utilizing the power by-product of certain important industries along lines which would result in the conservation of fuel and a reduction in the cost of power to the industry.

A number of these possibilities appear in sight which may be proved profitable to both interests and go far to place an even greater approval upon the use of purchased energy.

D. S. Boyden.[5] Mr. Gunby's paper gives many valuable data that will be useful for reference purposes. It shows a definite trend toward the use of purchased power by the industries. I would like to point out a few facts in reference to the use of steam for process and heating which materially affect the eco-

[4] The Edison Electric Illuminating Co. of Boston, Boston, Mass.

[5] The Edison Electric Illuminating Co. of Boston, Boston, Mass.

nomics of the problem of purchased power compared with generated power.

To a considerable extent the economical use of steam in the industries has not always received the careful consideration and study which it deserves. Where the exhaust of prime movers is used for process and heating it is sometimes treated as a by-product of little value, not justifying much effort to conserve it. This is due to the difficulty of determining the real value of the by-product steam. In fact, few industries know the demand or consumption of steam by their various processes and services. Furthermore, steam metering equipment has been high in cost and has not been altogether satisfactory because of the varying flow and pressure. It is often difficult, therefore, to make an intelligent comparison of the cost of purchased power and of generated power.

The general tendency to overestimate the steam requirements for heating and process under the guise of "playing safe" reduces the apparent cost of generated power. Quite often careful study will show that much steam is being wasted through inefficient utilization. Many cases have come to my attention where the manufacturer has continued the operation of his plant at a considerable loss, still believing that he was operating under the most economical plan. A careful study of the situation based on accurate records of steam utilization will often pay handsome dividends.

Fortunately these conditions are being gradually corrected due largely to the results obtained in plants where power is purchased and steam for process and heating is supplied independently. In these plants the cost of the steam service is accurately known and focuses the attention of the management upon its efficient utilization.

Proper metering equipment is usually justified because it can be made to show where the steam is being wasted and steps can then be taken to stop the waste. Meters are also a constant check on the operation of the various processes in the plant and often indicate improper routine of production. This last factor alone often justifies the expense of the metering equipment.

In the last few years the engineers of the company with which I am connected have cooperated with many industries in an effort to determine the most economical balance between generated and purchased power. In many cases which at first seemed to be especially suited for generation of their own power we found that when all factors were taken into consideration the industry would save money by purchasing at least a considerable portion of their power requirements.

Quite often it has been found economical to use some other heating medium than steam. The change of heating medium has often showed not only higher economy but also an improvement in the product being manufactured.

Where these savings have been effected production has not suffered but has usually been speeded up.

I have thought it worth while to point out these facts because more attention to the efficient use of steam will result in a proper division between purchased and generated power. This, in turn, will result in lower power rates to the industries and will bring the rates in New England as low as the rates in the Middle Atlantic and Central West.

PHILIP CABOT.[6] There are two points on which I should like to comment briefly.

The first is in regard to the probable future growth of the use of industrial power. The author shows that during the last few years the rate of increase has been between 1.5 and 2 per cent in spite of the fact that during that period the textile and shoe industries have been so depressed that their consumption of power showed an actual decrease and the situation has been saved only by the growing use of power by other industries. This is a condition which in my judgment is temporary. The boot and shoe industry already shows signs of improvement. The cotton textile industry of New England has been brought to its present condition by unskillful management. This may have been because the managers followed the teaching of the theoretical economists as to the operation of "the law of supply and demand." This so-called law is very misleading—in fact, the most recent studies on the subject seem to indicate that there is no one law of supply and demand but that there are several and, moreover, that the problem of dominant importance has long since ceased to be that of regulating supply and has become that of stimulating demand. This important fact our textile manufacturers seem to have overlooked. In the early days of the industry it was possible to run a mill successfully with almost a single eye on manufacture, the objective being to reduce the cost of production to a minimum by running the mill full for long periods of time on some standard line of goods without much attention to the demand or market side of the business. The mills have found to their cost that this cannot now be done. The stimulation and regulation of demand now are the major problem; not manufacturing but selling is the chief duty of the manufacturer; herein the New England manufacturers seem to have been weak.

This situation is temporary, however. New men will be found who understand modern conditions and it will not be long before our textile mills will resume their place as consumers of power upon an increasing scale. The result will be that the market for electric power, which during the last few years has appeared to be saturated, because it showed a rate of growth about equal to the growth of population, will increase at a normal rate—at least double that of recent years.

My other comment on Mr. Gunby's paper is this: The new men in the textile industry will not tie up their quick assets in power plants unless they are forced to do so. If power of reliable quality can be bought as cheaply as it can be produced they will buy power and will keep their money in quick assets where by rapid turnover it can be made most profitable. This means that there will be an opportunity for the central stations of New England to build up a much larger power load if they are alert and skillful merchants. Their major problem will be to ascertain first the prices at which a maximum volume of business can be obtained, and second, whether they can produce this quantity at a cost that will show a profit. The community has a right to demand that they exert themselves to the utmost to attain maximum volume, which means a low price; and in order to make any profit the highest possible efficiency in production is essential. But to reduce production costs much below their present level is not a simple problem; in fact, it seems improbable that the cost at the switchboard of steam generated power *at a given load factor* can be reduced by any substantial amount from the figure now reached by the more efficient stations. So far as hydroelectric power is concerned the same holds true because the cheapest and best located sites have already been developed. Those that remain are either so far from the market that the transmission costs will be high or involve a high development cost. A method is in sight, however, which if skilfully used may enable the companies to make a substantial reduction in price without an undue sacrifice of profit. I refer to the possibilities of improving load factor by interconnection.

If all the principal producing stations in New England are tied together by a well-designed transmission network and if the operation of them is coordinated with skill, great improvements in the load factor and the capacity factor of the whole group can be made. This will result in reducing operating expenses by produc-

[6] Professor of Public Utilities, School of Business Administration, Harvard University, Cambridge, Mass.

ing the power at the most efficient point in the system taken as a whole and also in reducing fixed charges because the same total system load can be carried with a smaller investment in generating equipment.

One good way to accomplish this result would be to combine all the operating units in New England by means of a holding company. There have always been too many small independent producers in New England for the good of the customers; and the area, population, and market are not too large to be handled successfully by a single organization. The efforts of the New England Power Association seem to look in this direction and it is earnestly to be hoped that no narrow or selfish interest will be allowed to hamper this scheme of coordination.

It must be admitted that the provincialism of New England people and politicians is a somewhat serious obstacle in the road of progress in this direction. It is still illegal in Massachusetts to combine the operating companies of the state in the way which would be most useful to their customers and the state of Maine is still inclined to prevent the development of its water powers by prohibiting the sale of the output in the only markets now available, which are outside the state.

Fortunately, so far as all the other New England states are concerned, there is a method by which the advantages of combination can be secured without sacrificing the independence of the present operating units. The objective is such coordination of all efficient generating stations that the diversity factor of all the loads in New England may be used to give the maximum system load factor while at the same time the power is generated at the most economical point. This can be done by a well-designed transmission network centering on a load dispatcher who has complete control. Experiments with this method have already been made in the Connecticut Valley Power Exchange through which the operations of the stations at Turners Falls, Springfield, and Hartford have been coordinated with profitable results. Similar arrangements for interchange have been employed by the New England Power Company. These are only beginnings and if important economies are to be achieved the thing must go much further. The economy of quantity production in all industries depends upon a large and constant market. As already noted, demand determines supply, and large-scale or quantity production must rest upon a large market. Big units of production and small or fickle markets cannot live together.

The power market of New England taken as a whole is large enough to sustain large units of production; broken up, as it now is, such production is not profitable. Before really low production costs can be reached the whole New England market must be combined at some central point in the office of a load dispatcher, or rather a power broker, where all the power produced in the area will be bought and sold. Such a broker would act as the agent of all the producers, who would call on him daily, or even hourly, to know the prices and quantities of firm or secondary power which his clients had for sale. This market would be open not only to all the central stations but to those manufacturers for whom, as noted by Mr. Gunby, power was a by-product and who at times might have power to dispose of at a very low price. Such an arrangement operating like a wheat or cotton market might introduce a form of competition into the electric power market which would keep the producers on their toes and prove to be a factor of major importance in the industrial development of New England.

H. E. Thompson.[7] Both conditions of interconnections of companies and exchange of power exist at the Amoskeag, and a description of the manner in which they are handled may be of interest.

Enough steam is used in process work to justify the installation of an exhaust turbine generating 4000 kw. with an initial pressure of 140 lb. gage pressure, and exhausting at 25 lb. back-pressure. This steam is delivered directly from the turbine to the dyehouses, wet finishing department, slashers and tenters, and is used for heating in the winter.

The regulation of the turbine is controlled entirely by the back-pressure, the steam demand in the mills determining the load generated by the turbine. This load varies tremendously during the day, sometimes as much as 1500 kw. within two or three minutes. This change in load is automatically taken care of at our hydroelectric plant a mile away, which has two 5000-kw. and one 6000-kw. units, synchronized with the steam plant.

During the middle of the day, especially in winter, the exhaust turbine generates as much as 4200 kw. about 4 p.m., but just when our lighting load is coming on, the turbine will have dropped its entire load, so we must be prepared to produce about 5000 kw. by some other means for the remainder of the afternoon.

Part of this power we produce by starting a 3000-kw. condensing turbine located in the same station. The boilers are going, the men are in the boiler house, and the same engineer can run it, so practically the only cost is the fuel used. The balance of 2000 kw. can be made up from water if available; and if not, it can be purchased from the Public Service Company of New Hampshire, with which we are interconnected.

This interconnection is of great benefit to both parties as we often have a surplus of water power when the Public Service Company can use it to advantage, and during the low-water period it is often a great advantage for us to be able to take power from them and not be obliged to keep an auxiliary steam plant in readiness.

William H. Larkin, Jr.[8] Mr. Gunby's interesting paper brings to the front once more the need of some standardized method of power cost accounting for use in the industrial plants of New England and the country at large. Until such a method is generally used, it will be difficult to make intelligent comparison between individual plants, between privately generated power, and purchased power, or from year to year at the same plant.

Such a standard power report should be compiled at regular intervals, preferably monthly, and should be largely financial, with enough supporting data of technical and engineering character to show underlying causes of fluctuations in power production costs. Such a report should show a certain amount of general data such as amount of factory production for period; amount, characteristics, and cost of fuel; total productive man-hours, cost of all power, etc.; a certain amount of engineering data sufficient to check the main facts of the report, such as total evaporation, boiler efficiency, engine, generator, water power and purchased power loads, with total horsepower-hours or kilowatt-hours produced or consumed; a section containing operating costs, labor, supplies, repairs, and charges covering the various departments of the power plant, that is, boilers, engines, generators, water power and purchased power; and, finally, a section containing the important unit costs, such as steam per thousand pounds, engine power per horsepower-hour, generated or purchased electric power per kilowatt-hour.

Such a report should be quite different from the usual engine-room log and should not concern itself with numerous engine-room details usually found on such operating records. Boiler and engine-room logs or records are useful and are needed but not generally outside the power plant itself. From them are drawn

[7] Mechanical Superintendent, Amoskeag Manufacturing Co., Manchester, N. H. Mem. A.S.M.E.

[8] Division Power Engineer, United States Rubber Co., New Haven, Conn. Mem. A.S.M.E.

the engineering facts which, with other facts and figures from the accounting department of the factory, go to make up the monthly report.

The "monthly power report" is for the use of the manager of the industry rather than for the chief engineer. Its function is to let the manager know how well he is being served in his power department—whether his costs for steam and power are greater or less than in previous years; whether or not the considerable expenditure made at the chief engineer's recommendation resulted in the expected reduction in unit cost; whether or not his engine or generated power unit costs compare favorably with the unit cost of purchased public service power offered. Such a report has essentially the nature of a continuous plant test made by the chief engineer and his assistants over long periods, which, if properly done, is more valuable than a short test, however carefully made, by some outside engineer.

One or two of our large industries operating several power plants have such power reports which have been in continuous use for many years. The writer believes that one long step in the direction of fuel conservation and elimination of economic loss in the power field would be the adoption by the industrial power users of some standard method of power cost accounting and report.

SAMUEL FERGUSON.[9] Mr. Gunby mentions the fact that our New England prices are higher than those paid by competitive industries in the Middle West and properly attributes this to our distance from the coal fields.

I wish to take this opportunity to state that public utility executives in New England very generally recognize their responsibility so to conduct their business that their customers shall not labor under this handicap longer than is absolutely necessary. The relief will come from the dilution of our fuel costs with our water power resources, but, as the author intimates, this will be fully effective only when interconnections are more general and more complete than at present.

Without interconnection the steam companies' costs are high due to cost of fuel; and water power companies' costs are high due to the impossibility of using the seasonal full flow of our streams during every hour of the month including Sundays and holidays.

The start has been made, however, but as with every new undertaking at first the fixed charges on the very large investment are consuming a large percentage of the benefits. It is my belief that a few years will see us all well beyond this stage as every month sees an improvement over the preceding one.

The use of averages by the author is possibly a little misleading in the case of his comparison of prices because the spread in prices between companies in the same region is quite as great as the spread indicated between New England and the Middle West.

To illustrate, I have compiled a graph, two years old, which explains the point. The spread between the high and low city at both the one-shift and the two-shift points is quite comparable with the spread in averages which the author mentions. Superimposed upon these curves are those of Hartford and Waterbury, showing, as of 1926, a reasonable accord with the prices in cities located much nearer the coal fields. In the case of the companies in both these cities, a reasonable start has been made toward an amount of interconnection which will maintain a proper balance of water- and steam-generated power.

Another point on which Mr. Gunby touched is bound to become of importance, namely, the use of the central station load to absorb all of the power which the factory process and heating steam is able to generate.

The reason that this has not already been done to a greater extent is because the industries have not been ready to recognize the fact that the extent of the saving to the power company is the increment fuel cost only. I expect to see the power companies bearing the cost of the installation of turbines to extract this power which will be used in part on the premises and in part on the system; and to see the savings effected equitably divided after the carrying charges on the turbine are absorbed.

We have recently installed a 500-kw. turbine in a customer's factory for the dual purpose of (1) insuring a 10-mile single-circuit transmission line to his plant and (2) effecting fuel economies. In this case, since the cost of the turbine was less than the cost of an otherwise necessary second circuit, the estimated fuel saving of 6 mills per kw-hr. is divided on a 50–50 basis. All the power generated is therefore fed into the system on the system side of the customer's meters. Consequently, customer pays his regular power bill and is paid 50 per cent of the savings effected by running the turbine to the extent of the steam necessary for other purposes; or 3 mills per kw-hr. generated.

Obviously it would not be equitable to credit the customer with more than the savings effected as would be the case if he reduced the amount of purchased power by feeding into his load inside of the meters.

C. W. CONRAD.[10] Colonel Gunby's excellent paper on the power situation in New England is not encouraging. Our higher cost of purchased power and probable higher cost of power generated by the industrial is a serious menace in that more industries may be attracted with the textile and shoe industries to other sections of the country. In order that this factor may not contribute to further exodus of industry it is essential that the power cost per manufactured unit be reduced. The engineer, public utility operator, manufacturer, and other business men must cooperate to secure the most economical generation and utilization of power.

To secure cheaper power, popular clamor appeals for development of water power. Projects like those proposed on the St. Lawrence River and the Bay of Fundy have encouraged hope. Unfortunately these developments have serious limitations from the standpoint of investment required and feasibility of transmission of output to market that make then economically unattractive. Water power development may help somewhat in reducing power cost, but it is certain we can never reach the limit necessary until we utilize more economically the heat in the fuel consumed.

The generation of power from fuel and the utilization of heat are problems that present enormous possibilities for economy if they are properly analyzed on a thermal efficiency basis. The operations of the central station are compared on the B.t.u. per kilowatt-hour output. Analysis of an industrial plant on the basis of useful and total B.t.u. per manufactured unit will bring out some amazing conditions, particularly where large quantities of process steam are required. The 13,000-B.t.u. per kw-hr. central station indicates something quite definite. The 6000-B.t.u. per kw-hr. industrial power plant, which utilizes all exhaust from back-pressure generating equipment for process, may mean little because the heat in the process steam may not be utilized efficiently. As some one has well expressed it, we must become "B.t.u.-minded" in order that heat will be as efficiently used as other manufacturing materials.

I am going to express some opinions on generation of steam and power, part of which may not be attainable now, but I am confident that the time will come when they will be common practice.

1 In localities where manufacturing is concentrated, central steam-generating plants should be established and the industrials

[9] Hartford, Conn.

[10] Plant Engineer, Bird & Son, Inc., East Walpole, Mass. Mem. A.S.M.E.

should purchase steam. As it is necessary to use medium pressures for steam transmission each industrial should have sufficient equipment to generate the maximum power economically attainable to supply its process heat requirements. Any additional power needed should be purchased and if there is a surplus it should be sold. The central steam plant would operate at higher pressure and utilize back-pressure generating equipment to reduce steam to proper distributing pressure. This steam plant would be owned by an industrial, groups of industrials, the power utility operating in the district, or by a corporation which would have the viewpoint that its principal business is to generate and distribute steam and that the power obtained is in the nature of a by-product. If the power company did not operate the steam plant it should purchase the power available.

2 In localities where manufacturing is not concentrated the industrial plants should generate only steam required for process, using efficient back-pressure equipment to generate the maximum power economically attainable in reducing steam pressures for process requirements. Additional power necessary should be purchased.

3 The utility should have efficient equipment to generate and distribute a reliable power supply to the manufacturing plant at a cost cheaper than the industrial can generate power with condensing equipment.

In New England we have a large interconnected power system which can be expanded and utilized for distribution. Its operators are cooperating in making it more reliable and useful. However, we need the cooperation of the engineer, the manufacturer, the utility operator, and other business men to study the economical use of heat to try to weld these forces into an organization which will solve the problem and result in cheaper industrial power.

W. W. Gaylord.[11] Mr. Gunby's paper gives a very interesting survey of the power supply situation in New England and especially that part of New England within seventy-five miles of Boston.

In western Connecticut, although we notice the same general trends, there are several factors which modify conditions considerably.

First, our largest power users are the metal-working industries rather than any of the three mentioned by Mr. Gunby.

Second, our water power resources are of relatively small importance, although one of the power companies is making the interesting experiment of using a storage reservoir located on a small watershed as a giant storage battery. (See paper by E. J. Amberg on Rocky River Hydroelectric Development, presented at meeting of A.I.E.E., New Haven, Conn., May 11, 1928.)

Third, the policy of certain public service electric companies of "educating the public to service interruptions" has compelled some industries to generate at least that part of their power which cannot be subject to interruption without loss of a large amount of work in process.

The brass mills of the Naugatuck Valley are large power users not only for metal working but also for electric melting and annealing. As they have relatively small steam demands for process and heating they make a very desirable load for the central station. But because an interruption of over half an hour in the power supply to an electric melting furnace results not only in the loss of the charge but usually of the furnace lining as well, it has been found desirable in most cases to install at least enough generating capacity to take care of this portion of the load.

The industries using large amounts of process steam are becoming increasingly alert to the need of balancing steam and power demands, and some interesting plants of this type are now under construction.

Mr. Gunby suggests the possibility of the power company's coming in to act as the balance wheel by supplying power when the process steam demands were lower than the power requirements and by buying power when an excess was available. This looks like an interesting possibility, but from several studies we have made of such cases we are inclined to believe its application will be decidedly limited as there are several serious obstacles which must be overcome before such an arrangement can be made successful. Among these are:

1 The difficulties of running non-condensing turbine-driven generators of relatively small size (unless of the induction type) in parallel with the power companies' generators.

2 The fact that as the industries' excess power seldom comes at the time of the power companies' peak loads the saving to the power companies, and therefore the amount they can afford to pay, is less than their fuel cost of the power received.

3 The additional cost of installing such a system will increase the fixed charges and further reduce the value of any fuel saving.

4 The rates a power company will have to charge for intermittent service will be almost, if not quite, as high as the cost of generating the power non-condensing and wasting the exhaust steam.

5 The added cost of dispatching and accounting to both the industrial plant and power company.

Mr. Gunby states that industries using less than 500 kw. probably cannot show sufficient savings to justify such an arrangement, but from studies I have made I doubt if industries using less than 2500 kw. can show any attractive savings.

The suggestion of central stations' using very high initial pressures and supplying both power and steam to industrial plants appears to have interesting possibilities in places where there is a sufficient concentration of industrial plants to warrant the building of a fair-sized station.

There is another possible way of reducing the cost of industrial power, which, although it has some objections, we believe should be given more consideration than it has had. That is the common power plant for groups of industrial plants located adjacent to each other, this common power plant to supply both steam and power as needed by the various plants. This scheme would certainly reduce the labor cost and should reduce the fixed charges by eliminating the duplication of spare equipment.

In cases where plants using large quantities of process steam are located near plants having large power loads a considerable saving in fuel would be possible. A study of the savings possible was given by the writer in an article in *Power Plant Engineering* for May 15, 1928.

Of course, as already stated, each case must be studied on its merits, but the fact that there is such a widespread interest in power problems by industrial executives indicates that substantial progress has been made.

Harry W. Benton.[12] I am not enthusiastic on the subject of central station power for industries located where the buildings require heating for seven months out of the twelve. In plants the size of Pratt & Whitney it is an absolute paying proposition to produce their own power because of the fact that for the winter period they produce all necessary electric current as a by-product of the heating system and at no extra cost for fuel.

Irving E. Moultrop.[13] I have read the paper several times

[11] M. E. Westcott & Mapes, Inc., New Haven, Conn. Mem. A.S.M.E.

[12] Plant Engineer, Pratt & Whitney Company, Hartford, Conn.

[13] Chief Engineer, The Edison Electric Illuminating Co. of Boston, Boston, Mass. Mem. A.S.M.E.

and I get something new out of it each time I read it. The author's summation in reference to the question of purchased power versus installed plant is very good. There are undoubtedly cases where an industry can afford to install its own power-generating plant, but such cases are few and far between.

Professor Cabot in his discussion has said that the cost of central-station power is not going to come down very much. He has stated that many central stations are overbuilt. I am not sure that either of these statements is correct.

It is true that the thermal efficiency of steam-electric generating stations has been raised to a point where material improvement in the near future is probably not economically justified; but do not forget that fuel costs are only a part of the cost of generation. The fixed charges on the generating station are much greater than the fuel costs, and I expect that in the near future we are going to be able to reduce these costs the same as we have reduced the fuel costs. We are at this time more interested in dollar efficiency than in thermal efficiency. I believe that by better design we are going to be able to obtain a material improvement in dollar efficiency.

In comparing the cost of power in New England with the cost of power in other parts of the country, you should not forget the fact that practically all of the coal burned in New England for power-generating purposes is hauled approximately 400 miles by railroad and 600 miles by water. When you consider this fact, I think you will admit that we are doing mighty well in generating power as cheaply as we are.

In reference to the central stations being overbuilt, I would say that when all factors are considered I do not believe we have installed any more generating capacity than is economically justified. There are many factors that govern this situation that are not obvious unless you are thoroughly familiar with the requirements of the service.

Another factor that materially affects the cost of generating power is the load factor of the system being served. We have made great strides in this direction during the past few years, and I believe that we will make further progress in the future. The development of high load factor business, the increase in the reliability of equipment, and extensive interconnections are all helping to increase the load factor of our generating stations and will no doubt help materially in our efforts to supply cheap and reliable power to the New England industries.

Charles H. Bigelow.[14] In relation to unit costs I have worked out these costs from month to month for different plants from the actual expenses and find that it is not possible to get a constant figure as is given in estimated costs, to be expected with any particular arrangement of apparatus. The unit cost per kilowatt will vary over a considerable range due to various reasons, and this applies whether the power is purchased from a public utility or is manufactured in an isolated plant.

The management and accounting departments think that they should have a constant figure, so they can say that their power costs one and a half cents, two cents, or whatever it may be per kilowatt-hour, but the actual results do not give this.

In one company, located in Pennsylvania, where the power was purchased, the net cost per kilowatt without any change in the rates varied from 1.78 cents per kilowatt to 2.33 cents per kilowatt, an increase of 32 per cent within a few months. This was due to changes in load, the increased unit cost coming when the load had decreased about 51.5 per cent, due to slack business, and was mainly caused by the fact that the demand charge was based on the maximum demand in the year and did not change for a year unless the demand increased, even although the total load had decreased over 50 per cent, the demand factor being 25.5 per cent of the total with the heavy load and 40.5 per cent with the small load.

In another company the cost varied from 1.60 cents to 2.31 cents from the same reason.

In New Jersey the Public Service Commission requires the public utilities to base their maximum demand charges on the average maximum pulls of the working days for each month, which is much fairer to the customer, making the necessary changes each month.

If the company makes its own power, the same variable results will be obtained, depending on the various factors involved, such as load, heating in cold weather, maintenance, repairs, etc.

In general the charges are made up of "fixed charges," such as depreciation (in one plant I was in that was taken at 10 per cent, which is high), taxes, insurance, etc., and over this factor, which in this case varied from 20 to 30 per cent of the monthly expenses, the operating department had no control. Of course the larger the output the less the unit cost.

"Maintenance" was due to repairs, breakdowns, etc., but the amount charged depended on the bills paid during the past month irrespective of the time when the work was done, although the labor would come into the proper month.

"Operating labor" had been reduced to a practical minimum of one man on watch in the turbine room and one in the boiler room, plus some extra help in the daytime during the heavy load. Here also the larger the output the lower the unit cost.

"Fuel" is the only item that varies in any kind of ratio to the power produced, and even that would not be in exact ratio.

Therefore, it can easily be seen that the unit cost in this case will not be constant, but will vary over a large ratio.

Where process steam is used together with the heating, etc., particularly in a plant that is already built and the investment made, it would not pay to buy power, because the fuel cost would be the only variable, and if the pro rata of fixed charges, maintenance, and operating labor was taken off of the electric power, it would greatly increase the charges for heat, process steam, etc.

In one case, where the prorated charge for electric power was a little more than the power could apparently be bought for, if the power was bought the charges for the other services would be so increased that the gross cost of both services would be increased about $24,000 per year, besides an extra investment of $16,000 to $20,000 for transformers, switchboards, etc., and they would still have the old equipment.

In conclusion, I would say there is no real constant unit cost, whether power is bought or made, and the question of buying or making must be determined in each case on its own merits.

A. W. Milliken.[15] One of the reasons for early New England's prominence in manufacturing was the availability of power. If now, as shown in Colonel Gunby's paper, New England power costs slightly more on the average than elsewhere, other factors must be more important than cheap power, since manufacturing in New England is steadily advancing as shown by the increasing power use. This leads to the conclusion that cheap available power is no longer of the primary importance it once was, as compared to many other economic factors affecting industry generally. Furthermore, I would call attention to the fact that if there were some method of weighting the average of the utility rates studied, according to population, number of industrials served, value of products manufactured, or some other measure of the importance of the individual rate structure as applied to industry within the territory for which the average is being computed, a more nearly accurate average would be obtained.

Author's Closure

I will take up the points in the order in which I made a few notes. No one would be more delighted than I to see the tendency in the textile work of New England reversed promptly and enthusiastically. Mr. Cabot said that he thought it was going to be. I hope that he is as good a predictor on that as he has been on other things. It would be a very desirable result. He also mentioned interconnections, and put in a thought that has been in the back of my mind for a long time. That was that there ought to be interconnection not only between the central-station people, but also between them and many industrial generating plants. As you noticed very roughly from the curve showing our total load, a little over one-half of our total requirements are now generated by the public-service people, and a little less than one-half is generated by the industries, and if we can get a closer cooperation between those two groups, we are undoubtedly going to get some actual savings. Never mind how they divide; there will be an actual saving to the pocketbook of New England from whatever economy can come about. And interconnection has some large possibilities of economy.

Mr. Elden and Mr. Milliken bring up the question of how the rates for which I gave you some graphs were made up. Perhaps I not only "muffed the ball," but also dropped it in the mud, in not making it entirely plain that it is not the rates of power companies that I am trying to compare. I am trying to compare the cost of power to industrial users. Perhaps if we had, let us say, some cotton mills located in each one of the sections mentioned, and I had the costs from them, they would serve my purpose admirably. We did not have them, so I used the things we did have in all communities; namely, the power rates as published by power companies.

Now, as a matter of fact, there are some fundamental things that affect the cost of power. If you have a central station, one of your costs is going to be fuel, and roughly speaking, the relative cost of coal is not very different in those communities from what the charts show about the relative cost of power, except that in New England the cost of coal bears a greater disparity than the cost of power, which can only mean one thing, that we have been more efficient in the use of coal in our central stations up here than some other people have. Here we pay nearly $7 for coal; in some other sections of the country coal costs $3 to $4; so under similar load conditions power can be made for less. The companies selected for the South get most of their energy from water power. They have the same problem we do—will their large customers buy power or generate it? The economics of the situation are the same in all sections.

Remember, the curves I showed are just an arithmetical average and are for companies in cities picked out as fairly representing general conditions. They might be illogically selected, using the wrong companies. I was not trying to prove anything. I wanted to find out what might be the facts as regards average conditions. They do not present a finished picture of the situation, but they do, I believe, in general, show that our power costs a little more than it does in some other sections. I think if we figured it out more closely we would get a greater disparity. In fact, I am surprised that the graphs show as little difference as they do. I believe, for instance, that we in New England require a higher degree of reliability of service than has been the custom in some other sections. This would tend to make our costs higher.

Now, another thing. I wonder if Mr. Milliken was entirely correct when he said New England grew up on cheap power. I am not a native New Englander, so I do not know as to the price. Some of the information I have is only hearsay or from documents that we have come across once in a while in connection with some old plant. I doubt if it was cheap power that made New England. I think it was power. I doubt if those old manufacturers did know what power cost them. I doubt very much if they cared. Up in Lawrence a while ago we got hold of an old document showing where they paid the people every three months if the plant ran, and the mill ran when they had water; they always shut down on a cloudy day because they did not have enough light, as they had no method of artificial lighting. The operation was entirely dependent on getting the combination of circumstances under which they could run the factory. I ran across another funny case, interesting only in showing some of the crudities they had back in those days, as they appear now. This was the letter to the treasurer by an agent of a mill about one hundred miles from here, in which he said that the help were kicking on account of being paid once a year, and they wanted to be paid once in six months. He said that of course it was going to increase the amount of clerical work, but he thought it probably would be a good thing. And he further thought that they would kick next to be paid more often, as often as once in three months. I do not believe those fellows knew much about the cost of power. They were trying to get the power, and I believe that is still our problem. We can keep better track of the costs today than we used to, but I think the power, getting the power, is the important thing.

I saved Mr. Cunningham's comment until last, because he said that he would like to be shown that New England was growing. I think the facts show that she is growing. I will talk now entirely about the industries that use power, and will leave out the central stations, which undoubtedly are growing very fast. The arithmetic shows that there is no question of that, but the thing that Mr. Cunningham has on his mind is the industrial situation. Admitting that we have had 150,000,000 kilowatt-hours drop in the amount of power that is used by cotton textiles alone in a five-year period, the fact remains that applying the same hours of use to the rest of the industry, you get an increase in the amount of power used. Another way of looking at the same thing is to take that same cotton industry, the worst thing we have as far as decreased activity is concerned. In 1922 it had installed 535,000 horsepower, and by 1925 it had 572,000 horsepower, and in 1926 it had dropped back to 550,000 horsepower. These were installed capacities. It actually decreased about 30,000 horsepower in the amount of power. In other words, that much horsepower had gone out of business in this industry. This decrease is easy to account for in liquidation and things like that. But despite this, the total power installed in all industry had not decreased at all, but had gone up a little bit. Some other industries, of necessity, had to make up for that 30,000 horsepower dropped by the cotton mills. I think what is happening is that new industries are coming up to take the place of those which are going down. Many of these new industries are in small units. We saw the same thing happen to our farming people a couple of generations ago. The farms were doubtless quite valuable when they built all those stone walls on them. That value is very largely gone now. Our cotton mills were very valuable a few years ago. Even we young fellows can remember that. Now you can buy many of them fairly cheaply, just like farms. The farming largely disappeared, and something else took its place. The cotton mills may go, but something else will come along and take their places. All that is going to happen is a perfectly natural development, and when somebody beats us at our game, we will get into some other game.

Balancing Heat and Power in Industrial Plants

By R. V. KLEINSCHMIDT,[1] CAMBRIDGE, MASS.

The purpose of this paper is to indicate the importance of various factors in increasing the amounts of by-product power that can be generated in industrial plants using process heat. It has been shown that there are opportunities for economies in increased boiler pressures, higher superheats, and particularly by reducing the back pressure on turbines and engines to the lowest possible point. Utilization of waste heat from furnace gases offers an opportunity for additional power generation in mixed-pressure turbines or in low-pressure condensing turbines. It is shown that hot air can be most economically used by returning it to the boiler furnace and heating air for process work with exhaust steam.

Two curves are presented which give the results of a detailed analysis of the problem of water heating, one showing the advantages of two-stage water heating as compared with heating by exhaust steam only, and the other giving the best condenser vacuum for various initial and final temperatures of water in a two-stage process. Attention is called to the importance of an adequate study, both of the heat and power requirements of the process and of possible improvements or alterations of the process as a basis for the improvement of the heat-power balance.

INDUSTRIAL plants use large amounts of heat in such processes as drying and evaporating, water heating, cooking and digesting, and in kilns, furnaces, and ovens. Practically all plants in the Northern States have a substantial space-heating load during six months or more of the year. Moreover, all industrial plants have power and electric-lighting loads. In plants like paper mills, textile finishing mills, and chemical factories, where there is a substantial heating load, the possibility of generating power as a by-product of the process steam presents an opportunity for possible economy.

When all of the power used in the plant is thus generated without rejection of heat in condenser water, the power and heat loads may be said to be balanced.

This paper discusses the most important factors that determine or affect this heat-power balance. These factors are:

1 Boiler steam pressure and superheat
2 The pressures and temperatures required by the process
3 Type and characteristics of power-generating equipment
4 Utilization of waste heat.

Basic Principles

Before discussing these factors in detail, it will be desirable to recall the fundamental laws of the interconversion of heat and power. These may be simply stated as follows:

1 Power can be completely converted into a definite amount of heat at any desired temperature. A kilowatt-hour of electric power is convertible into 3412 B.t.u., whether in producing an electric arc or in melting ice.

2 Heat can never be completely converted into power. Only a definite maximum percentage is theoretically capable of conversion, and this only by a proper prime mover. (Fig. 1.) The maximum percentage depends on (*a*) the temperature at which heat is supplied to the prime mover, and (*b*) the temperature at which the remaining heat can be rejected from the prime mover.

3 For every kilowatt-hour of power generated, a definite quantity of heat (3412 B.t.u.) is actually used up and disappears as such.

4 The conversion of this portion of heat into power is accompanied by a definite drop in temperature of the remaining heat not so converted.

In more familiar terms, the maximum theoretical power that can be developed by an engine per pound of steam handled depends fundamentally on the temperature of the steam entering and leaving the engine, and therefore on pressures and superheats.

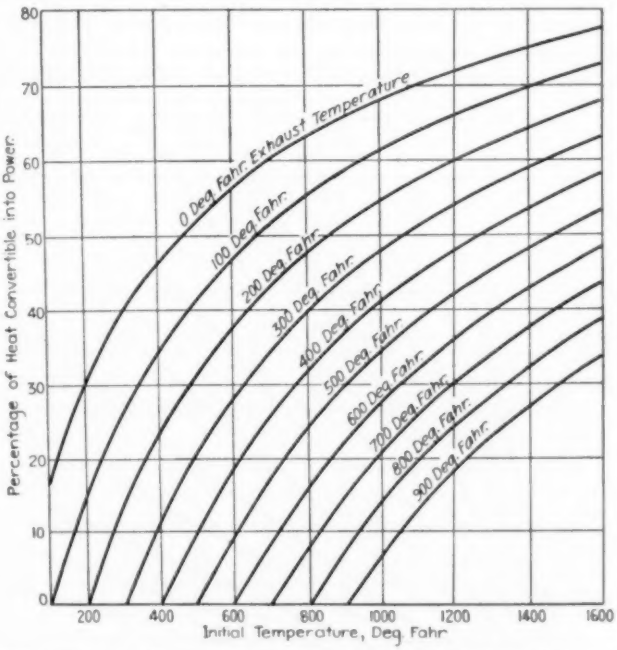

Fig. 1 Heat Convertible Into Power Between Various Initial and Final Temperatures

The portion of this maximum theoretical power which the engine will actually deliver depends on how closely it follows the theoretical cycle and on mechanical losses.

By-Product Power

Since the combustion of coal liberates heat at a temperature far above that required in most industrial processes, this heat can generate power before being used in process. The power so generated will be referred to in this discussion as "by-product power." In the near future power-plant engineers will regard this by-product power as too valuable to be neglected. We are frequently told that it is a crime to burn raw coal because of the waste of tar and gaseous by-products that are of value as basic chemicals. The value of these material by-products from a pound of coal is roughly $^1/_4$ cent, and the remaining coke has $^3/_4$ of the heating value of the original coal. In generating by-product power, a pound of coal may easily yield $^1/_2$ kw-hr., worth at least $^1/_2$ cent, and $^7/_8$ of the heating value remains for use in such processes as drying and water heating. The burning of coal to

[1] Research Engineer, Arthur D. Little, Inc. Jun. A.S.M.E.

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., Dec. 3 to 7, 1928, of The American Society of Mechanical Engineers.

furnish low-pressure steam for heating only is therefore a greater crime.

Most industrial plants can find a use for an almost unlimited amount of power if it can be obtained cheaply enough. Mechanical power is readily convertible into electrical, chemical, and luminous forms of energy as well as into heat, and in proper form can be readily transmitted, controlled, and applied to an endless variety of processes. In Northern paper mills, where water power is cheap and coal is difficult to obtain, electric boilers are economically used to furnish steam for cooking pulp and drying paper. A textile finishing plant was able to save $2000 per month by replacing gas singers with electric-plate singers operated on by-product power. The problem of balancing heat and power therefore resolves itself into the problem of generating from the process heat the maximum by-product power that can be economically used.

The Heat-Power Survey

The first step in attempting to balance the heat and power loads of an industrial plant should be a careful survey, involving accurate measurements, of the heat and power required by the various processes. In making this survey, careful attention should be paid to points where slight changes in operating procedure may make substantial improvement in the balance of heat and power. For this work, intimate knowledge of the process concerned and cooperation with the plant superintendent are necessary. While it is not usually regarded as within the province of power-plant engineers to consider changes in process, experience has shown that intelligent study of conditions frequently brings about changes that are desirable not only from the power standpoint, but from the point of view of decreased labor and improved product. In one paperboard mill, a rearrangement of the steam supply to the driers not only decreased the back pressure on the turbine from 40 lb. to 10 lb., but also increased the daily production beyond all previous records. The advantages of a survey, quite aside from any saving of fuel, are further illustrated by the case of a large Southern sawmill, where redistribution of steam saved a contemplated investment in additional boilers. Table 1 summarizes the results of a heat-power survey of a large mill making coated book paper. This plant is of particular interest on account of the great variety of its heat and power requirements. The table is very much condensed.

TABLE 1 HEAT-POWER SURVEY OF BOOK-PAPER MILL

Unit	Live steam, lb.	Power developed, kw.	Exhaust, lb.	Exhaust steam used, lb.	Pressure, lb. per sq. in.
Beater engine	20,000	520	17,700	....	175
Variable-speed engines	4,400	100	4,000	....	175
Boiler-room auxiliaries	1,000	10	900	5,000	175 and 10
Paper-machine driers	8,000	...	....	4,000	40
Coating-mill driers	400	...	....	13,600	10
Evaporator	5,000	...	....	....	40
Sulphite digesters	5,000	...	....	....	80
Soda digesters	2,000	...	....	....	110
Bleaching	4,200	...	....	....	10
Chemical plant	2,000	...	....	....	40
Total summer steam	52,000		22,600	22,600	
Winter space heating	10,000				
Total winter steam	62,000				
Total engine power		630			
Water power, owned rights		350			
Water power, purchased water		750			
Conversion losses		120			
Total load if all electric		1850			

Distribution of Process-Steam Requirements

Pressure, lb. per sq. in.	10	40	80	110	
Exhaust steam, lb.	18,600	4,000	...	...	
Live steam reduced, lb.	4,600	15,000	5000	2000	
Total, lb.	23,200	19,000	5000	2000	Totals
Available kw-hr. from 175 lb. per sq. in. sat.	740	355	54	11	1160
(Based on 60% eff.) from 300 lb. per sq. in. sat.	865	523	92	28	1508

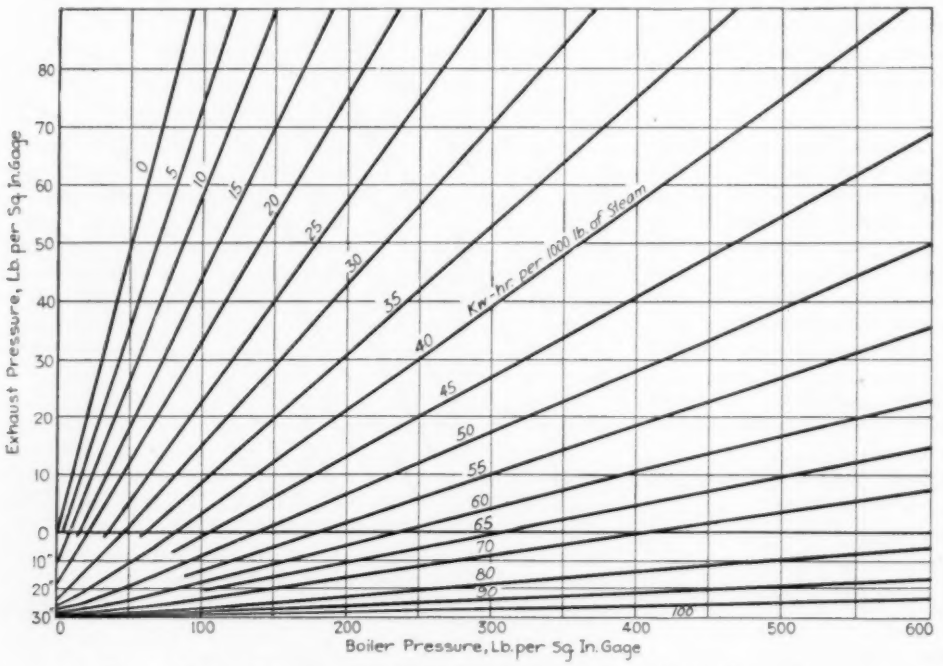

Fig. 2 Power Developed by Ideal Engine for Various Steam Conditions

Heat-Power Ratio

In order to determine at the outset whether a balance of heat and power can probably be worked out, and along what lines, it is desirable to determine the overall heat-power ratio for the plant. This ratio is the total process-heat requirement divided by the total power requirements, and is expressed in B.t.u. per kw-hr. By comparing this ratio for a given plant with the values given in Table 2, the probability of a balance of heat and power will be readily determined.

TABLE 2 TYPICAL HEAT-POWER RATIOS

Plant	Exhaust temperature, deg. fahr.	Heat-power ratio B.t.u. per kw-hr.
Non-condensing plant	212	30,000 up
High-pressure central station, condensing	80	15,000
Mercury-steam plant	80	10,000
Diesel-engine plant	700	10,000
Diesel-steam plant	80	8,000

Effect of Pressures

The accurate determination of the necessary steam and power conditions to produce a proper balance can be greatly simplified by certain charts that have been used with success for this purpose by the author. The object of these charts is to show at a glance what steam conditions are necessary in order to get a given

amount of power from a definite quantity of process steam. Fig. 2 shows one such chart which is very useful in considering the effect of decreasing exhaust pressure or increasing boiler pressure. This chart is based on an ideal engine, but it is a simple matter to allow for any actual efficiency with regard to the ideal Rankine engine. The type of information that can be obtained from this chart can best be illustrated by an actual example. The present boiler plant of a paper mill operates with saturated steam at 160 lb. pressure. The plant uses 40,000 lb. of steam per hour at 30 lb. pressure in driers. It is necessary to generate 1150 kw. from this process steam in order to balance the heat and power loads. By making certain changes in the paper machines, it will be possible to reduce the back pressure to 10 lb. in the driers.

The problem to be considered is: Are the changes in the paper machines justified, or shall a new high-pressure boiler plant be considered? By referring to Fig. 2, we see that 160-lb. steam in expanding to 30 lb. back pressure will theoretically generate 31 kw-hr. per thousand pounds of steam. Assuming 70 per cent turbine efficiency, the 40,000 lb. would generate $31 \times 0.70 \times 40$ or 828 kw. The required 1150 kw. represents 139 per cent of this 828 kw. power which is available under present conditions. Assuming the same turbine efficiency under higher boiler pressure or lower back pressure, we shall require theoretically 31×1.39 or 43 kw-hr. per thousand pounds of steam. From the chart (Fig. 2), we find that this can be obtained by raising the boiler pressure to 290 lb. with the present 30-lb. back pressure, or by reducing the back pressure to 10 lb. with the present 160-lb. boilers. A detailed consideration of costs showed the second to be the more desirable solution. This illustration serves to bring out very clearly the great importance of keeping down back pressures, since a decrease in back pressure of 20 lb. (from 30 lb. to 10 lb.) was equivalent to raising the boiler pressure by 130 lb. (from 160 lb. to 290 lb.).

Fig. 4 shows the importance of back pressure in the case of the actual performance of a 1500-kw. turbine.

Although decreased back pressure is usually the simplest method of increasing the power from process steam, it is frequently necessary to use high boiler pressure as well. It is possible to deduce, from Fig. 2, the fact that the percentage increase of available power due to raising the boiler pressure a given amount is greater for high exhaust pressures than for condensing plants. For example, raising the boiler pressure from 200 to 400 lb. with 42 lb. back pressure will increase the theoretical power per thousand pounds of steam from 30 to 45 kw-hr., an increase of 50 per cent, while at 26-in. vacuum the same increases in boiler pressure will raise the available energy from 90 to 102 kw-hr., or an increase of only 13 per cent. The industrial plant that is using exhaust steam under pressure may well consider the advantages of boiler pressures as high as are used in the best condensing central-station plants.

Superheat

Although Fig. 2 is by far the most convenient to use when pressures alone are to be considered, as is the case with saturated steam, it is not convenient to take account of superheat in this particular type of chart. For problems involving superheat, which includes practically all power-plant problems today, it is necessary to use some such chart as Fig. 3. This chart shows the theoretical power obtainable in going along the theoretical expansion line from any pressure and superheat indicated in the lower right-hand quadrant to any final pressure. The saturated-steam condition is taken as the horizontal axis, and the total power

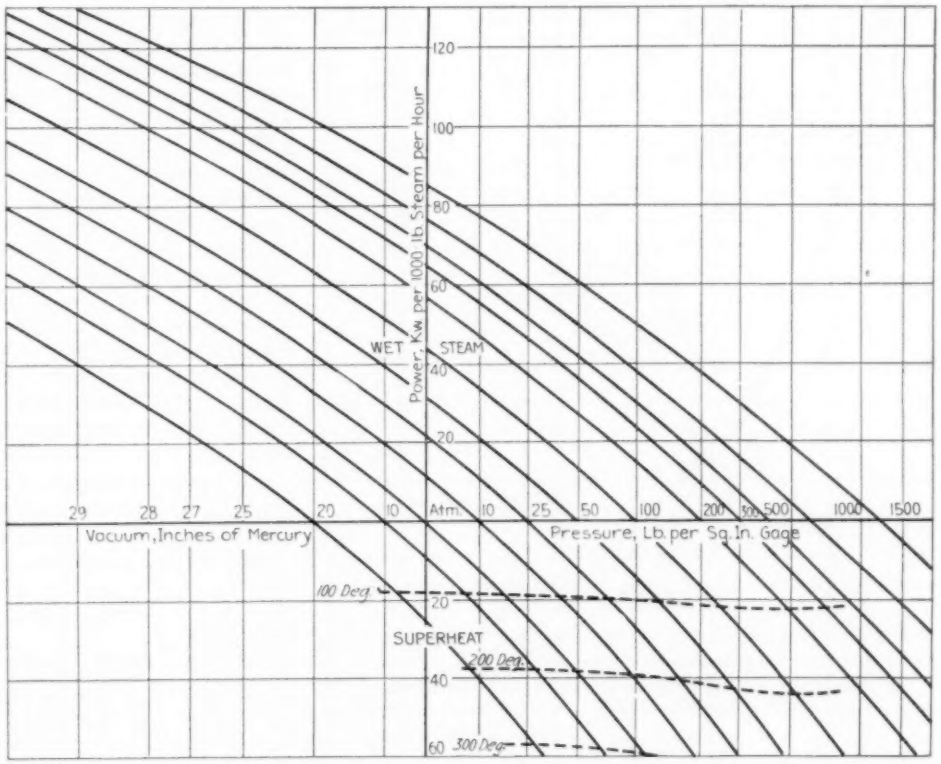

Fig. 3 Power Developed From Superheated Steam by Ideal Engine

developed by 1000 lb. of steam is the sum of the powers indicated in the superheated and wet-steam regions. Suppose that it is desired to use dry saturated steam for bleaching at 50 lb. pressure, bled from a turbine operating under 300 lb. boiler pressure. Fig. 3 shows that the expansion line intersecting the saturated-steam line at 50 lb. intersects the 300-lb. line at 44 kw. on the power scale. If the turbine efficiency is 75 per cent, the actual power developed will be 75 per cent of 44 kw., or 33 kw., and the 33-kw. point on the 300-lb. line represents about 160 deg. of superheat. It is therefore necessary to use 160-deg. superheated steam at 300 lb. in order to bleed dry steam at 50 lb. pressure.

While considering the effect of superheat, it may be possible to clear up some mystery which seems to surround the effect of superheat on steam economy. It is quite obvious that higher pressures increase the indicator-card areas of a reciprocating engine and hence develop more power. The effect of superheat is less obvious. Its action can be indicated by noting that the volume occupied by a pound of steam at a given pressure increases very considerably with superheat. Thus a pound of saturated

steam at 215 lb. pressure occupies 2 cu. ft., while at the same pressure and 150 deg. superheat, it occupies $2^1/_2$ cu. ft. A given cylinder volume filled with the superheated steam has, therefore, only 80 per cent as many pounds of steam in it as when it is filled with saturated steam, although the pressure exerted on the piston is in both cases the same. Many other factors modify this crude conception slightly, but it is illuminating to note that the addition of 8 per cent of heat in the form of superheat increases the volume of the steam by 25 per cent.

One other factor must be borne in mind in considering the effect of superheat on power developed by process steam. When saturated steam develops power in an engine of reasonable efficiency, a portion of it condenses into moisture which is ordinarily removed in a separator before the steam is used in process. In

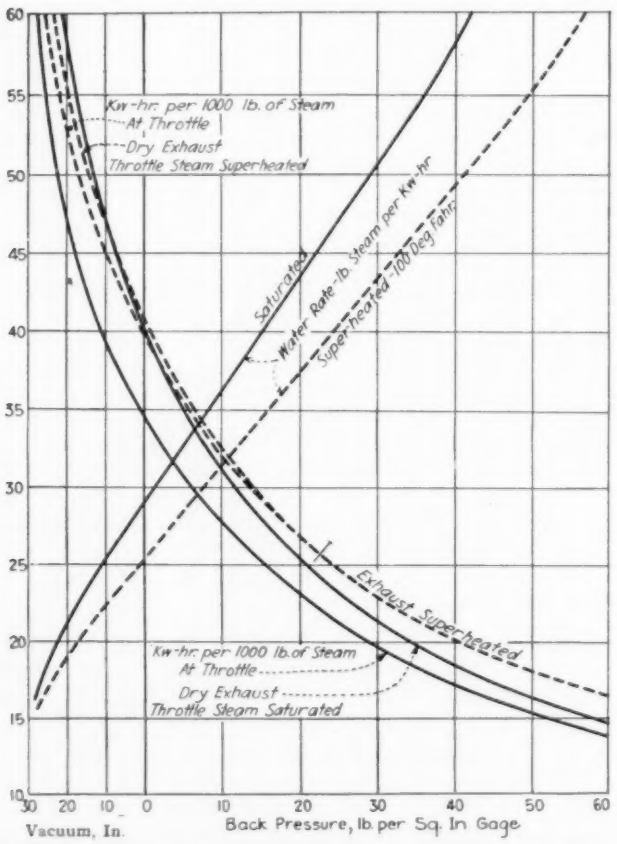

FIG. 4 EFFECT OF BACK PRESSURE AND SUPERHEAT ON HEAT-POWER RATIO OF 1500-KW. TURBINE, THROTTLE PRESSURE 160 LB. PER SQ. IN. GAGE

this way, the dry steam sent to process is less than the steam supplied to the engine throttle by an amount which may easily be as high as 10 per cent. When any large amount of superheat is present in the throttle steam a correspondingly smaller amount of steam is condensed, so that the dry exhaust steam will in this case usually be very nearly equal to the steam supplied to the throttle. It follows that, although superheat decreases the steam supplied to the engine throttle, there is not a proportional decrease in the pounds of dry process steam discharged. Fig. 4 illustrates this point very well. These curves show the power generated both per thousand pounds of throttle steam and per thousand pounds of dry exhaust steam which later would be used in process. In the case of superheated steam the exhaust would be dry at 22.5 lb. back pressure and superheated at all higher back pressures. At vacuums below about eight inches of mercury, the superheated steam actually generates less power per thousand pounds of exhaust process steam than does the saturated steam. This will usually not be the case, however.

Although the effect of superheat in increasing the power developed from a given amount of steam is not large, the addition of superheaters is usually not a difficult problem in an existing boiler plant, and it frequently happens that the resulting economies are very substantial. Quite aside from any question of heat and power balances, superheat is always essential in high-pressure boiler installations in order to insure dry steam to as many as possible of the turbine stages. It is probable that the advantages of superheat even in low-pressure boiler plants have received far too little attention in the past.

CHARACTERISTICS OF POWER-GENERATING EQUIPMENT

The theoretical curves given in Figs. 2 and 3 must, of course, be modified in any actual case by the efficiencies and characteristics of the equipment in which the steam is to be used. This subject is one that might well take up an entire paper and an extensive one at that. A brief résumé of the facts is, however, pertinent here.

The two main types of steam power-generating equipment—turbines and engines—have very different characteristics. The efficiencies of turbines do not vary greatly over various pressure ranges. There is some decrease in stage efficiency at very low pressures. But factors of equal or greater importance are the size of unit and the degree of efficiency that is justified in view of increased costs of high-efficiency designs. Turbines below 1000 kw. decrease rapidly in efficiency with decreasing size. Such small turbines range from 40 to 65 per cent in efficiency. The sizes above 1000 kw. range from 50 to 85 per cent in special cases. Special high-efficiency turbines are expensive, but are frequently justified in such plants as paper mills, where the loads are steady and continuous. Such mills occasionally operate with overall

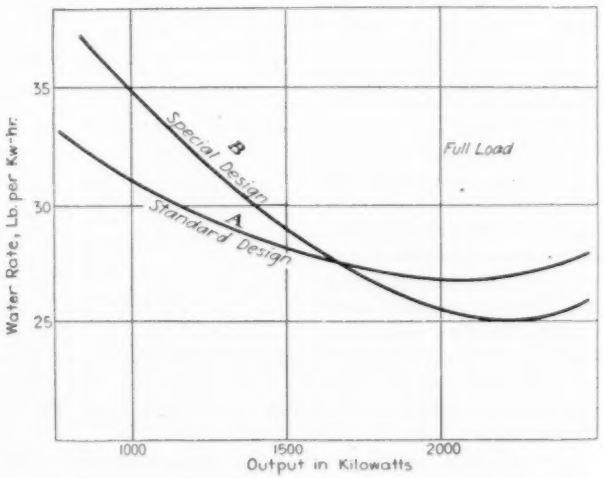

FIG. 5 COMPARATIVE WATER RATES OF STANDARD AND HIGH-EFFICIENCY TURBINES

annual load factors of over 75 per cent, and under such conditions specially designed turbines are in order. However, attention should be called to the fact that special high-efficiency turbines are normally designed for very closely limited conditions as to pressures, steam flows, and power loads. If plant conditions are subject to considerable fluctuation, overall efficiencies may not be improved by such design. Fig. 5 shows the water-rate curves for two turbines; *A*, a stock machine, and *B*, a special design. Machine *B* is essentially a base-load machine and as such gives high economy, but on fluctuating loads machine *A* is as good in overall performance.

The efficiencies of reciprocating engines vary much more than do those of turbines. The efficiencies in small sizes are noticeably higher than for small turbines when the engines are in good condition. Engines do not utilize low or very high pressures as well as turbines. The steam consumption of a reciprocating engine is not affected nearly so much by changes in back pressure as is that of a turbine. If a small amount of steam at high back pressure is needed, it can frequently be obtained from engines having throttling governors without a measurable increase in their steam consumption.

The maximum-efficiency point of an engine usually occurs between $^1/_2$ and $^7/_8$ load, while for a turbine it is generally at or near full load.

Utilization of Waste Heat

We have so far considered only steam because it is by far the most frequently used medium for distributing and utilizing heat. There are several sources of heat for power generation which are usually referred to under the general heading of "waste heat." When process heat is used at high temperatures as in cement kilns, furnaces, retorts, etc., a large amount of heat is lost in the high-temperature exhaust gases. The development of waste-heat boilers has made it practicable to utilize this heat. Since this heat is essentially at a lower temperature than that usually found in boiler furnaces, an analysis is required to indicate the most suitable steam pressure at which to operate a waste-heat boiler, both from the point of view of percentage of heat recovered and the power that can be developed from this recovered heat. Even small amounts of waste heat can frequently be utilized by the use of a mixed-pressure turbine. Reference to Fig. 3 will indicate the very considerable amount of power that can be developed by relatively low-temperature heat in condensing engines running under high vacuum.

In connection with the utilization of waste heat, the use of air heaters as developed for power-plant work is of special interest. It is frequently suggested that, where air is used in large quantities for drying, the most suitable source of heat is an air heater in the

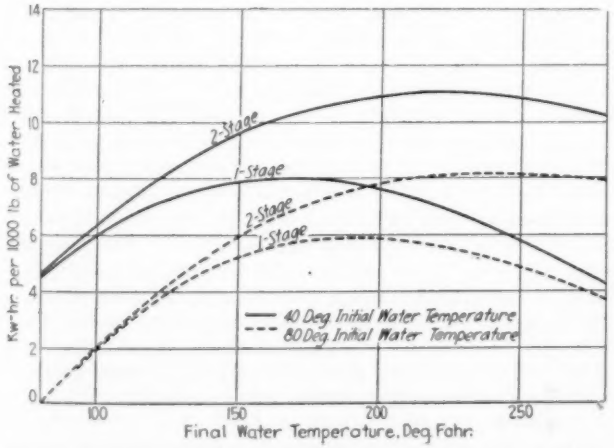

Fig. 6 Comparison of Single-Stage and Two-Stage Water Heating

boiler flue. A more careful analysis shows, however, that from the point of view of obtaining maximum power from a given consumption of coal, it is more desirable to use this heated air as far as permissible in the boiler furnaces, thereby increasing the liberation of high-temperature heat and the output of high-pressure steam. This steam can then develop by-product power, and the low-temperature exhaust can be used for air heating. There is a definite theoretical advantage as well as the added convenience of steam piping, as compared with air ducts, for transferring large quantities of heat.

In some industrial plants there are certain other sources of waste heat that deserve more attention as sources of heated air, either for combustion or for process work. In one interesting re-

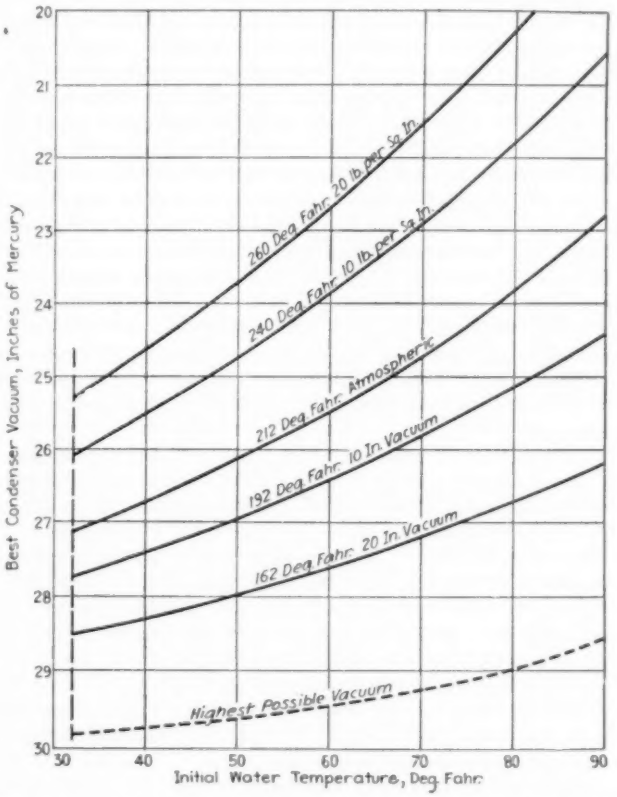

Fig. 7 Best Condenser Vacuum for Two-Stage Water Heating

arrangement, an economizer was removed from the boiler flues and put into the exhaust stack of a black-ash burner and its place was taken by air heaters. In this way, the apparent output of the boiler plant, neglecting the heat from the black-ash burner, was close to 90 per cent.

Internal-Combustion Engines

A development which gives promise of materially widening the field of balanced heat and power loads in industrial plants is in connection with high-efficiency internal-combustion engines. The power developed per heat unit by such engines can, under proper conditions, exceed that of any of the other commercial types of power-generating equipment. While there are a number of factors in the economic utilization of such engines which have not been worked out with complete satisfaction, it is equally true that analyses of performance of these engines have usually not been given proper credit for the waste heat that can be utilized. Hot water from the cylinder jackets of these engines, heated further, if desired, by the exhaust gases, can be used in many industrial operations. There is also a possibility for the commercial development of a heat and power unit based on a Diesel-type engine which will combine an efficient and compact small-size generating unit with a boiler heated by exhaust gases to furnish small amounts of process steam.

Water Heating

Although most process-heat requirements are too specialized to

permit a general analysis, the problem of water heating is one of great importance, and offers an interesting field for improvement of the heat-power balance. The old idea that water heating with live steam is 100 per cent efficient because all the heat units in the steam appear in the hot water is, in view of the concept of by-product power, entirely obsolete. Under certain conditions, the use of an injector operating on live steam for combined pumping and heating of water, especially at fairly high temperature, is permissible. In the near future, however, the condensing bleeder turbine will become the standard equipment for water heating. The simplest method of heating water, which we shall refer to as "one-stage heating," involves the operation of a condensing engine or turbine at a suitable vacuum so that the condenser cooling water is discharged at the temperature required by the process. The idea that it is economical to operate a condensing engine at 28 or 29 in. vacuum using large amounts of cooling water and then using either atmospheric pressure or live steam for water heating is one which cannot be tolerated in the modern industrial plant. Any heat discharged from the plant in condenser water is to be regarded as a serious loss. If all the water that can be heated by the steam from the engine can be used, the heat and power loads will be balanced, even though the engine is running on a condensing cycle.

A more efficient arrangement for heating water has been designated as two-stage water heating. In this arrangement the condenser is run at a somewhat higher vacuum and steam is bled at a pressure corresponding approximately to the final temperature required in the water. A comparison of the power theoretically developed in one-stage and two-stage water heating is given in Fig. 6. It will be noted that as the final water temperature increases, a point is reached at which the power generated per 1000 lb. of water heated is a maximum. If temperatures beyond this point are required it is more economical to use live steam or an additional stage of bled steam for heating. Fig. 7 shows the best relation between condenser vacuum and final water temperature for various initial water temperatures. These analyses are similar to those that have been made in connection with multistage feedwater heating in central stations.

Discussion

F. M. Gibson.[2] To secure that balance of heat and power in an industrial plant which will give the best dollar efficiency requires the consideration of a great number of factors. To secure a satisfactory balance it is necessary to study the hourly change in the ratio of heat demand to power demand under all conditions of operation. Various processes, types, and sizes of equipment and the cost of each must be considered and be compared with the various systems, sizes of equipment, and costs of generating heat and power. Not only is it necessary to determine the most economical balance of present conditions, but the possibilities of the next 15 or 20 years must be considered as well in order to provide the best economy over the life of the equipment. Such consideration requires patient study and time, factors that are not always appealing to the management.

The large plants could well afford to spend a period of time, up to two years, purchasing their excess power and correcting methods and equipment employed in the utilization of heat and power in order to reduce their demands to an economical minimum before determining the system of generation. Recognition must be given to the fact that heat and power are service commodities, and therefore the primary consideration is service. Too zealous an effort to reduce the amount of installed horsepower unit of manufactured product or the cost per installed horsepower may interfere with profit-making production. The important factor is the effect of the cost of heat and power upon production rather than the basic cost of heat and power.

Furthermore, the time is rapidly approaching when the major consideration will be the balancing of heat and power in a group of plants rather than that of the isolated plant. In a few cases some firms are seeking locations for small plants near larger industrial plants for the purpose of purchasing heat. Large industrial firms and central-station companies have combined in joint ownership of a power station. It is probable that the next major development in industrial heat and power will be in the direction of central systems and exchange of heat and power in groups of plants.

In contemplating the use of high-pressure steam, sufficient consideration is not given to the advantages to be secured in its utilization in process equipment. Particularly is this true in those industries using a moderate steam pressure (60 to 80 lb.) for process work and a low-pressure exhaust system (5 to 10 lb.). In plants of this class at least 30 per cent of the steam generated passes through the prime movers into the exhaust-steam system, and when the high-temperature head on the heating surfaces in the boilers is compared with the low-temperature head on the surfaces in the process equipment, it is evident that the total heating-surface area in the process equipment is several times the area of the heating surface in the boilers, an item large enough to be given major consideration. With material processed at 160 deg. fahr., an exhaust system of 10 lb., and a process system of 75 lb., the temperature head on the heating surface is doubled if process steam is used instead of exhaust steam. This means much greater heat transfer per square foot of heating surface, or much less area to accomplish the same amount of heating.

The existence of two steam systems throughout the manufacturing portion of a plant involves a large amount of piping, many valves, regulation, interconnections, and duplicate condensate system. If all heating could be done with steam from the process system, the economy and simplicity of a single system could be obtained. This can be obtained by high steam-pressure and high back-pressure turbines, and in some plants at least the advantages in the utilization of the heat would more than offset the additional cost of generation.

A few months ago Messrs. Jacobi and Shoudy demonstrated the advantage of a term expressing 1000 B.t.u. Those who calculate industrial heat balances find the need of a term that will express 1,000,000 B.t.u., or approximately the heat content of 1000 lb. of steam. In determining total heat demands in process work the B.t.u. must be used, and it involves unwieldy figures. In calculating the supply of heat it is more convenient to use the unit of 1000 lb. of steam to express heat content. This is a generality, and when it is necessary to be accurate, long expressions must be used in explaining the pressure, superheat, or moisture of the particular pound of steam under discussion. In these calculations there must be considered steam generated at high pressure with superheat, process steam at a moderate pressure, and exhaust steam at low pressure with a percentage of moisture, a different heat content for each condition.

The heat unit is the basic factor and would be used to a greater extent in discussions if there were short terms to express large quantities of heat units. The item itself is not of great importance. Fate might just as well have made the Watt a Smith or a Jones, or have made it a unit of heat instead of power. It is not reasonable that the advantage of such terms should be lost because of the difficulty in supplying a term. If it is necessary that the construction of the terms should indicate the definition, I would suggest the words "betu" to express the B.t.u. "thoutu" to express 1000 heat units, and "milltu" to express 1,000,000 heat units. These terms are short, easily pronounced, indicate their

[2] Plant Engineer, American Sugar Refining Co., Brooklyn, N. Y. Mem. A.S.M.E.

meaning, and are at least consistent in that they do not apply to the English system of measurement quantitative prefixes of the metric system. This is not an effort to coin trick words, but an endeavor to hasten the consummation of the thought of Messrs. Jacobi and Shoudy and to carry it one step farther.

THOMAS J. SULLIVAN.[3] Dr. Kleinschmidt's interesting paper lays down a general strategy for the intelligent guidance of industrial power engineers in their study of heat-power balance. Fitting the general principles to specific cases is "a job for the cobbler," who in this case is the power engineer.

The point of departure or datum in the study of economic heat-power balance in any industrial plant is the process itself. What is the heat requirement of the process, in what form is it released, and what is now done with the excess either before or after the process? With these basic data, carefully assembled, we are ready for the next step. What are the power requirements, is this power purchased or generated in the plant, and what does it cost per unit? If the power is purchased, its cost is quickly and accurately found; if generated in the plant, the engineer must not permit either accounting or engineering myths to deter him from nailing it down. With these tools supplemented by his own engineering skill, the power engineer is ready to sharpen his pencils and prove his case. Let the pencil labeled "economics" be the sharpest in his kit, for—assuming the soundness of his plan—the convincing presentation of the dollars-and-cents angle determines his success or failure.

In a copper-refinery heat balance it was found that 14 per cent of the total heat input, including all combustibles, fuel oil, poles, brands, and coke, went to the copper and 42 per cent to the generation of steam in waste-heat boilers. In another department where the practice persists of installing waste-heat boilers directly over reverberatory furnaces, the boiler-heating surface seeing the furnace hearth, the heat to steam was 54 per cent. The installation of well-designed recuperators rather than waste-heat boilers with waste gases around 2000 deg. fahr. would return to the furnace 40 to 45 per cent of the total heat generated, speed up the refining operation, and reduce furnace outage for refractory repairs. Let me interpose here that the practice of installing waste-heat boilers to "see" the furnace results in the theft of radiant heat from its primary purpose, the melting of the product, and diverts it to the secondary operation of steam production. This practice is uneconomical and unwise, since a leak in the boiler shuts down the furnace, sometimes disastrously.

The elimination of the waste-heat boiler unties the hands of the power engineer, who may now go unfettered to the higher pressures and superheats indicated by current practice. Steam required for process heating and drying may then be bled from two or even three stages of the prime mover.

The reduction of back pressure on prime movers is another important method of improving the heat-power balance. Where large quantities of solution are to be heated, stage bleeding may be employed very economically with heaters of the jet or surface condenser type. The corrosiveness of the solution need not stop the power engineer if resistant metals are available. In some cases the use of a small prime mover exhausting directly into such a heater, the solution to be heated used as the cooling medium, may be indicated.

The function of the power engineer in relation to process changes to improve heat-power balance or general plant operation may be illustrated by two concrete examples:

1 In a copper refinery where the power load-factor was nearly 100 per cent, study of the waste heat and direct-fired boiler steam-production curves superposed showed spots on the same time ordinate, 35,000 lb. apart. The condition was corrected by la-

[3] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

dling two of the day furnaces at night. This was done without increase in personnel, the regular night shift having to extend itself, however. A beneficial effect also was the reduced congestion on the production floor during the day.

2 In a heavy chemical plant where the product involved a reaction in a closed vessel at high pressure and temperature, the non-interference of the power engineer brought an unhappy result. The process, imported from abroad during the war, had proved economical when the reaction occurred under a pressure of 20 atmospheres. The steam pressures available to start the reaction in our plants were such that the operation could not be carried above 15 atmospheres. This greatly increased the time increment. The existing vessels, in which the reaction occurs, are rated at a working pressure of 24 atmospheres. The new high-pressure boiler plant is designed for 250-lb. operation. Obviously the reaction vessels cannot be worked up to their designed rating, and very little if any speeding up of the process may be expected.

The aggressive engineer in an industrial plant who dares to peer into the process in an endeavor to improve the power and heat balance is frequently disliked but never despised. To discharge his function fully the power engineer must literally chase every B.t.u. released and every watt produced to its point of useful employment.

ANDREW A. BATO.[4] The question of balancing power and heat in industrial plants with the aim of utilizing all the forms of off-fall heat is neglected to such an extent in small, medium, and even large industrial plants that every endeavor to promote and to spread the solution of this question is very welcome to all those interested. As the author begins with the statement that it is desirable to generate as much power as possible in connection with the various forms of heat figuring in industrial processes, first of all another method of utilizing waste heat should be mentioned to complete the list of the possibilities in this field.

One of the greatest industries in Germany is the manufacturing of briquets out of lignitic coal. This coal contains about 45 per cent of moisture and is dried before further processing. The water vapor driven out from the coal is absorbed with the aid of water screens, and warm water at a temperature of 160 deg. fahr. is thus obtained. This water is brought to boiling under vacuum, and the steam formed is used for the driving of turbines.

An example of utilizing heat contained in hot waste liquids is that of heat exchangers recently installed in power laundries, distilleries, etc. These exchangers, in the case of laundries, transmit part of the heat contained in the soapy, hot discharge of the washing machines to the cold, clean water that is to be heated for use in the washing. On one hand, coal savings up to 30 per cent have been thus obtained; on the other hand, the heat balances of such plants were revolutionized. Before the installation of the heat exchangers there was a great demand for exhaust steam to heat the water; consequently, engines with a low economy were used. The preheating of the washing water with the aid of these heat exchangers, however, cut down the demand for exhaust steam to such an extent that now in most cases even the most economical engines can hardly fit into the heat and power balance of the plant.

Another example demonstrating the value of medium-pressure steam as compared with lower is the method of compressing low-pressure steam to higher pressures with the aid of a compressor called sometimes a "heat-pump." This is being done, for example, in sugar plants and refineries, where there is a great amount of steam available at pressures too low for the process. If the initial pressure of the steam used in the engines or turbines is increased, additional power can be obtained to compress this

[4] Consulting Engineer, East Orange, N. J. Mem. A.S.M.E.

low-pressure steam to such pressures as are sufficiently high for the process in question. A modified application of this method is represented in the case of a steam laundry in Detroit installed in a building in which only low-pressure steam at 15 lb. was available. For use in steam mangles this steam is now compressed to 75 lb. by using power from the public-utility station.

The utilization of exhaust steam for heating is neglected in many cases on account of the time factor; that is, because the exhaust steam cannot be utilized at the time it is generated. In cases in which the waste steam should be used to heat water in tubs, vats, etc., it is not done, because the men in charge do not realize that the heat could be stored in a central hot-water-supply tank even better and cheaper than in a steam accumulator.

The way the author presents his material is in itself a proof of the fact that the personnel of plants he had to deal with, while highly specialized in the manufacturing of their respective products, are very ignorant in the matters of efficient and economical steam engineering. For such people the effect of superheat might be, as he called it, a "mystery;" but it is hardly a mystery to those reading or listening to the presentation of his paper, making the explanations referring to it superfluous. On the other hand, some other points might need more elucidation. Thus, in connection with the chart shown in Fig. 4, the statement that, when using a vacuum of more than 8 in. of mercury, 1000 lb. of exhaust steam will correspond to more power in the case of saturated steam than in the case of superheated steam is quite surprising. The explanation may be that the chart refers to one turbine designed for conditions which are very different from the superheat used and the 8-in. vacuum, and does not refer to turbines especially designed for every case shown on the chart. Explanations in connection with this point will possibly be of a far greater interest.

While the paper as a whole renders a very good service to the cause of heat and power economy by giving a general view of the question in the text and especially in the charts, the most valuable part of it is, it is believed, the chapter on single-stage and two-stage water heating, in the charts of Figs. 6 and 7, through their clear presentation as well as their originality.

The National Laundry Owners Association estimates the cost of power generated in a way so that the exhaust steam is utilized at from $^1/_2$ cent up to 1 cent per kilowatt hour, including all costs, such as depreciation.

H. D. Fisher.[5] The writer agrees with Dr. Kleinschmidt's engineering data, but is inclined to view the problem from the business angle; that is, what return will the expenditure on higher pressure boilers, etc., produce? It is only recently that power equipment has been commercially available for 400 or 600 lb. pressure with 150 to 200 deg. fahr. superheat, and already a number of plants are under construction and some of them in operation. In most locations they show very satisfactory returns, but one instance that the writer saw investigated by a well-known firm of engineers, where coal and hydroelectric power were available at low prices, showed too low a return to warrant tying up capital in the venture.

One feature of the greatest importance in the economical operation of installations of this sort has been rather slighted in the paper. Process heat and power requirements can be approximately balanced in the design, but no process is self-balancing in this respect, and some means of supplying the deficiency or taking care of an excess of steam economically must be provided. A process in which the steam required would just generate the necessary power at full capacity would be badly out of balance at partial capacity, since every plant has certain auxiliaries whose steam or power requirements will be approximately constant regardless of mill output, and also the steam consumption of prime movers is higher per unit of power at the lower loads; so, as in most processes the heat required per unit of output varies to a much less extent with varying output, there would be a considerable surplus of exhaust steam to be wasted. Where process steam and power requirements are reasonably uniform and the cycle of change is long—for example, as between operating one of two or more paper machines or the whole mill or as between summer and winter load conditions—the most desirable solution is to design for a balance with the maximum power development per unit of output occurring in any regular operating period and supply the excess process steam required at other times through reducing valves. Where the variations are extreme and their period comparatively short, thermal storage of one sort or another may be used, steam accumulators being available for higher temperatures and comparatively short cycles, and water heating providing an excellent means of balancing in processes requiring considerable quantities of hot water. One woolen mill with which the writer is acquainted heated the morning dyehouse supply with the exhaust of the turbine on the night load, which was chiefly lighting and power-plant auxiliaries.

Dr. Kleinschmidt's remarks on possibilities of savings by changes in process requirements deserve the careful attention of factory superintendents and managers, as in many cases back pressures are increased much beyond the point where proportional increases in output are secured. Temperatures, with which process work is chiefly concerned, increase much more slowly with increase of pressure as the higher pressures are reached, thus:

Gage pressure, above 14.7 lb. abs.	Increase in temperature per pound increase in pressure, deg. fahr.
0	3.3
10	2.1
20	1.7
30	1.3
40	1.1
50	1.0

But apparently the increase in steam consumption of prime movers is more nearly proportional to the increase in pressure. This factor of diminishing returns with increase of back pressure is shown in drying paper, as beyond 20 lb. gage the increase in drying is very slow and beyond 30 lb. negligible.

The company with which the writer is connected manufactures paper-box board and is at present installing a boiler and turbine for 400 lb. gage with 160 deg. fahr. superheat. From available information, companies making the higher grades of box board but not operating converting plants can secure a satisfactory balance at this pressure, but those which must generate additional power for box shops, etc., must operate at about 600 lb. gage.

TABLE 3 OUTPUT 110 TONS PER 24 HOURS; AVERAGE TURBINE LOAD, 1360 KW.

	Summer	Winter
High-Pressure Steam		
Steam to turbine throttle, lb. per hr.	35,500	35,500
Steam to boiler-feed pump, lb. per hr.	3,000	3,600
Supplied through reducing valve, lb. per hr.	4,500	19,100
Condensation, etc., lb. per hr.	3,000	3,500
Totals, lb. per hr.	46,000	61,700
Exhaust Steam		
Paper-machine dryers, lb. per hr.	30,000	35,000
Heating beater water, lb. per hr.	3,000	6,500
Fan coils, lb. per hr.	4,000	10,000
Feedwater heater, lb. per hr.	1,000	1,200
Condensation, etc., lb. per hr.	2,000	2,500
Totals, lb. per hr.	40,000	55,200

[5] Plant Engineer, New Haven Pulp and Board Company, New Haven, Conn. Mem. A.S.M.E.

These require, however, very economical prime movers and, it will usually be found, complete electrification so that all the power may be generated at the very low water rate of the main turbine.

A comparison of our design figures with those for the book-paper mill cited by Dr. Kleinschmidt may be of interest (see Table 3).

In order to provide a safe margin for operating one paper machine, a 2000-kw. 37-stage turbine is being installed with steam at the throttle 370 lb. gage, 160 deg. fahr. superheat, to exhaust against 20 lb. gage back pressure, the water rates being:

Kilowatt load	Power factor	Pounds of steam per kw-hr.
1000	0.80	28.75
1500	0.80	25.65
2000	0.80	24.20

The twin-slide-valve variable-speed engines are being replaced by single-motor variable-speed drives. One boiler to carry the full load is being installed, having integral economizer section, partially water-cooled furnace, underfeed stoker with clinker grinders and air preheater; stoker, forced- and induced-draft fans, and one boiler-feed pump being motor driven, the other boiler-feed pump being turbine driven. We expect to get this plant into operation early in the coming year and to be able to report operating data later.

R. J. Gordon.[6] Dr. Kleinschmidt has made a substantial contribution to a question that is becoming more important every year in the industrial field. Necessarily he confined his discussion to the bare essentials, but this subject is of such importance that it would be of much value if at least two additional papers could be submitted—one of which would treat the application of the high-pressure steam engine and the other of the application of the steam turbine in the industrial field. If similar conditions could be assumed in considering the advantages and disadvantages of each type of prime mover, the papers would be of greater value.

It was noted that the use of load curves was not included in the paper. Load curves plotted over the same intervals for both steam and power will readily indicate the limitations of the use of back-pressure-type steam-generating equipment. These load curves used in conjunction with the charts shown by Dr. Kleinschmidt would make it possible to determine quickly in a general way the applicability of back-pressure-type steam-generating equipment.

Dr. Kleinschmidt mentions that the efficiency of reciprocating engines varies much more than does that of turbines. Is it to be understood that this variation extends to the high-pressure type of engines now being built abroad? Recent developments in Europe indicate that high-pressure reciprocating engines are being received with considerable favor, and it would be interesting to have Dr. Kleinschmidt furnish any information that he has regarding the performances of the latest type of high-pressure engines.

I. E. Moultrop.[7] There have been so many papers of late years on the subject of the heat balance of steam-electric generating stations that it is indeed refreshing to remember that the same subject is also receiving the attention of mechanical engineers who have to deal with the operation and construction of industrial plants. There is the opportunity for as great an improvement in the heat balance of industrial plants as there was in the central stations of ten years ago.

The most important facts brought out in Dr. Kleinschmidt's paper are that to obtain an economical heat balance in an industrial plant requires a careful engineering study and that quite often the best solution of such problems lies in the utilization of existing boiler plants rather than in the construction of new high-pressure boiler plants.

Supplementing the comments of the author, I would like to point out that surprisingly often an engineering study of the processes of an industrial plant for the purpose of heat conservation will produce much greater savings at less capital cost than an engineering study to determine the maximum amount of by-product electrical energy that can be generated from the steam being used.

In the majority of cases, industrial plants are started on a small scale with limited financial backing that precludes the installation of the most efficient apparatus for the processes of the industry, let alone the most efficient apparatus for the production of the by-product, electrical energy. As the industry grows, plant extensions are made with low first cost as the primary requisite, with the result that often a large property is brought into being which is a great waster of heat both in the processes of the industry and in the factory-building heating. A careful study followed by a moderate expenditure of new capital for rearrangement of the equipment which utilizes heat will quite often, in fact almost always, pay a handsome dividend on the money and effort expended. The most common excuse for deferring such changes is the lack of money. Many factory managers will admit that such changes are worth while, but also will declare that the same money invested in new manufacturing equipment will pay a greater dividend.

If the steam requirements of the industry are such as to warrant the installation and operation of power-generating equipment, it is very seldom economical to install equipment for utilizing the space-heating steam for power generation. A well-designed space-heating system very seldom has an annual load factor in excess of 25 per cent. With such a handicap to start with, the possibilities of showing a profit with equipment for utilizing such steam for power generation are remote.

Even large steam-distribution companies, serving large central-heating systems, find it difficult to justify such equipment.

The statement in the paper that most industrial plants can find a use for an almost unlimited amount of power, if it can be obtained cheaply enough, is dangerous. Many are of the opinion that the only expense chargeable to power generated by pressure-reducing turbines is about one-half pound of coal per kilowatt-hour. To those persons it should be pointed out that the fuel costs are only a part of their power costs. Fixed charges are the big item; and operating labor, maintenance, supplies, and supervision are probably greater than the coal charges. If the total costs of generation are compared with the costs of purchased power, it will be found that purchased power is generally the cheaper. This is logically true, for the electric utilities specialize in the generation and distribution of electrical energy, and it would be expected that they can do this at a lower price than someone else who is specializing in some other business. The utilization of purchased power also releases capital for use elsewhere in the industrial plant.

When an industrial plant is faced with the necessity of increasing its steam supply it will, in the large majority of cases, find it more economical to revamp its existing boiler plants for operation at higher ratings rather than to rush into the construction of high-pressure boiler plants with the idea that the plant will be able to make a handsome profit by the generation of its own power requirements.

---

[6] Power Engineer, Procter & Gamble Co., Cincinnati, Ohio. Mem. A.S.M.E.

[7] Chief Engineer, Edison Electric Illuminating Company of Boston, Boston, Mass. Mem. A.S.M.E.

The writer cannot agree with the author in his thought that industrials should consider boiler pressures as high as are used in the best condensing central-station plants. Very few industrials can show a profit by the installation of such equipment, and even where they can break even under normal conditions a business depression will very quickly turn their expected profit into a loss.

This condition is inherent in the economics of the situation. The financial structure of most successful industrials is based on a large gross income per dollar invested in plant, whereas the very nature of the electrical generation and distribution business requires such heavy investments in plant that the gross income per dollar invested is relatively small. The industrial must keep its fixed charges low to prevent a serious loss at times of curtailed output due to business depression or to loss of business to competitors. The electric utilities very seldom show a reduction in output from year to year and so can afford to operate with a financial structure wherein the fixed charges on the money invested in plant are a large part of their total annual expenses. These differences are inherent in the economics of the public-utility business as compared with industrial business.

High-pressure equipment has proved economical and profitable in steam-electric generating stations where the expense of high-grade operating labor and supervision is distributed over a large installation. Very few industrials, however, can afford to operate and maintain a high-pressure boiler plant unless the high-pressure steam is essential in their processes.

Warren B. Lewis.[8] Dr. Kleinschmidt's paper is a scholarly presentation of a fundamental principle which unfortunately is not understood by mill executives who make final decisions. It would be well if such a paper with full discussion could be presented to a group of such executives and repeated again and again.

Certain paper mills and many bleacheries and dyehouses present opportunities for an almost complete balance between heat and power, but there are many mills all over the country where the power requirements are very much in excess of the heat requirements, and in many of these cases water is not available for condensing purposes. The writer presents a solution of such cases which has proved satisfactory from every angle, and it has been made possible through the altered attitude of the public utilities.

It is safe to say that with few exceptions mechanical power cannot be produced with a non-condensing prime mover exhausting to the atmosphere in competition with purchased power and that exhaust steam flowing to the atmosphere is an indication of economic waste. Where a limited amount of process heat is required, the solution is the combination of a non-condensing unit exhausting to a process line and synchronizing with public-utility power, with automatic control of the prime mover to maintain a uniform back pressure in the process line.

As an illustration the writer refers to a paper mill where the demand for low-pressure steam is 15,000 lb. per hour in the coldest weather and 5000 lb. per hour in warm weather, with daily fluctuations of considerable extent at any season. In this mill a low-speed Corliss engine drives a generator, the engine taking steam at 125 lb. pressure and 100 deg. of superheat and exhausting at 7 lb. gage. The generator is synchronized with the incoming power from public utilities, and the total mechanical load is 800 kw. The load on the engine is governed entirely by the amount of exhaust steam taken from the process line. The load on the engine varies from 250 kw. as a maximum, which is a limit of safe load, to as low as 75 kw., under certain conditions. With this arrangement full advantage is taken of the principle laid down in Dr. Kleinschmidt's paper, and in this particular case the over-all cost is a minimum.

[8] Consulting Engineer, Providence, R. I. Mem. A.S.M.E.

In a new installation it is probable that high steam pressures and superheats with a different type of prime mover would develop a larger amount of mechanical power with the same amount of steam passing through. Many plants have equipment which with slight changes could be adapted at small cost to operate as outlined. This same plan has been carried out in a chemical manufacturing plant with equally satisfactory results.

A few years ago public utilities did not favor this method of operation, but at present there seems to be a recognition of advantages to both parties, and whatever objections have existed heretofore have been removed through the installation of protective devices such as reverse power relays and current limit relays.

Great emphasis should be placed on the use of process steam at the lowest possible pressure and with the least waste, as in too many instances the mere fact that exhaust steam is available has brought about an uneconomical use of it and the real principle of economy has been more or less violated.

R. A. Langworthy.[9] Dr. Kleinschmidt has made a timely contribution to the literature of heat and power in industrial plants. This subject is one that has been discussed for many years, but definite action has been lacking. Far too many plants having heavy demands for process steam are generating this steam at boiler pressure and taking it through reducing valves to the lower process pressure or pressures required. This in most cases is an economical waste and should be eliminated from any modern manufacturing establishment.

In most plants having any appreciable demand for process steam, the entire electric-power requirement can be generated from this steam before it is used in the process work and at a very low cost. This not only reduces the operating expense of the plant, but is a conservation of our natural fuel resources.

It has been the experience of the writer that in many plants the changes in process pressures can be made without having any serious effect on the quality or quantity of the output. It is often difficult to bring this home to the men in charge of production if they have become accustomed to certain process pressures and have formed the opinion that any lower pressure will not properly accomplish the purpose.

Manifestly, the lower the pressure on the process the greater the amount of power which can be taken out of the steam before it is so used. It is therefore necessary to make a thorough study of the process work and arrange to carry it on with the lowest permissible pressure. This requires the cooperation not only of the power engineer but of the factory executives and the men in responsible charge of the operations.

In studies of this kind it should be borne in mind that the steam accumulator has a very good application in many plants. The electrical-load peaks and the steam-load process peaks seldom coincide, with the result that the amount of power that can be obtained from the process steam is a compromise between these two conditions. If a steam accumulator is placed in the system, it will balance the two loads and allow the generation of much more power from the process steam than would be the case were the accumulator omitted.

The tendency for the last few years has been toward large networks of the electric power lines covering various parts of the country. It is to be hoped that some day when a full realization of the economies of the situation is attained many industrial plants located along these lines will not only generate the power required for their own use but will feed their excess of very cheap power into the system.

[9] United Engineers and Constructors, New York, N. Y. Mem. A.S.M.E.

CROSBY FIELD.[10] One fact has become impressed upon my mind in listening to the very able discussions of this most excellent paper. That fact is that the engineers studying this problem of the utilization of steam are most woefully limited by the fact that they have become self-conscious. They remind themselves constantly that they are power engineers and that there are many chemical engineering features involved. Some day when we realize that engineering is fundamentally engineering and most of these classifications of power engineer and chemical engineer are passing fads, then we will only have the natural limits of the problem to confront us and not the additional handicaps we self-impose by these arbitrary distinctions.

Because our engineers studying this problem are power engineers and not chemical engineers, they go right up to and then stop before one of the most important points of the whole proposition, the time factor. We then apologize for not seeing it through to its ultimate, laying stress on the fact that it has its basis in chemical or other engineering problems, and therefore we are not competent in ourselves to study and must therefore have cooperation with other branches which cooperation is mainly important because of its lack. Since 1914 the writer has been confronted with the problems of high back-pressure steam and knows of several cases where the taking away of the title "power engineer" and renaming the individual "engineer" and letting him loose in a plant has resulted in a large number of economies, not only in the power situation, but also in the chemical process itself. For example, in one plant where over 4,000 boiler hp. was recommended by the power engineer, because of the constantly increasing demand of steam of the units of a large chemical plant, this engineer, by a simple management study including the ordinary handling of materials, use of power, and scheduling of operations, found that by a simple rescheduling of several steps of the process he was able to eliminate all thought of the 4000 boiler hp. additional. It was simply a matter of not letting everybody use steam at the same time, but working out the several steps so that they could use it intermittently and in a dove-tailing fashion without in any way deleteriously affecting production.

The author's example, of course, was taken to illustrate his various recommended steps, but the average reader may fail to realize the very complicated condition in the average plant. In this example the process shown is fairly well balanced and the machines more or less run continuously, so that the character and sudden changes with a wide diversity of connected steam loads ordinarily found in such a survey are missing. For an example, one is summarized herewith, in which there was finally worked out one line-steam pressure and two back-pressure systems and to provide for one duplication of back pressure in any one locality. In order to obtain this there had to be several novel installations, such as the use of steam compressors in certain isolated spots.

In this survey, 379 vats consuming steam in open boiling widely varied their requirements, from 110 lb. in 5 minutes for one to 33,500 lb. in 18 hours for another. The pressure also varied from 5 lb. per sq. in. to 100; with very slight changes to some they were all made to operate satisfactorily on the final back pressure selected. The total steam consumed in this way each day amounted to 634,000 lb. There were 39,000 sq. ft. of room heaters (radiators), requiring 13,000 lb. of steam per hour; 42 pieces of chemical equipment, using steam at 5 lb. per sq. in. pressure or less, requiring maximum of 10,000 lb. per hour; 80 pieces using from 5 to 10 lb. per sq. in., requiring maximum of 33,000 lb. per hour; 120 pieces using from 10 to 20 lb. per sq. in., requiring maximum of 33,000 lb. per hour; 170 pieces using from 20 to 25 lb. per sq. in., requiring maximum of 32,000 lb. per hour; 537 pieces using from 50 to 100 lb. per sq. in., requiring maximum of 13,000 lb. per hour, of which 239 could be changed to 25 lb. or lower, with a maximum of 90,000 lb.; 80 pieces using from 100 to 150 lb. per sq. in., requiring maximum of 15,000 lb. per hour; 12 pieces using from 150 to 250 lb. per sq. in., requiring maximum of 7000 lb. per hour; 5 pieces using from 250 to 300 lb. per sq. in., requiring maximum of 2000 lb. per hour.

There has been quite some discussion regarding the 75 per cent steam load factor on a 24-hour basis, 360 days in the year. The writer has seen this duplicated in seven plants under one management having a wide diversity of chemical products, so it is by no means out of the question to obtain.

J. D. ROBERTSON.[11] In considering the specific application of the principles of the paper to a particular case, the cost of the by-product power and the investment required to make it available are the governing factors. The writer wonders if the author had average figures as to the cost of by-product power per kilowatt hour, also has he formulated procedure for predicting the cost of by-product power if its consumption were increased in any given plant. Such a standardized procedure would be of value when considering the advisability of changing processes so as to use more current.

In the case of a plant whose demand for process steam at exhaust pressure is in excess of the exhaust from its power units, the question of changing processes so as to use more electricity depends on an accurate comparison of the present cost of the process using exhaust-pressure steam from a reducing valve with the cost of the process using electricity.

A carefully worked out procedure for finding the cost of by-product power including all items of direct cost and overhead would give added standing in the eyes of some treasurers to an engineer's comparison between the cost of a process using such by-product power and an existing process using purchased central-station power. Possibly at some future meeting it may be considered worth while to present such a paper.

WARREN VIESSMAN.[12] This paper has opened a field of discussion which has been gratifying because the field of industrial power work has been considerably neglected and now is quite ready for extensive development. The writer has in mind two large meat-packing plants on the opposite sides of the same street. One concern continually made every effort to improve its power plant. The other one neglected it. So far as one could see, the two establishments were otherwise about the same. Due to the recent depression in that industry one plant has gone into the hands of receivers, but the other one is still in existence and now doing an extensive business. The concern with the improved power facilities has won out, and it is entitled to the profits that will come to it principally because of its reliable and economical power plant.

Engineers in the past have been somewhat inclined to decide that a certain type of power installation should go into a particular plant because some other plant has one of that type. But with the wide field in the selection of bleeder turbines, low-pressure turbines, accumulators, and the use of purchased power detailed studies must be made of every heat requirement and every power requirement.

The author cited the case of a paper mill where large economies were effected by the rearrangement of a steam plant. In a paper mill which was operating its own electric power and steam

[10] President, Flakice Corporation, Brooklyn, N. Y. Mem. A.S.M.E.

[11] Plant Engineer, Mount Hope Finishing Co., North Dighton, Mass. Assoc-Mem. A.S.M.E.

[12] Director, Bureau of Mechanical and Electrical Service, Baltimore, Md. Jun. A.S.M.E.

heating plant five years ago, the electric requirements were about 2000 kw. It operated 24 hours a day at practically full load. This plant was about to increase its size to twice the capacity, and it made a study of how to improve its power plant, which had been very much neglected in regard to heat balance. A decision was made to purchase power, but still generate its own heat, and immediately after doubling its plant, business fell off to such an extent that it was practically at a standstill. If it had doubled its steam installation, the concern would have been out of existence now. But as it was it was able to get through with a low plant investment and it is now doing very well.

The fluctuations in the industrial load certainly are an important item in determining the advisability of a heavy private plant investment, and purchased power should always be taken into consideration as well as any other sources of supply for heat and power.

This one item of investment is very much neglected in the comparison of various plant operations. In making studies of certain types of plants, pumping stations in particular, the writer recently went to one of the largest cities in this country and asked for their costs on various stations; they had eight or ten steam and electric plants. They produced a nicely tabulated blueprint made out month by month showing what was supposed to be the total cost of pumping water at these plants. These figures were used as a criterion on which to build new plants. In every one of those tabulations, when analyzed, the cost of construction was entirely eliminated, and that is a very big factor.

In a water-pumping station, with an output at present of about 30,000,000 gal. per day, the new station being built will require new units of about 4500 hp. The present station is steam. It was decided to build a new station, an electric station, and abandon the old steam one because of economies. This would not always apply and could not be done in every city. In this particular case the cost of coal was $5 a long ton. The cost of electricity was 0.62 of a cent per kilowatt hour. But when operation costs were considered, labor, maintenance, and investment, in this particular case no heat being required, an electrical installation was much to be preferred. Every case must be decided on its own merits and full consideration given to every heat and power requirement.

Author's Closure

The author heartily agrees with Mr. Moultrop's remarks on the amount of room there is for improvement in the average industrial power plant; also, that the place to make your original saving is in cutting down the use of steam to the minimum at the very start. Money is saved only by not buying coal. After you have bought as little coal as possible, then get as much power from it as possible. We usually estimate 4 lb. of steam lost per kilowatt-hour of by-product power generated.

One feature that Mr. Moultrop did not mention which should perhaps be taken into account is the interruption of service on the central station company's lines. In the Middle West this has been a deciding factor in some cases, where an interruption of service of even as much as 2 or 3 hours would so seriously disrupt a necessarily continuous process as to mean the loss of many thousands of dollars.

Mr. Gibson brought out an exceptionally good point in regard to looking into the future of the plant. That is the most difficult of all the problems of the engineer who is attempting to make a power survey. In the case of a paper mill which we surveyed about three years ago we were informed shortly after submitting our report that they expected within two years to entirely change their production schedule so that it would be necessary for us to make another complete survey when that was done. Some people do not realize that a complete change in the production schedule necessitates a new survey, and they attempt to fit a recommendation to a very much altered situation.

Regarding the relative heating surface in boilers and in steam-using equipment, the discussion failed to take account of the fact that heat transfer in a boiler is from gases to boiling liquid with a relatively low heat transfer coefficient, which is further cut down by scale and soot. Therefore the boiler requires a relatively large surface, whereas equipment using steam very often transfers the heat from condensing steam to a liquid, or to wet paper passing over the surface of a drier where the heat transfer coefficient is perhaps 100 times as great as it would be in the boiler. The boiler will ordinarily have surfaces comparable with if not greater than the steam-using equipment.

It is a point well taken that if we can raise the boiler pressure and then raise the pressure at which the steam is used we will increase the flexibility of the process very considerably.

The use of a heat pump is an interesting possibility in certain cases, particularly where there is an excess of power such as water power and where evaporation is one of the major problems of the plant.

High-pressure engines are not as yet in very extensive use in industrial plants. No doubt it is possible to produce a reciprocating engine which will have a high economy over almost any particular pressure range except the very low pressure ranges. But, in general, a single turbine will operate (with reheating) from even 1200 lb. down to any vacuum required, in one or several cylinders operating as a unit, and get high efficiency throughout the range, and I think no one would attempt to make a single reciprocating engine that would cover any such pressure range with high efficiency.

In connection with the use of water power let me mention the case of a mill having a high load factor—the condition under which by-product power will always be most interesting—which had recently completed a 1000-kw. hydroelectric plant. They were buying the water for this plant from a local water company, at a cost of 7 mills per kilowatt hour. By putting in high-pressure boilers in place of their old hand-fired, horizontal return-tubular boilers, the increased efficiency alone would pay for the new boilers, and charging the excess cost of high pressure over low pressure boilers to power, the actual cost of by-product power was between 3 and 4 mills. It would therefore pay to shut down the new hydroelectric plant, in so far as they could generate by-product power. The hydroelectric plant was a great comfort for standby, but not an economic proposition.

The question of hot water for heat storage is one that deserves a great deal of attention. Heating a large supply of water from off-peak steam to be used throughout the day should be of interest in a number of industries.

In connection with Mr. Sullivan's discussion, one must of course be sure that waste heat is really going to waste and that it cannot be otherwise utilized. The idea of exposing boiler surfaces to direct radiant heat from a furnace is not what could be called waste heat practice, although similar conditions are often encountered.

Whenever clouds of steam are rising into the atmosphere, it is pretty certain that a plant is wasting money. A small exhaust to atmosphere will waste more money than is necessary to pay the investment charges on a higher pressure boiler or other equipment to conserve that steam.

Cooperation with public utility plants should receive more attention. Rate schedules of public utility plants should be so arranged as to take over those portions of the industrial power load which cannot be generated economically by by-product power. It has in the past been largely the custom of public

utilities to make rates in such a way that the plant which has two or three hundred kilowatts of load that it cannot generate as by-product power is charged such a high rate, 2 or 3 cents, that it can afford to put in a condensing bleeder turbine rather than the cheaper back-pressure turbine. When the public utilities realize that they are losing a field in which they could be of real benefit to the community, perhaps they will arrange to take over some of this excess power load.

Mr. Field's example of a really complex survey strikes a sympathetic chord. The complexity of the apparent uses for steam startles one at first, but as a rule we find that steam at 10, 30, 40, 60, 80, 110, and 150 lb. is not necessary.

In one strawboard mill the superintendent solemnly informed me that it was impossible to cook straw at any pressure but 60 lb. Below that too much water got into the straw, and above it the straw was burned. With the approval of the plant manager, we arranged a connection which would turn the 10-lb. bleeder line from the turbine into the straw-cooking line, and turned it on secretly one Monday morning. The straw came out as good as ever, and they have continued it ever since. I do not know whether they ever broke the news to the man.

Meat packing plants are interesting because they have a large refrigeration load, as well as some heating and power load. Refrigeration load can usually be best treated as a power load, although occasionally the absorption system using low pressure steam is indicated.

As to the average cost figure of by-product power, the figure of 5 mills to 1 cent strikes me as being a little high for most conditions. In paper mills we can usually figure by-product power at around $3^1/_2$ to 4 mills, $^1/_2$ to 1 mill for the heat (that is, the excess coal consumption) and about 3 mills for equipment cost. Extra operating labor is in many instances negligible.

FSP-51-28

Coal Pulverizers

By W. J. A. LONDON,[1] WALDEN, N. Y.

Commercial coal pulverizers vary greatly in their performance. While there are two principles of attrition and impact on which pulverizing mills are based, there are such radical differences of design as to raise the question of correct fundamentals. Guarantees are given on performance when the engineering problems are difficult of determination with any degree of accuracy. Analysis of what actually takes place in a mill leads to a suggested design.

THE serial report on pulverized fuel issued by the National Electric Light Association, dated August, 1927, contains much information for all those interested in this subject. This publication, containing reports from the operating engineers of nearly all stations using powdered coal, is of value to all prospective users of this system and of still greater value to the designers of pulverizers. It gives data on actual performances. In Fig. 1 there are plotted all of the complete tests published in this report, with a few odd additions taken from other publications to date. It is generally accepted that the power consumption per ton bears a direct relationship to the fineness of the fuel, so that in this chart only those tests are plotted that give the fineness performances. Leaving out a few of the tests that are "off the map," it will be seen that approximate curves can be plotted showing that the power consumption at 60 per cent through 200 mesh varies from 13 kw. per ton to 22 kw. per ton. Taking the 13 as a basis, we get a difference of no less than 70 per cent between one figure and the other.

Looking at the subject from a strictly engineering standpoint, this cannot be said to be a very flattering commentary on the state of the art today. There are few examples in engineering practice where we see such a large discrepancy in the performance of commercial machines.

It can hardly be said that the pulverized-fuel problem is in a state of infancy, inasmuch as powdered coal has been used for 50 years in the cement industry, and there has been a development going on for many years in the application of this fuel in our largest and most up-to-date power plants.

It is generally accepted that there are only two actual principles employed today in the different mills on the market, attrition and impact. Attrition mills comprise those of the ball and roller types and the impact mills those of the hammer type. An analysis of the design of the different mills will show that while all attrition mills operate on substantially the same principle, there seems to be a difference of opinion among the designers of impact mills as to the proper or most efficient way of attacking the problem. A brief review will be given of some of the more generally used machines with the object of pointing out that there are sufficient radical differences in design to ask ourselves if all of them are correct, and if so, why the art of pulverizing coal should differ so greatly from the development of other engineering devices, where only one or two fundamental principles are finally accepted as the correct ones on which to base commercial design.

A considerable part of this paper is devoted to the subject of guarantees and their relation to subsequent performances in the field.

Many unknown factors enter into the problem confronting the manufacturer when requested by a purchaser to make specific guarantees. There is no question that the builder today will guarantee performances that he should not be expected to; the customer, on the other hand, is demanding performance guarantees that reputable manufacturers should refuse to give. There should be an appreciation on the part of the purchaser of the difficulties encountered in making guarantees, and these difficulties should be emphasized by the manufacturer. Guarantees have never been known to run a plant. A better basic understanding would lead to a more rational handling of the guarantee and contract situation.

Types of Impact Mills

In the following descriptions of various mills only those of the impact or hammer type are considered. While accepting as true that all mills pulverize coal by the combined actions of impact and attrition, the impact forces in a ball or roller mill must be relatively very small—so small in fact, that a mill of this type would operate just as satisfactorily if no impact forces were introduced at all, except perhaps for the breaking up of the larger lumps. That there is a difference between the breaking up of lumps of coal and pulverizing is obvious.

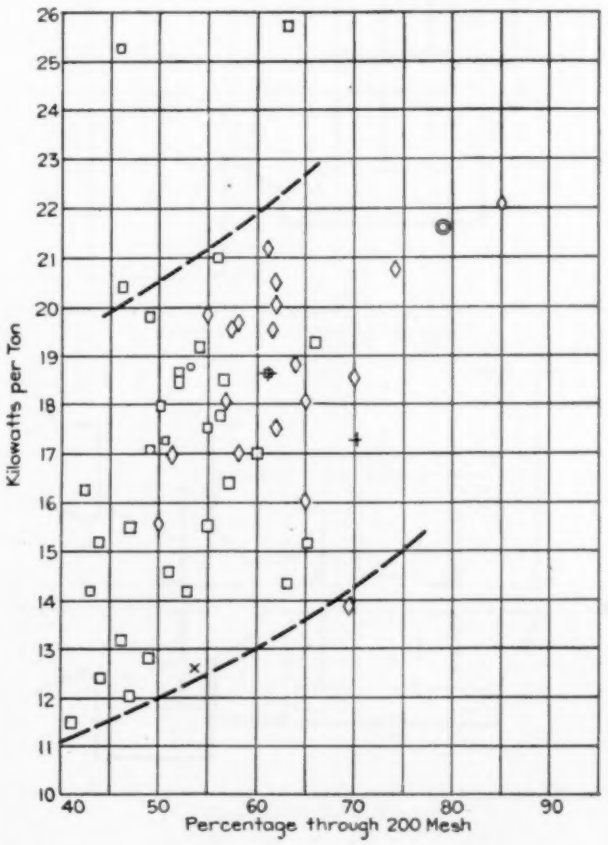

Fig. 1 Chart of Tests, Giving Fineness Performances
(Shape of symbols indicates types of mills.)

In support of this contention it is necessary only to state that designers of impact mills consider paddle or hammer velocities of 200 or 250 ft. per sec. necessary for efficient pulverization. If

[1] Consulting Engineer. Mem. A.S.M.E.

Contributed by the Fuels Division and presented at the Annual Meeting, New York, December 3 to 7, 1928, of The American Society of Mechanical Engineers.

we consider the effect of impact forces varying as the square of the velocity, and then take a roller velocity of 20 ft. per sec. as compared with the 200 ft. mentioned, the deduction is obvious.

In any attempt, therefore, to analyze the internal performance of mills, we find the ball or roller mill conforming to the general principles of grinding, while mills of the hammer type contain one or two interesting problems as to how the work is actually performed in the mill. Designers attack the problem in so many different ways that it is quite interesting to compare these, and then follow this with an analysis as to what is taking place at any one time in the mill and see if we can satisfy ourselves as

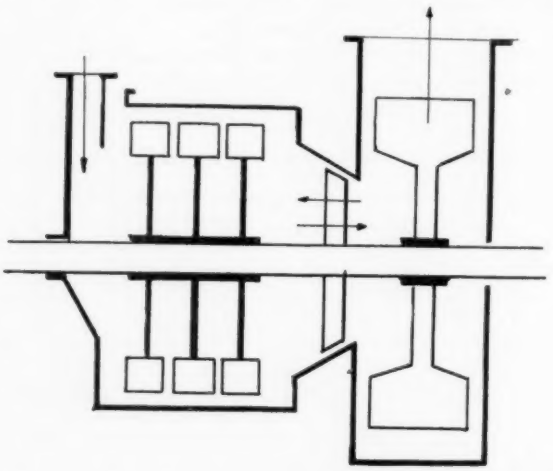

FIG. 2 MILL WITH COAL ADMITTED AT CENTER AND WHIRLED BEFORE CONTACT WITH HAMMERS

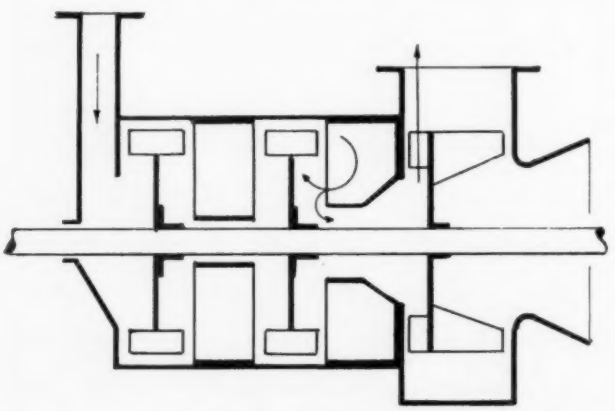

FIG. 3 MILL WITH COAL ADMITTED AT CENTER AND WITH TWO SETS OF HAMMERS

to how much is done by impact in the so-called impact mills, how much is really done by straight attrition, and how much by shear.

It has been asserted that the prevailing idea that all hammer mills operate on substantially the same general principles is erroneous, and this will be substantiated by Figs. 2 to 6, which show diagrammatically the general designs of some of the more important mills.

Fig. 2 represents a mill with coal admitted at the center and which receives a certain whirling motion before its contact with the hammers. The coal flows through the mill in a horizontal direction, and at the outlet it is met by a whizzer which picks up the unground particles and returns them to the mill for further treatment.

In the mill shown in Fig. 3 the coal is again admitted at the center. After passing through the first set of hammers it is brought substantially to rest by a series of stationary ribs, and then submitted to a second treatment by another series of hammers similar to those in the first stage. On leaving these hammers it is led to a large pocket fitted with radial ribs. The object of this pocket is to whirl the heavy particles back to the wheel for further grinding while allowing the fines to escape along the small opening around the shaft.

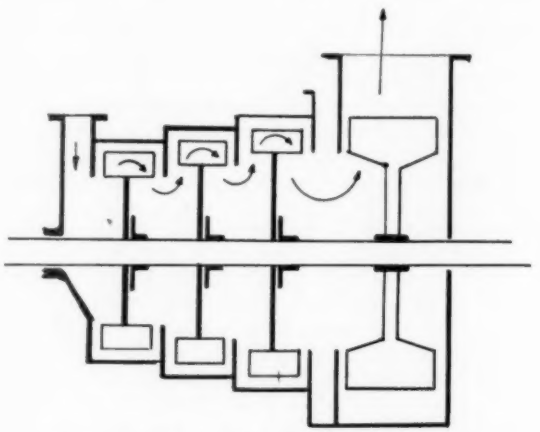

FIG. 4 MILL WITH SEVERAL SETS OF HAMMERS

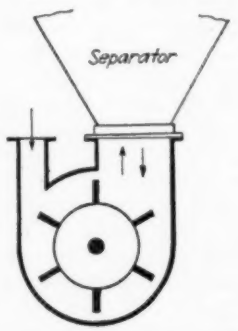

FIG. 5 MILL WITH COAL ADMITTED DIRECTLY IN PLANE OF HAMMERS

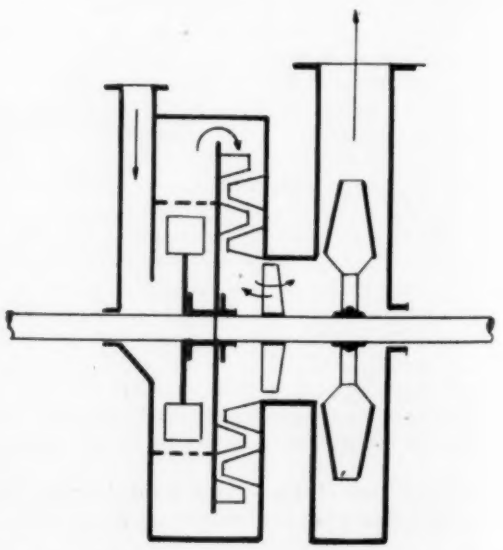

FIG. 6 MILL DESIGNED TO INCLUDE BOTH IMPACT AND ATTRITION

Mills of the type shown in Fig. 4 are built with a varying number of stages. Each stage has the hammers surrounded by a pocket in which it churns the coal to a certain fineness before it passes on to the next stage. In this mill the coal is again fed to the center of the mill.

Fig. 5 shows a mill employing an entirely different principle to those mentioned. Here the coal is admitted directly in the plane of the hammers, insuring maximum impact. The coal is discharged in an upward direction, as distinguished from the mills previously described, and enters a separator, which liberates the fines and returns the coarse particles to the mill.

Among the builders of this type of mill a great difference of opinion exists as to the most efficient speed that should be used. One maker at least uses a relatively high rotative speed in order to obtain the maximum amount of work from impact forces, whereas other makers use a relatively low speed, getting what impact they can, and relying on attrition for the balance of the work.

Of particular interest is the mill shown purely diagrammatically in Fig. 6. The designer of this mill took cognizance of the fact that there were two separate and distinct actions taking place in a so-called impact mill. He appreciated that impact could go only so far and that attrition must do the rest. This mill is divided into two separate stages. Coal is subjected to the regular hammer action in the first stage, and from there it is immediately discharged in a natural direction, outwardly radial. After passing over a partition it has to find its way in again toward the center against restrictions and eddying counter-currents. In other words, everything has been done to create attrition, either by friction against projecting pins or by collisions and rubbing of the particles against each other created by counter-currents of air in the attrition chamber.

Fig. 7 Diagram to Show Ratio of Circumferential Flow of Air to Horizontal Flow

How Fine Pulverization Is Produced in Impact Mills

Having described the general principle of operation of these various mills, let us try to analyze just what takes place inside of them during operation.

How much work is done by impact and how much by attrition? It can, the author thinks, be shown that no mill using impact forces alone can pulverize coal to a useable fineness. There are several ways in proving that this contention is correct. Let us first take the analogy of a ball suspended by a string, this ball in itself having a certain mass. We can take a bat and hit that ball with sufficient force to break it into small pieces. On the other hand, if we suspend a feather by a string and attempt to break this feather with a bat we will not be successful. The feather will begin to fly away from the bat before the bat hits it because of the cushion of air between the bat and the feather; in other words, the bat will just catch up with the feather, and when it does catch up with it, will not have sufficient relative velocity to do the feather any damage.

In a hammer mill having a tip velocity of 250 ft. per sec. the ratio of circumferential flow of air to horizontal flow is extremely high, as will be seen by the diagram in Fig. 7. This diagram is plotted in the following way: A mill of standard design has been used and the velocity of the mixture of air and coal has been computed in a horizontal direction, through the annulus A. This horizontal component will be seen to be almost negligible compared with the circumferential velocity created by the paddles. We therefore have air pockets between the paddles, with the air in these pockets traveling at substantially the same speed as the hammers.

Now if we could design a mill to give maximum impact, it would be in the form of that shown in Fig. 8, and the hammers would rotate in the direction indicated by the arrow.

Neglecting the slight downward velocity due to gravity and assuming a particle in the position shown, a certain upward

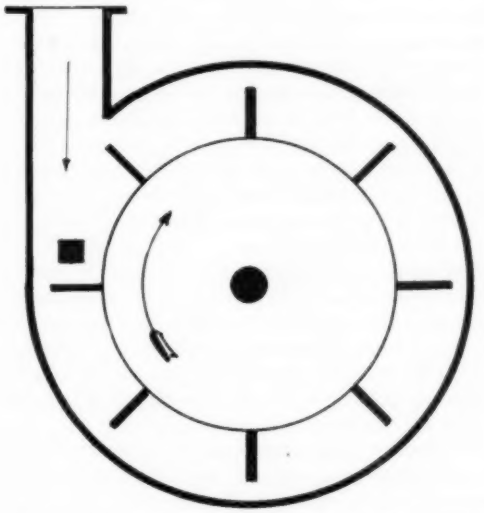

Fig. 8 Suggested Design of Mill to Give Maximum Impact

velocity of air will be sufficient to retain a particle of given weight in constant suspension.

Assuming the weight of coal to be 0.047 lb. per cu. in., then 1 cu. in. of coal would exert a downward pressure at rest of 0.047 lb. per sq. in.

The theoretical velocity of air to create this static pressure will be found from the approximate formula

$$V = 350\sqrt{p}$$

Where V = velocity in feet per second
p = pressure in pounds per square inch

Therefore assuming the particle in question in the diagram to be 1 cu. in., the upward velocity to keep this in suspension is only 75 ft. per sec. Any velocity less than this will permit the hammer to hit it. Any velocity in excess of this will drive it away. Now where do we stand with mean hammer velocities of 200 ft. per sec.? The size of coal in suspension would be very much larger.

Commercial mills, for obvious reasons, cannot operate in the direction of rotation shown in the diagram, so that in practice the impact forces are considerably less in consequence.

Theoretically, therefore, unless the hammer strikes the coal immediately upon its entrance to the mill, before the air currents have time to affect it, little impact can actually take place, provided the coal particle remains in the zone of the rotating hammers and air pockets.

But we have every reason to believe that the hammers in the mill are doing quite a little work in breaking up the coal. Let us go a step further. The high velocity of the hammers creates centrifugal forces sufficient to throw all solid particles out against the casing. Their contact with the casing will tend to bring these

particles to rest, with the result that positive impact can then be obtained. Judging from the character of the wear that takes place in the hammer of these mills that have fine radial clearances, it is fair to assume that a great percentage of the work done is confined to a very narrow zone extending from the casing to a very short distance down the hammers.

We are not considering pulverization at this time. We are only considering the first process of breaking up, and this brings in another factor. With lump coal concentrated at the periphery of the casing, and hammers rotating at high velocities close to it, granting that there is breaking up due to impact, is there not a possibility that there is quite an appreciable amount of work being done by direct shear?

In support of this argument we might again refer to the wearing of the hammers at the tips, and we could go a step further and argue that these shearing forces might account for the big differences that occur in fineness when the clearances are small, with new paddles, and when they are large, due to wear. The author, however, does not feel that this shearing effect has anything to do with fineness and that the change in the production of fines with small or large clearances can be traced to contributory conditions attendant upon said clearances.

We have been considering the work done by impact, with the possible assistance of shear. If we consider the analogy of the ball and the feather, and if we calculate the effect of windage in the casing, there are strong arguments to support the theory that in the so-called impact mills once the coal is broken up into small lumps (with a certain amount of attendant fines), impact forces cease so far as pulverization is concerned.

As a contributory argument it might be mentioned that pure impact mills have been experimentally built with velocities of impingement of 640 ft. per sec., the effect of which is 10 times as great as that of the average mill with a hammer velocity of 200 ft. per sec., but without satisfactory results so far as pulverization is concerned.

Once the coal is broken up into small lumps, the centrifugal force created by the rotating paddles is sufficient to throw all the particles of coal against the casing. Referring again to Fig. 7, the horizontal velocity of the mixture (air and coal) was computed to be 680 ft. per min. when passing 8000 lb. of coal through the mill per hour and assuming 18 cu. ft. of air per pound of coal. The coal in this mixture will hug the casing in its passage through the mill. This being the case, given a certain discharge from the mill, the thickness of this film of coal can be approximately calculated.

Assuming the coal to weigh, in round numbers, 80 lb. per cu. ft., then the cubic feet of coal per hour will be 100, or 1.66 cu. ft. per min. Assuming the velocity of coal through the mill to be the same as the mixture, or 680 ft. per min., then the film of coal will be less than one-tenth of 1 in. thick.

In commercial mills the minimum clearance usually allowed between the tip of the hammers and the casing is about $^1/_2$ in. If the material is thrown out against the casing, as we have every reason to believe, then all particles less than $^1/_2$ in. will be immune to impact or even shearing.

Let us now consider the question of pulverization as distinguished from breaking up. It has been shown that when the coal is broken up into particles less than the clearances in the mill it is out of the way of impact or shearing forces, because the film of coal at any one time in the mill is less than the clearance. In the grinding down of our coal from small lumps to 100 and 200 mesh, attrition and only attrition must be doing this all-important work. And this attrition will naturally be a function of the whirling velocities of the particles and the time element.

Regarding the marked effect of the wear of hammers on fineness, we cannot look for the answer to this because of any great loss in impact or in shearing. We can look for the answer in the effect that increased clearances have on the velocities of rubbing.

Take for instance the case of a mill having zero clearance: the particles will be whirled around the casing at the speed of the hammers. We can now add sufficient clearance between the hammers and the casing so that the induced windage created by the hammers will be insufficient to overcome the frictional resistance of the coal rubbing against the casing, in which case the particles would remain stationary.

Conclusions based on the foregoing arguments would be:

1 In any so-called impact mill, the actual work done by impact forces is relatively small.

2 In hammer mills, where the no-load power or windage losses vary somewhere between the square and the cube of the speed, are high-speed hammer losses warranted by the fact that they are probably doing little hammer work, but the velocity energy created by the hammers rotating at high speed is only producing velocities necessary for attrition that might be accomplished in a more efficient and scientific way?

Guarantees

It is hard to conceive a more difficult engineering problem than the determination, with any degree of accuracy, of the exact performance of a coal pulverizer.

Steam engines, turbines, pumps, and blowers can all be tested accurately by short runs in a manufacturer's plant, and these can be made without prohibitive expense. Readings can be made with sufficient precision to establish reliable guarantees and performance curves.

This condition unfortunately does not hold good in pulverizer work. Tests are extremely expensive, and any attempt toward an accurate determination of true performances in a manufacturer's plant involves an expense entirely out of proportion to any return that can now be expected.

Friability, moisture, load, and fineness all very materially affect the horsepower per ton. With the difficulties and expense involved in carrying out shop tests, the manufacturer has been obliged to rely on station tests for a great percentage of the data he uses in determining subsequent guarantees on future installations.

We are again confronted with the question as to the accuracy of the best station tests. The manufacturers owe a great deal to the cooperation that has been afforded them by the engineers of large power plants, not alone in allowing the manufacturer to inconvenience him a great deal by conducting experiments in his plant, but by whole-hearted cooperation in arranging his loads so that the manufacturer could get data as reliable as possible. Under the best of all these conditions, however, it is difficult to obtain data that will enable the manufacturer to state with any degree of accuracy what he will get on the same mill in another station. Referring to the difficulties involved in getting accurate data from station tests, one specific example is sufficient to explain this point. A series of tests were run under the best possible conditions, extending over a period of five weeks, tests being conducted practically every day. During this period the moisture content of the coal varied from 4 per cent to 14.5 per cent. There was no record as to whether the friability remained constant.

With the foregoing difficulties confronting us, therefore, is it plain common sense for the purchaser to demand guarantees on something that he himself knows must only be a good (or bad) guess on the part of the guarantor? Is it good engineering for any manufacturer to make guarantees with no concrete data to back them up? Are such demands and acceptances conducive to the development of an art, the prime object of which should be the mutual interest of all concerned in the conservation of natural resources?

In asking the builder to make guarantees, let us ask ourselves just what the purchaser is really interested in. The answer will be that he is interested in the following factors and in this order of importance:

1 Satisfactory continuous operation

2 Efficiency.

Regarding item 1, the engineer appreciates that he cannot get continued satisfactory operation unless the machine fills the following specifications:

(*a*) The design must be such that it will operate without legitimate mechanical troubles

(*b*) Over a legitimate period of time between shutdowns for replacements of worn parts, he must not experience excessive "snowstorms;"[2] in other words, during this period he is interested from an operating standpoint in his 40 mesh performance and he is not interested whether his 200 mesh is 60 per cent or 90 per cent

(*c*) The design must be such as to facilitate quick replacement of all worn parts, including bearings.

Item 2 is considerably involved. It contains many factors that must be taken into account if we are to make an absolute analysis as we would in a heat balance in a station over a period of one to two months.

Major items necessary for the tabulation of absolute data would include the following:

(*a*) Reliable information relative to the power consumption over the whole range of operating conditions

(*b*) A close approximation as to the mean fineness performance over a satisfactory period of operation

(*c*) Maintenance in cents per ton.

Regarding the factors mentioned in item 1, the purchaser is entitled to expect and the builder should be willing to give protective guarantees to cover all these points.

When we come to item 2, however, it is a different story. If we make calculations to determine the answer to any problem, we must know all the factors involved. If there is a variable x in the problem, the answer is not correct until we find the absolute value of this x for the particular case we are considering. In coal pulverizer calculations there are many x's.

As *a*, *b*, and *c* of item 2 are all more or less affected by the same variables, we must, to consider the situation properly, make a new classification. This classification is confined to only two subjects, but it will be seen that in each one treated the variable x must be so multiplied as to include a great many other letters of the alphabet.

The first subject to be considered will be the nature of the material to be pulverized. By this is meant the complete nature of the material, including friability, moisture, and chemical characteristics. All these factors affect power per ton for pulverizing and materially affect the cost of maintenance.

With all these variables, how can a purchaser expect to get any reputable manufacturer to give guarantees unless he himself is in a position to furnish all the data necessary for the making of such guarantees?

If this same purchaser is buying a turbine he will state that he will furnish to the turbine steam at a certain pressure and quality and will guarantee to take the exhaust steam from this machine at a certain pressure. Under these conditions the turbine builder can make concrete guarantees that should always be met. In the case of a pulverizer, however, until the purchaser can give the same definite particulars with regard to the coal that is to be pulverized—i.e., complete physical and chemical characteristics of the coal—he has no more right to demand or even to expect the builder to make binding guarantees either on kilowatts per ton or maintenance than he would to expect the turbine builder to make guarantees with unknown steam conditions.

Again, looking at the matter from the builder's standpoint, if the prospective customer could give all of the information outlined, has the builder sufficient data today to make computations from standard performances so as to make positive guarantees? If not, he has no right to commit himself to guarantees.

The second subject to be considered under the general classification referred to is that of the meaning and understanding of the term "fineness."

All questions pertaining to the performance of mills, and in fact all discussions on the subject of pulverized coal, center on the performance through a 200-mesh screen. This is well illustrated by the fact that so many test reports refer only to this screening. Now there are many reasons why performances and comparisons based on a 200-mesh standard are neither logical, reliable, nor of any great value.

In support of this argument it is not necessary to go into any great detail. Some of the points to be enumerated will be self-evident to all, while others will be appreciated only by those having had first-hand experience in the collecting, screening, and weighing of samples.

1 What is a 200-mesh screen? Mr. Peabody pointed out in his paper before the Society of Naval Architects and Marine Engineers that so long as manufacturers of screens disregard any idea of adhering to recognized standards and use different sizes of wires (as unfortunately they do) various screens having different sizes of openings may be used, any of which might comply with the literal rule of so many "mesh to the inch," but no two of which would give the same results on screening a sample of pulverized coal. Incidentally, Mr. Peabody recommends the general adoption of the A.S.T.M. standard, which specifies the size of the screen by the size of the opening. Until we all learn to talk the same language with regard to screens, and especially with regard to the finer screens, all questions relating to reported performances are absolutely worthless.

2 What is the shape of the particle when it reaches the 200-mesh screen? Supposing it is slaty in formation and supposing that it just passed the 100 or 150 screen because its widest measurements permitted it to, but that its thickness measured $^1/_{500}$th of an inch, it might not pass the 200-mesh screen, but it would possess much better firing qualities than a cube or a sphere that did pass the 200-mesh screen.

3 The actual taking of representative samples is acknowledged to be a problem of no mean proportions to those who have attempted it. Assuming that a correct or representative sample has been obtained, difficulties are encountered in getting a proper screening. Where there is moisture in the sample, it is still more difficult, and the results are often unreliable.

When all is said and done, and the manufacturer has guaranteed 80 per cent through this ambiguous 200 mesh, and the sample only shows 70 per cent, the manufacturer has fallen down on his guarantee, probably owing to his ignorance of the coal used. Controversy arises over payments, but the boiler goes on operating with the same efficiency at 70 per cent as it would show with 80 per cent.

Now, if on the other hand, all guarantees were based on a flat and definite performance of 100 per cent with an allowance of, say, a minimum of 99.5 per cent through the 40 per cent screen, let us see what would happen. In the first instance the screening through a 40-mesh sieve is simple and it takes a very short time to get an absolutely accurate screening. That which does not go through a 40-mesh screen can be seen. It is in the form of easily visible lumps. On the firing end, the particles larger than 40 mesh can be seen in the furnace in the form of "snowstorms," which is a serious condition and liable to cause shutdowns. This

[2] A term used to describe large particles in the furnace.

constitutes one proposition relative to the importance of the 40-mesh screening.

Granted that the 40-mesh sample is what it should be and that snowstorms are not experienced, what guarantee have we that we are getting enough fines and superfines to give us the best economy in the boiler? The answer to this question, the author thinks, is given in Figs. 9 and 10. In Fig. 9 there are plotted over a hundred tests from seven different types of commercial mills.

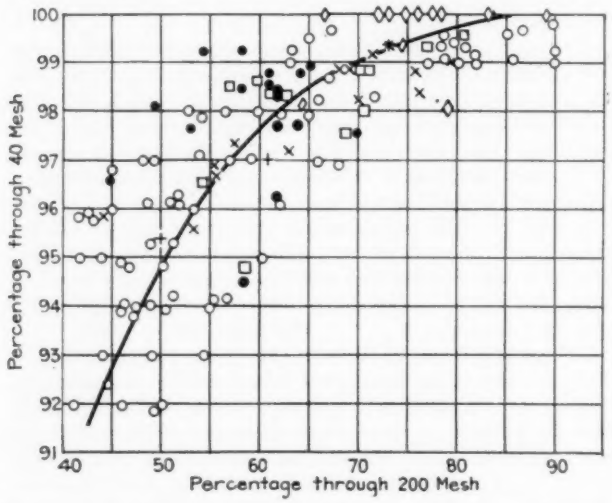

FIG. 9 TESTS PLOTTED ON BASIS OF PERCENTAGE THROUGH SCREENS OF DIFFERENT MESHES
(Shape of symbols indicates the seven types of mills included.)

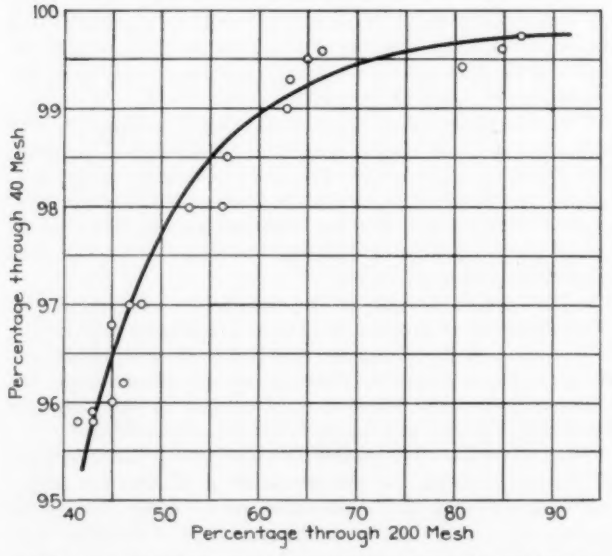

FIG. 10 CHART PLOTTED FROM ASHLEY STEEL PLANT TESTS

They are plotted on the basis of the percentage that went through 200 mesh and what the same sample did at 40 mesh. In taking the worst example it will be seen that 100 per cent through 40 mesh was not reached until the fineness at 200 reached 67 per cent. Taking a mean curve of all the tests, the average is about 85 per cent through 200-, with 100 per cent through 40-mesh screen.

In order that there can be no misunderstanding as to whether this characteristic holds good with various loads and conditions, Fig. 10 has been plotted from the Ashley Street tests given in the N.E.L.A. report referred to. In this series of tests we have loads varying from one-half to 20 per cent overload; we have the moisture content at 6 per cent, 9 per cent, and 12 per cent; and we have tests with new paddles and with paddles badly worn. Throughout all these tests the general characteristics are remarkably consistent.

If, then, the actual performance of all mills is such that with a given performance of, say, 100 per cent through a 40-mesh screen—and we cannot help but accept the plain fact that the 40 mesh is an all-important screening from the standpoint of operation and efficiency—what are the logical arguments against accepting this 40-mesh screen as the standard upon which to base all guarantees?

The average engineer in charge of a power plant is no fool. On the contrary, we find the best engineers in the country today in charge of our large generating stations. There never was a time when the manufacturer needed the cooperation of the station engineer as he does today for the proper development of his apparatus. The builder will not get this cooperation until he is honest with himself, and he cannot make ten or fifteen guarantees on a proposition with so many unknown quantities involved and be honest with himself.

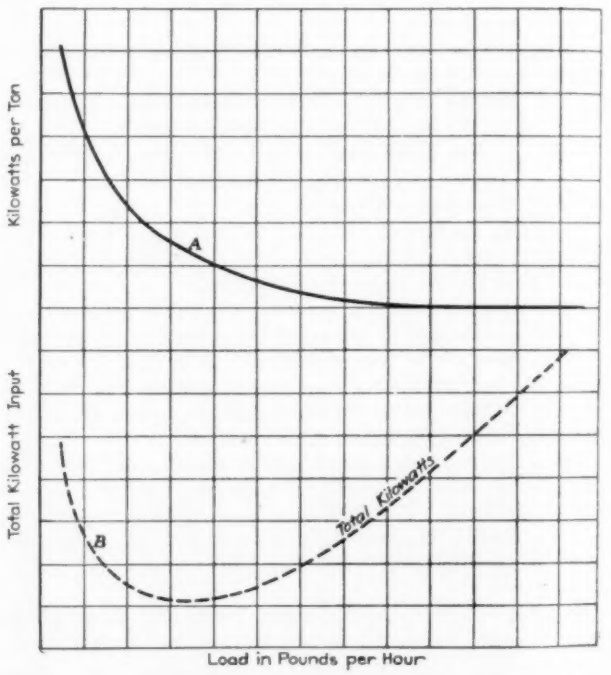

FIG. 11 CURVE OF AVERAGE POWER CONSUMPTION PER TON OF ONE MILL

On the other hand, this same engineer when properly approached with sufficient sane guarantees that protect him in the operation of his plant and with enough supplementary data backed by sound engineering judgment to enable him to estimate with a reasonable degree of accuracy what his general performance will be, will be found to be the most receptive of purchasers.

Apart from the question of giving impossible guarantees, the builder can be severely criticised for the publishing of unauthentic data in his catalogs. In Fig. 11 there is reproduced to scale a catalog curve of the average power consumption per ton of a certain mill. This is curve *A* and looks as though it might have the right shape. If we replot this curve, however, on the basis of totol kilowatts against load, as shown in curve *B*, we find curve *A* valueless and misleading.

Conclusion

Until we know more about the art of pulverizing coal than we do today, the builder should be honest with the purchaser in any guarantees he makes. Engineering judgment prompts us to confine all of our guarantees to the following simple code, which is presented here for discussion:

1 Guarantees for power per ton and maintenance to be based on one accepted standard grade of coal.

2 Moisture content under guarantee conditions must not exceed 5 per cent.

3 Fineness guarantees to be based on 99.5 per cent through a standard 40-mesh screen.

Multitudinous guarantees, based on guesses, are worthless to the purchaser and harmful to the builder. Simple guarantees can be made accurate and reliable and thus are worthwhile and mean something to the buyer.

Discussion

O. P. Hood.[3] There are other arts equally interested in fine pulverizers. The metallurgists are greatly interested in this subject. The metallurgist has wanted for some time a means of determining the efficiency of crushing machinery. It would appear that we have the same problem here. If it were possible to have a crusher with 100 per cent efficiency, what would be the form of the power curve as fineness increased? It has been questioned as to whether the amount of power required was in direct proportion to the amount of surface produced or not.

Work that has been done during the last year or two by the Bureau of Mines has shown that Rittinger's law is correct. If the amount of power required is in direct proportion to the amount of surface produced, why is it that in coal pulverization we get such scattering results?

I think it must be admitted that the absolute efficiency of any of these pulverizing machines is relatively low, so that the big factor is a variable waste factor which masks a great many of the real facts of the case. Also, it has been pointed out that pulverization varies greatly with the moisture of the coal.

The standard method of determining moisture is empirical. It is entirely possible with some coals, by using a different method of determining moisture, to find anywhere from 3 to 4 per cent more moisture than the standard method reveals.

Moisture in coal exists in several forms. Which form affects coal pulverization and which does not? Here again we have factors which when plotted mask the facts of the case.

It is not at all surprising to learn that different coals, even when dry or at the same moisture content, take a different amount of power to reduce them to equivalent sizes. If one will look at the shape of the particle that is produced, he will find a great deal of variation in the different coals. It is obvious that if spheres could be produced, you would have a minimum surface for a given size produced. The nearest thing you can get to that in coal would probably be small cubes. But if one looks at powdered lignite, or even some bituminous coals, the characteristic shape of the small piece only a few microns in average dimension may be plate-like or rod-like, having a considerably larger surface than either the cube or the sphere. There is, therefore, a characteristic form or surface area for each particular coal.

Not only that, but each different ingredient of the same coal presents this same group of moisture and breaking problems. The so-called mother of coal very prominent in black coal from Brazil, Ind., is made up of very fine friable particles to begin with. It is like fine charcoal. In that same coal will be a dark band named by our English friends vitrain because it breaks like a vitreous substance with a conchoidal fracture.

These factors which mask the facts of crushing should be borne in mind when plotting the results of experiments.

C. J. Jefferson.[4] The author emphasizes the important fact that manufacturers of pulverizing equipment should know exactly what their equipment can produce and their guarantees should be based on facts rather than on guesswork.

He states in his conclusion that guarantees for power per ton on maintenance should be based on one accepted standard grade of coal. This is quite in order, but it should be supplemented by coefficients indicating what the performance will be when using the various fuels that will be available at the plant where the pulverizer is to be installed. It is appreciated that at present this is most difficult, if not impossible, as there is not sufficient knowledge available as to just what are the "grindability" characteristics of the various fuels of the world. This quality of coal should be made a matter of research. As it is so vital to the whole coal industry the research should be sponsored by the mining interests, coal transportation interests, manufacturers of equipment, and the operators of the power plants themselves.

The second item in the conclusion states that moisture content under guarantee conditions must not exceed 5 per cent. This is ideal for the manufacturers of pulverizing equipment, but does not meet operating conditions. Our experience with actual bunkerings of the steamship "Mercer" has shown that out of seven different bunkerings the moisture contents in five were in excess of 7 per cent. This high moisture content is due to the exposure of barges and railroad cars to the weather during transportation of coal from the mines to the point of bunkering. Our experience therefore has forced us to adopt a policy that all pulverizing equipment submitted for test at the Philadelphia fuel-oil testing plant (where we are now carrying on our laboratory developing work for the adaptation of pulverized fuel to marine boilers) must function with a moisture content as high as 7 per cent; it is also understood that the fuel used is the ordinary bituminous coal found along the Atlantic seaboard.

If I were purchasing pulverized-fuel equipment for a plant using mid-West coal or Southwest lignite, I would insist on a still higher moisture content, as 5 per cent moisture content in Illinois coal would be practically dry coal.

The fineness guarantee to be based on 99½ per cent through standard 40-mesh screen may be suitable for boilers fitted with enormous refractory-lined combustion chambers, but where the combustion space is limited and a heat release of 30,000, 40,000, and 60,000 B.t.u. per cu. ft. per hr. is required, this qualification is meaningless, because in the case of these boilers it is necessary to have a great number of superfines in order to speed up flame propagation. In the case of such furnaces the guarantee should be based on the finer coal rather than on the heavy granulars. Personally I do not think it is practicable to set a definite standard on the degree of fineness required which will cover all boilers. The type of furnace relative to size and to whether or not it is refractory-lined or water-cooled affects this characteristic so much that a blanket specification as to the degree of fineness is not only ridiculous but dangerous. On the one hand, excessive power may be called for in obtaining the specified fineness, and on the other hand, failure to call for the required fineness will result in an impossible combustion condition.

[4] Head, Fuel Conservation Section, U. S. Shipping Board, New York, N. Y.

A. H. KRAUSS.[5] The author has discussed a subject of great importance to those concerned with the burning of fuel. The question of guarantees is a vital one, and there are several points upon which the writer does not agree with the author. It is necessary to obtain specific guarantees from the manufacturer in respect to both fineness and power consumption. It is true that guarantees do not run a plant, but the choice and selection of a given type of plant must necessarily be predicated upon guarantees. Also, the writer's experience has shown that by having guarantees, changes and adjustments have been made to mills in order to correct faults therein to meet guarantees, and such a procedure is conductive to the development of the art because it forces the manufacturer to work with the purchaser in obtaining the maximum efficiency from the plant.

It is admitted that there is bound to be a large variance in power consumption for pulverizing different coals. The author has plotted in Fig. 1 a chart of tests on fineness performances, with abscissas giving percentage through 200 mesh and ordinates giving kilowatts per ton. From this chart he shows a difference in power consumption of no less than 70 per cent between the upper and lower limits for any given percentage through 200 mesh. The author states farther on in his paper that friability, moisture, load, and fineness all very materially affect the horsepower per ton. In plotting Fig. 1, are the points plotted for maximum rating of the mills or any other specific rating? This factor has a great bearing upon the power consumption, and unless it is taken into account, the figure is misleading. The writer has found that there is an increase in power consumption per kilowatt of coal pulverized of 60 to 70 per cent between full rating and one-third rating on a type of impact mill with which he has had experience. This may account for a great part of the variation that the author shows in his Fig. 1.

Moisture in the coal also has effect upon the power consumption, as stated by the author, and this should be taken into account in plotting such a curve; in other words, those points in which the moisture is in great variance with the average should be discarded from such a plot.

The writer believes that if these various factors were taken into account it would be found that there is not nearly such a wide variation in actual performance as the author has stated. It is necessary for the purchaser to obtain power consumption guarantees, although it is admitted that there are various factors such as pointed out by the author which affect the results. These factors should be taken into account by the manufacturer in making his power consumption guarantees, and the writer does not agree with the author that there are too many variables and that it is unfair to ask the manufacturer to make such guarantees.

With regard to fineness, it is true that we are mainly interested from an operating standpoint in the 40-mesh performance but we are also interested in the 200-mesh performance. The writer has had experience with mills where the ratio, as shown in the author's Fig. 9, of 40- and 200-mesh fineness was not obtained until considerable adjustments and changes had been made to the mill and its classifiers. It is not seen how the maximum efficiency and best performance of the mill could have been obtained unless there had been guarantees to work to. Neither is there any apparent objection in making a guarantee on performance through a 200-mesh screen. Qualification, however, may be made as to what standard 200-mesh screen the guarantees are based upon.

Unless guarantees are made, there will be no incentive to obtain the best performance from the equipment furnished, and the writer believes that all facts necessary can be given to the manufacturer and that he should be in position to make guarantees which he can honestly give.

[5] Assistant Mechanical Engineer, Electric Bond & Share Company, New York, N. Y. Assoc-Mem. A.S.M.E.

AUTHOR'S CLOSURE

Mr. Krauss, Mr. Van Blunt, Professor Work, and others have made particular reference to that point in the paper where I recommended guarantees based on 40-mesh screen.

I know this is a very disputable question, but I think the gentlemen have rather missed the point I wanted to bring out, and that is that if we confine ourselves to a minimum of 99.5 or 100 per cent through the 40-mesh screen, we cannot get this until we have reached a minimum of 60 to 70 per cent through the 200-mesh. That is the main point, and the actual characteristics of the curves are immaterial. Now 60 to 70 per cent through a 200-mesh is considered in most power plants as very satisfactory performance.

Mr. Hood brought out the point that there is quite a difference in the methods of measuring the actual moisture in coal which has to be taken into account. This only emphasizes what I brought out in the paper, that until we have all of these variables boiled down to concrete factors and know just what we are talking about, only then will we be in a position to talk absolute guarantees.

I tried to point out in the paper that I think we ought to begin by the simplest kind of code possible, confining our guarantees for the time being to such factors as we have concrete data upon.

Mr. Jefferson has brought out that he considers it impracticable to confine guarantees to a maximum of 5 per cent. I agree with Mr. Jefferson that the moisture content in practice is generally very much higher than this, but the effect of moisture in different types of mills is quite different. We have very little data to tell us just what the difference would be in any mill with 5, 10, or 15 per cent moisture. Until we have this data, the performance with higher moisture content is purely conjectural, so I still feel that it would be much more sensible to confine guarantees to substantially dry coal and then to make what we consider approximate corrections for high moisture rather than to give definite guarantees on high-moisture coal without any data whatever to work with.

I was glad to note that Professor Work agrees with me relative to standardizing on some fixed grade of coal. The question has been raised by several speakers relative to the accuracy given in Fig. 1. I appreciate that this is a very approximate curve. It was introduced to show the immensely wide variation in commercial work. The tests plotted were at the manufacturer's rated full load. I think it was Mr. Van Blunt who brought out the point that the load has quite a marked effect on the performance. This is granted; but if a manufacturer, as he does in some cases, sells a mill for one-half the rated load that the mill will carry in some other cases, in order to improve fineness performances, then the full rated load automatically becomes one-half the normal, with a consequently higher power consumption.

I am sorry I could not raise a better discussion on the design of mill. Mr. Van Blunt pointed out that in his opinion the hammer mill is not a good mill for fine pulverization. Why not? I think I brought out clearly in the paper that in a hammer mill very little work is done by impact and the real pulverizing is done by attrition, and I therefore feel that a scientific study of this type of mill will demonstrate that it is quite possible to get fine pulverization, provided that proper attrition is provided for.

Mr. Hood brought out the fact that the efficiency of pulverizers is probably very low. It is in the full appreciation of this fact that I have endeavored to point out that very little scientific research work has been done in an attempt to improve this.

FSP-51-29

Steam-Generating Capacities of Boilers

By FAIRFIELD E. RAYMOND,[1] CAMBRIDGE, MASS.

In this paper the author gives reasons why the maximum steam-generating capacity of any complete boiler unit should be calculated entirely on a heat-liberation basis, except in so far as the features of design are reflected in the value used for the weight or volume of fuel consumed per hour in the furnace and in the overall efficiency. He presents formulas which represent the fundamental conditions, and gives several examples of their use.

THE selection of suitable boiler equipment to meet the steam requirements of a given power plant is becoming more and more complex, and recent developments and innovations in the design of boilers and furnace equipment present an increasing number of obstacles to the direct determination of the maximum steaming capacity of any unit. At present more consideration than ever before is being given to the amount of heating surface exposed to radiant heat, such was water walls, water screens, and the lower banks of boiler tubes, as such surfaces have a much greater capacity for steam generation than those which are more remote and obtain heat by convection only. Besides, the amount of fuel that can be burned in the furnace under any boiler has been greatly increased by the use of pulverized coal, as well as oil. Likewise the effect of air preheaters, heat exchangers, feedwater heaters, air-cooled walls, economizers, etc., must be considered in determining the overall efficiency of the proposed boiler installation and the ultimate generating capacity of the boiler. Eventually all this must be reduced to terms of pounds of steam generated per hour in order to compare it with the requirements of the power plant. This problem assumes serious proportions when it comes to the determination of the number of safety valves required for each boiler unit, as the methods available for solving this problem follow in most cases arbitrary rules which do not provide for the conditions encountered in modern practice. It therefore seems desirable to establish a direct method of obtaining the maximum steaming capacity of any complete boiler unit without involving indeterminate factors.

Existing Methods of Determination

In the past the accepted method of determining the steaming capacity of a given boiler depended upon the assumption that the rate of heat liberation in the furnace, or the rate of heat absorption by the boiler tubes, was practically a constant for most installations. In general this was true as long as hand firing existed and boiler pressures remained moderate. Evidence of this fact is visible in the various boiler codes in use up to this time.

Certain codes refer to the unit of grate area (lb. per sq. ft.) as a measure of the fuel burned per hour, having assumed that a uniform amount of coal is supplied during the hour to each square foot of grate surface and that the heat content of that coal is the same for all conditions; and following this it is assumed that the rate of evaporation is also uniform for all conditions, and thereby an expression is arrived at which represents the probable steam-generating capacity of the boiler. The conditions here mentioned are naturally those existing when the boiler is being forced to its maximum. Examples of this type of code are to be found in those published by the United States Board of Inspection Service of Steam Vessels, and in the Massachusetts Steam Boiler Rules, and the Canadian Interprovincial Regulations—for Boilers.

Other codes refer to the unit of heating surface (lb. per sq. ft.) as a measurement of the steam generated per hour in the boiler proper, omitting the conditions existing in the furnace and the amount of fuel fired. This method therefore implies that the rate of firing is constant for all installations, and assumes that the rate of heat transfer from the products of combustion to the water in the boiler is constant for all cases except where corrective factors are given for special types of boilers or various pressure ranges. Here, too, the boiler is considered as being forced to its maximum. Examples of this type of code are to be found in those published by the Committee of Safety Valves of the American Railway Master Mechanics' Association, in the statements given in Par. 274 of the A.S.M.E. Boiler Code, and in the codes applying to the regulation of boilers throughout the British Empire.

Improvements in Firing Rate

With the improvement of firing methods and the use of mechanical stokers it was found that boilers could be forced to higher steaming rates than had ever been possible by hand firing. As a result a greater amount of fuel could be burned under any given boiler, with a consequent greater rate of heat liberation. Therefore the original assumption of a constant rate of heat liberation, as found in the codes referred to, no longer holds true. To account for this it became customary to state that a boiler was operating at 200 per cent or 300 per cent of the nominal boiler rating given by the manufacturer and as calculated on the original assumptions. This method proved satisfactory in most instances until the advent of oil and pulverized coal, by means of which it is possible to force a boiler with a properly designed furnace to 500 per cent or 600 per cent of rating, and finally, with the development of boilers similar to the "Combustion" steam generator, it is possible to obtain 1500 per cent of the nominal rating. It seems that with ratings increasing so rapidly, any method of calculating the maximum steam-generating capacity of a boiler which depends on such arbitrary assumptions and corrective factors is entirely unreliable and fails to represent the actual conditions.

Improvements in Boiler Design

Likewise, with the introduction of water walls and water screens it was found that such surfaces, as well as the lower banks of tubes which are exposed to the direct effect of radiant heat, absorb more heat in proportion than more remote sections of the boiler, and that the rate of heat transfer from the products of combustion to the water in the tubes is no longer a constant for all sections of the boiler. Accordingly, in order to calculate correctly the actual steam generated on the basis of total heating surface, it would be necessary to segregate each section of the boiler and calculate the steam generated therein by applying the appropriate rate of heat transfer for that section. The combined results would give the total generating capacity of the boiler. Practically this would be impossible as it would require tedious calculations involving details of design the data for which can rarely be found outside the possession of the boilermaker, and therefore it would seem desirable to have some simpler and more direct method established.

Present Practice in Purchasing Equipment

Moreover, it is becoming common for engineers and designers

[1] Assistant Professor, Industrial Research, Massachusetts Institute of Technology, Cambridge, Mass. Assoc-Mem. A.S.M.E.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of boiler plants to select the most efficient type of firing system and grade of fuel for a given plant, and design the furnace and equipment to suit; whereupon a boiler which will most satisfactorily fulfil the conditions is superimposed upon the furnace design. Auxiliary equipment such as air preheaters or economizers, etc., have become a definite part of the complete boiler installation and therefore must also be considered, as the effect of these units upon the overall efficiency of the boiler will influence the final choice of equipment for the power plant. Therefore, it is becoming impossible to purchase a boiler as a unit, complete in all respects, as was customary in the past, and likewise to expect arbitrary rules to hold for determining the generating capacity when the component parts are obtained from unrelated sources.

Use of Fundamental Principles

At this point it becomes apparent that the methods provided in the codes mentioned are inadequate for modern conditions and that in the future the actual maximum possible steaming capacity must be calculated from facts derived from the actual layout of each installation. To avoid complex calculations involving details of design it is proposed to utilize the fundamental principle that the heat input must equal the heat output, by basing the calculation upon the heat liberated in the furnace, and upon the heat content of the steam as delivered by the boiler to the main steam line, with due consideration of the losses, expressed as a factor of overall efficiency. The data for such calculations are readily obtained from the original determination of the heat balance for the power plant and from the guarantees of the manufacturers whose equipment has been selected.

Recognition of Fundamental Principles

The soundness of this principle was definitely recognized by the A.S.M.E. Boiler Code Committee as early as 1914 and was incorporated in the code published that year, being continued in subsequent editions, and may be found in Par. A-12 of the Appendix. Other codes have come to recognize to a small degree, as already mentioned, that the heat liberation per unit of grate surface or the heat transfer per unit of heating surface is not constant for all fuels or pressures, and have provided, in a superficial way, arbitrary tables or factors for corrective purposes. These other methods, however, do not approach the problem from the right angle, and show that the authorities responsible for them have not grasped the fundamental conditions involved or else have not applied them to the fullest extent possible.

Proposed Method of Calculation

The maximum steam-generating capacity of any complete boiler unit, therefore, should be calculated entirely on the basis of heat liberation without regard for the details of design, except in so far as the features of design are reflected in the value used for the weight or volume of fuel consumed per hour in the furnace and in the overall boiler efficiency. The following formulas represent the fundamental conditions:

$$W = \frac{C \times H \times E_0}{q + xr - q_f} \quad \text{(for use when steam is saturated or wet)} \quad [1]$$

$$W = \frac{C \times H \times E_0}{q + r + C_p\,(t - t_{sat}) - q_f} \quad \text{(for use when steam is superheated)} \quad [2]$$

where W = maximum steam-generating capacity of any complete boiler unit (lb. per hr.)
C = total weight or volume of fuel burned per hour at time of maximum forcing, lb. or cu. ft.
H = heat of combustion of fuel, B.t.u. per lb. or per cu. ft.
q = heat of the liquid, B.t.u.
r = latent heat of vaporization, B.t.u.
x = dryness factor (for saturated or superheated steam $x = 1.0$)
C_p = specific heat of superheated steam at constant pressure ($C_p = 0$ if steam is saturated or wet), B.t.u. per deg. fahr.
t = temperature of superheated steam, deg. fahr.
t_{sat} = temperature of saturated steam, deg. fahr.
q_f = heat content of the feedwater, B.t.u.
E_0 = overall boiler efficiency = per cent ÷ 100.

The derivation of these formulas depends entirely upon simple thermodynamic principles and the data required can be obtained from the calculations for the individual plant. The value of C is obtained from the manufacturer of the firing equipment; the value of H is obtained from the vendor of the fuel as his average analysis for the grade required; the values of q, x, r, C_p, t, t_{sat}, and q_f can be found from any steam table of the proper pressure-temperature range. The efficiency factor E_0 includes the effect of all primary and auxiliary equipment composing the boiler unit, and accounts for all heat losses such as stack temperature, incomplete combustion, radiation, and moisture. Heat that is reclaimed from other sources outside the boiler is represented in the term for the heat content of the feedwater, and is subtracted from the total heat in the live steam. The denominator thereupon represents the heat required to generate one pound of steam at the maximum pressure and superheat from feedwater having the highest obtainable temperature. It may be well to note here that the data required are consistent with the present practice of purchasing such equipment.

The A.S.M.E. Evaporation Factor

Another important step in the same direction was the adoption by The American Society of Mechanical Engineers of a new unit of boiler rating, the "evaporation factor" (equal to 1000 B.t.u. of heat transferred), in place of the commonly used "boiler horsepower" (equal to 34.5 lb. of steam per hour from and at 212 deg. fahr.). Engineering practice has so changed in the past few decades that the term "boiler horsepower" has become purely nominal, as its use involves obscure factors and tends to avoid the underlying conditions of heat transfer. The new term, "evaporation factor," states exactly the proposed number of B.t.u. a boiler can absorb for the purpose of generating steam, and lends itself readily to the simple determination of the style of boiler to be superimposed upon the furnace, depending entirely upon the heat liberated in that furnace. This also conforms to the practice of purchasing the boiler equipment in separate units.

Approximate Method of Calculation

Where only general or approximate results are required, the formula as given in Par. A-12 of the A.S.M.E. Boiler Code is most applicable and sufficiently accurate. It is derived from Formula [1], wherein it has been assumed that the difference between the total heat in the steam and the heat returned in the feedwater is constant, so that the denominator of the first equation becomes equal to 1100 B.t.u., as follows:

$$W = \frac{C \times H \times E_0}{1100}$$

where the various terms have the same meaning as already given.

Overall Boiler Efficiency

For general purposes the overall boiler efficiency can be assumed as 75 per cent. However, if test data are available or the

manufacturers' guarantees indicate a definite efficiency, whether of a higher or lower value, that should be used in preference. If any uncertainty exists as to the proper efficiency to be used, one should choose a higher value rather than a lower one, especially if a safety factor is concerned. Such doubt implies extraordinary conditions of operation and new methods or designs, which might give exceedingly high ratings of steam generation and a resulting increase in overall efficiency. As efficiencies of 90 per cent have been attained, it is wholly within reason to use in such cases the figure of 100 per cent until a more accurate figure can be determined from actual operating conditions.

Application to Safety-Valve Problems

All these facts apply particularly to the determination of the proper number of safety valves. Many times in the experience of the author, as well as of others richer in such knowledge, has the number of safety valves provided proved insufficient to relieve the boiler due to the discrepancy between Boiler Code requirements as represented by existing formulas and the actual maximum steam generation possible. The number of safety valves required to protect a given boiler can be found simply by dividing the maximum amount of steam generated (lb. per hr.) in a boiler (W from the formulas) by the stated discharge capacities (lb. per hr.) of any make of safety valve as guaranteed by the manufacturer and stamped upon the casing or tag permanently affixed to the valve. If no such data are provided, safety valves should be rated as specified in the various codes with minimum capacities until the correct data for them can be obtained. Here again, if the actual overall boiler efficiency is unknown or it seems inadvisable to use an efficiency as low as 75 per cent owing to radical features of design, an efficiency of 100 per cent can be safely used without involving too great an expenditure for extra valves; the 25 per cent added efficiency above the average efficiency will only require one additional safety valve per boiler at most, and often this extra valve must be supplied as it is practically impossible to provide an aggregate safety-valve relieving capacity exactly equal to the steam-generating capacity of the boiler, and the resulting reserve capacity will cover a possible increase in efficiency even up to 100 per cent. Again this is evidence that a more exact method of determining the maximum steam-generating capacity is needed similar to that proposed in this paper.

Conclusions

In conclusion, the necessity for rating boilers on a heat-liberation basis in B.t.u. units for the English system cannot be overemphasized. The steam-generating capacity should be stated in one of three ways:

(*a*) Pounds of steam evaporated per hour
(*b*) Heat liberation in the furnace; together with an overall efficiency and the operating or limiting steam pressures and temperatures and feedwater temperatures
(*c*) A.S.M.E. evaporation factor (1000 B.t.u.) together with the operating or limiting steam pressure and temperatures.

Similarly, specifications for safety valves should give the steaming capacity of the boiler in one of the three ways expressed, and if the second way (*b*) is preferred and the total B.t.u. input is not at hand, the data should include the maximum weight or volume of fuel that can be consumed in the furnace and the heat content of the fuel as also stated, but *never* the grate area or the heating surface alone. Engineers and responsible authorities should give this subject much consideration, as progress demands a change in existing practice, and sufficient influence should be brought to bear upon them so that formulas for the determination of the maximum steam-generating capacity of a complete boiler installation, based on fundamental facts, will be adopted by them and incorporated in all codes regulating boilers.

Examples

Specific examples may well illustrate the suggested methods:

CALCULATIONS FOR STEAM-GENERATING CAPACITIES OF BOILERS

(Using Formula [1])

Example 1 Original Condition.

Data: Maximum coal fired = $6\frac{1}{2}$ tons per hr.
= 13,000 lb. per hr.
Heat content of coal = 14,500 B.t.u.
Overall boiler efficiency = 80 per cent
Maximum steam pressure = 385 lb. gage
Maximum superheat. = 150 deg. fahr.
Feedwater temperature = 445 deg. fahr.

W = pounds of steam generated per hour

$$= \frac{13{,}000 \times 14{,}500 \times 0.80}{422 + 780 + 0.5(150) - 422} = \frac{150{,}800{,}000}{855} = 176{,}300 \text{ lb. per hr.}$$

Example 2 Firing Rate Increased.

Data: Same as for Example 1 except
Maximum coal fired = 8 tons per hr.
= 16,000 lb. per hr.

$$W = \frac{16{,}000 \times 14{,}500 \times 0.80}{422 + 780 + 0.5(150) - 422} = \frac{185{,}600{,}000}{855} = 217{,}000 \text{ lb. per hr.}$$

Example 3 Assuming 100 Per Cent Efficiency.

Data: Same as for Example 1 except
Overall boiler efficiency = 100 per cent.

$$W = \frac{13{,}000 \times 14{,}500 \times 1.00}{422 + 780 + 0.5(150) - 422} = \frac{188{,}500{,}000}{855} = 220{,}400 \text{ lb. per hr.}$$

CALCULATIONS FOR SAFETY VALVES

(For conditions given in Examples 1, 2, and 3)

Example 4 Original Conditions.

Data: Steam-generating capacity (W) from Example 1.
Discharge capacity of safety valve at 385 lb. = 56,000 lb. per hr.

N = number of safety valves required for boiler.

$$N = \frac{176{,}300}{56{,}000} = 3.15. \qquad \textit{Use 4 valves.}$$

Example 5 Firing Rate Increased.

Data: Steam-generating capacity (W) from Example 2.
Discharge capacity of safety valve at 385 lb. = 56,000 lb. per hr.

$$N = \frac{217{,}000}{56{,}000} = 3.88. \qquad \textit{Use 4 valves.}$$

Example 6 Assuming 100 Per Cent Efficiency.

Data: Steam-generating capacity (W) from Example 3.
Discharge capacity of safety valve at 385 lb. = 56,000 lb. per hr.

$$N = \frac{220{,}400}{56{,}000} = 3.95. \qquad \textit{Use 4 valves.}$$

In the foregoing examples it was assumed, first, that the original design data were used; second, that a change in the firing equipment was made, the increase in rating being known; and third, that a change in the firing equipment was made, the increase in rating being unknown. However, the resulting number of safety valves required for each case, as calculated in Examples 4, 5, and 6, is the same, that is, four, justifying the suggested use of 100 per cent efficiency in such calculations when the firing rate of a given boiler installation is unknown, as there is no penalty imposed in the form of the cost of additional valve equipment.

FSP-51-30a

Analysis of Costs of Variable-Load and Multiple Power Supply

By EDWARD H. SCOFIELD,[1] MINNEAPOLIS, MINN.

This study is based upon the actual performance of a plant in operation and includes a classification of costs designed to facilitate the calculation of the influence made thereon by a load of variable demand. Also it attempts to simplify the consideration of load characteristics and to determine the value of constants relating to certain factors of operation. Reference is made to the application of the results to a study for determining the economics of a power supply for the local electric railway system.

IN CONNECTION with an electric power load having a variable demand, the problem of costs as influenced by such variable demand becomes important. When such a power load is supplied from several sources, the problem becomes involved and must include a consideration of the various factors of manufacturing costs, the practical and economical distribution of the load to the sources of supply, and the apportionment of charges to the various operations to which this power is applied.

The problem in some cases also extends to a consideration of transmission, conversion, and distribution economies. The manufacturing costs may be listed under four general classes:

Fixed costs, including investment, overhead, and management costs, which are determined mainly by capacity of the plant, the character of its design and the amount of reserve units provided. These costs in the aggregate for an established plant are not influenced by the volume of output.

Service costs, including radiation losses, an element of attendance labor, idling or floating operation of power units, operation of house service and certain auxiliary equipment, emergency provision and other ready-to-serve elements, which are determined by the used capacity of plant during any period, and the policy of management regarding reliability of service, and not influenced by the output of the plant.

Demand costs, including the starting, stopping, and banking of power units, a part of fuel, labor, supplies, and maintenance cost, which costs are governed by the maximum power demand over a limited period. This maximum demand is usually considered as the average of daily maximum one-hour peak loads, occurring during an operating period of one month. The value of the constants determined for this factor will of course depend upon the manner in which the maximum demand is determined.

Output costs, including all operating costs for fuel, labor, supplies, and maintenance, which vary directly with the volume of net output of the plant, measured in kilowatt-hours, or average kilowatts of continuous output over a definite period.

The determination of values of coefficients for these various factors of cost is a matter of analysis. In predetermining the operating cost for a new plant, this analysis must be based upon equipment manufacturers' guaranteed performance and shop-test data as compiled and modified by the experience of the engineer. Some margin should be added to the summation of individual unit performance.

After a plant has been put into operation, observations may indicate the necessity of modifying the value of some of the items assumed in the preliminary determination. After a plant has been in operation over an extended period, and particularly where the conditions are such as to give experience over a wide range of power demand, detailed data may become available, from which an analysis may be made and values obtained which may differ materially from the predetermined value. This is true particularly because of the unknown and emergency conditions of operation, the divergence of variable-load performances from fixed-load performance of power units, the depreciation of performance due to efficiency of upkeep, lack of knowledge covering the character of load demand, changes in quality and price of fuel, supplies and wages, and operating conditions of labor.

Study to Determine Power Efficiency

With such data now available from the operation of the Twin Cities Electric Railway plant, a brief description of which appears later, over a period of 25 years, a study and analysis has been made and certain values for the factors and relations of costs have been determined. This study was undertaken for the purpose both of determining the economies resulting from the water powers now in use and for estimating the possible cost for additional power purchased, or the replacement of the present supply by a new steam power plant. As this study is still in progress it will be impossible to consider it in all its details or to give results or conclusions. All that is attempted is to indicate the general method employed in arriving at certain details of costs.

For properly evaluating the various items and factors of operation and expense, a number of charts are presented. As these charts are more or less general in character, the scale of ordinates in some cases is decimal. For specific values a proper constant is to be applied. For example, fuel costs as indicated on the charts will be modified by quality and price, also by efficiency of performance due to temperature and selection of generating units; labor costs will be modified by wage rates and conditions of employment; and supply costs by the variation of commodity prices.

In the operation of a steam plant the chief item of expense in this locality is fuel. The cost of fuel is made up largely of transportation and handling charges, which amount to from 50 to 70 per cent of the total cost. This makes the factor of fuel performance of first importance. The fuel performance depends upon the efficiency of firing, the adaptability of the furnace and boiler equipment to the coal used, the efficiency of generating and auxiliary units, the management of the plant, the seasonal weather conditions, and the character of load demand. On account of the number of variables involved and of the great divergence of their values, it seems impracticable to solve for values of all such variables by a mathematical process. However, it seems that by selecting a period over which the general conditions are fairly constant or vary over a limited range, plant performance may be grouped with relation to certain major factors and the data from such grouping introduced into equations, from which the relative values of these variables can be solved.

An attempt at a solution was made from data covering a period of thirty-six months' operation of the plant described at the end of the article. The method of grouping the data of major

Contributed by the Power Division and presented at the Summer Meeting, St. Paul-Minneapolis, Minn., August 27 to 30, 1928, of The American Society of Mechanical Engineers.

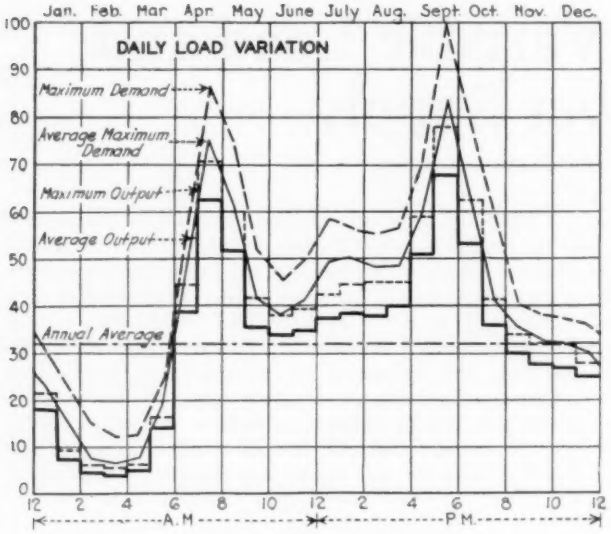

FIG. 1

(Shows the essential data of a typical urban electric-railway load in its relation to the hourly demand and the departure from normal of the maximum individual hours of the year, the average maximum hours during the months, and the maximum monthly average.)

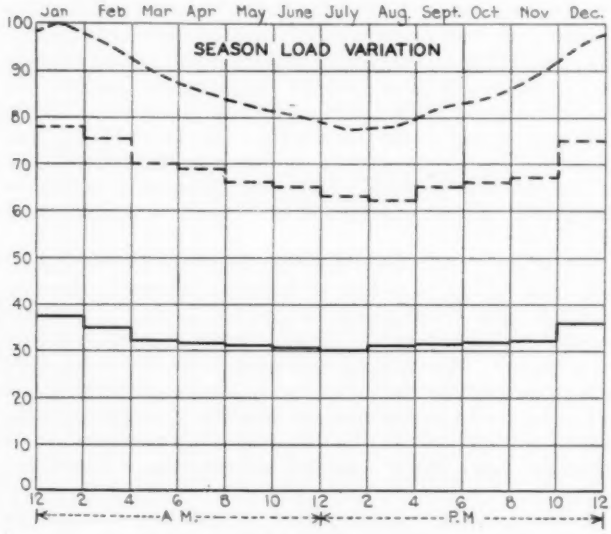

FIG. 2

(Shows the seasonal variation of the same data as in Fig. 1 for the total system load.)

importance and also the solution for value of constants are given in Table 1.

Fig. 5 was plotted to determine the relation of monthly average maximum one-hour demand to average output. This relation is described by the formula

Maximum kw. demand

= (1.5 average kw. output + 11,000 kw.) ± 10 per cent

The individual daily one-hour peak may, however, have a deviation as high as 50 per cent.

Fig. 6 was also plotted to show the relation of coal used to average output (the coal quantities being reduced to an equivalent heat value). This chart indicated a definite general relation with a deviation corresponding in character with the demand deviation, suggesting that the general form of equation should include a factor for maximum demand in addition to average output.

LOADING AND TEMPERATURE THE MAIN INFLUENCES

A controlling influence in the fuel rate of this plant is the loading of the preferential electric-generating unit. Also in plants of this character, the temperature, as relating to circulating water, air for combustion, condensate, and radiation losses, has a material influence on fuel rate. To compensate for these items, percentage factors are introduced. In the problem worked out these factors are made to modify only the average output factor. From some considerations it might be thought advisable to apply the temperature coefficient to both power factors.

The formula for fuel performance based on the foregoing influences may take the form

$$\text{Coal, lb.} = RX + Sy\left(\frac{100 \pm Ta \pm Ub}{100}\right)$$

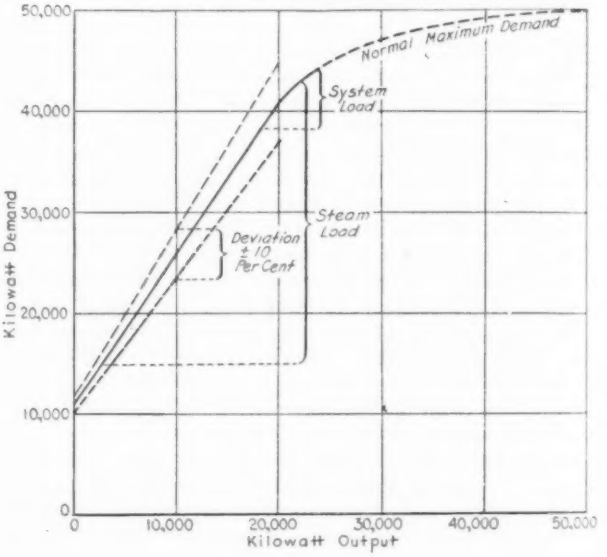

FIG. 3

(See description under Fig. 4.)

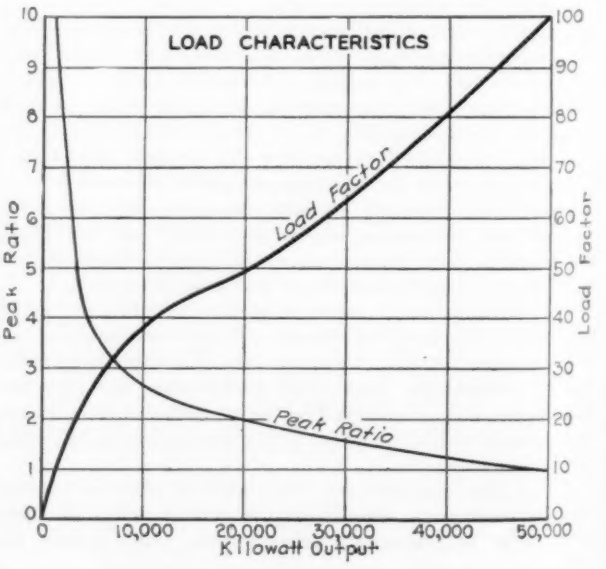

FIG. 4

(This, with Fig. 3, shows the relation of maximum demand to output were the loading of a plant carried to the ultimate of 100 per cent plant factor, and the corresponding load factor and peak ratio resulting therefrom.)

Where

R = average of one-hour peaks for each day of the month, kilowatts

S = average continuous output for the month, kilowatts

T = departure of temperature from normal, 45 deg. fahr.

U = departure of loading of No. 4 turbine unit from normal, 50 per cent of total turbine hours.

A solution gives values for constants as follows:

Maximum kw. factor	X	= 6.0
Average kw. factor	y	= 56.4
Temperature factor	a	= ±0.18
Unit hours factor	b	= —0.2

Substituting the values of these coefficients in the formula,

$$\text{Coal, lb. per day} = 6.0R + 56.4S\left(\frac{100 \pm 0.18T \pm 0.2U}{100}\right)$$

TABLE 1 MONTHLY AVERAGE PERFORMANCE

\end{aligned}$$

As a check upon these values of coefficients a calculation was made by this formula for the coal demand by months for the three-year period considered in the problem. The results of this calculation varied from the actual amounts charged to operation less than one-half of 1 per cent for the total period, 2 per cent for a one-year period, and monthly within 6 per cent,

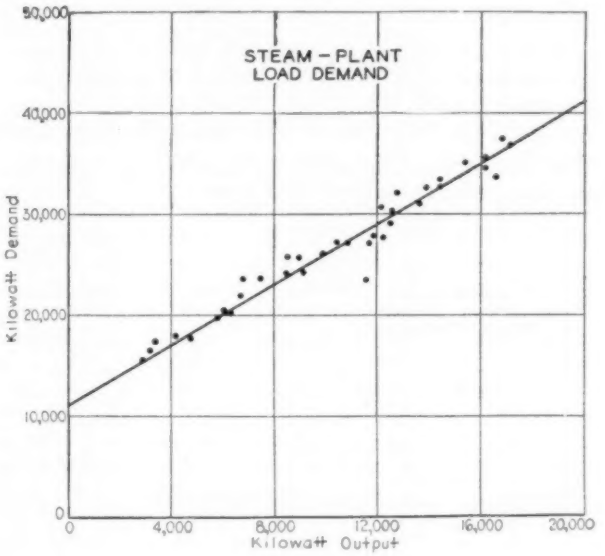

FIG. 5

(Shows the actual relation of maximum demand to output of the load imposed on a steam plant where a variable base load of the power system is diverted to a water power having no storage capacity. This chart and that shown in Fig. 9 coordinate when the proper constant factor is applied.)

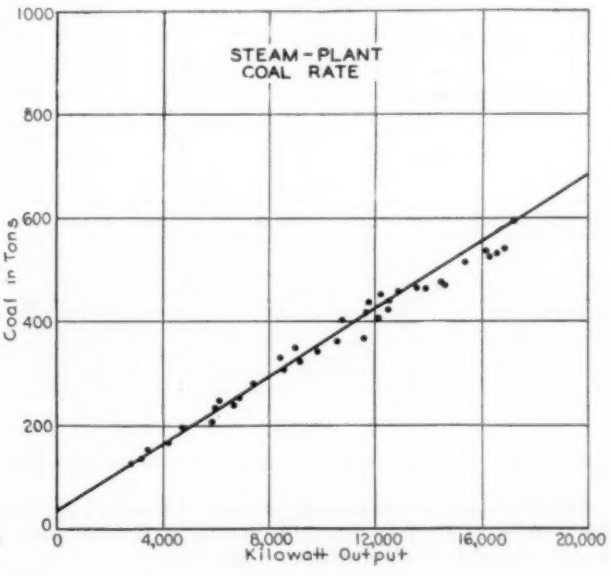

FIG. 6

(Shows the relation of coal demand to output, and in conjunction with chart shown in Fig. 5, indicates the influence of maximum demand upon coal demand.)

with the exception of two months when arbitrary adjustments had been made of the amount of fuel charged to the plant.

These satisfactory results were obtained notwithstanding the fact that the amount of coal charged to the plant each month is arrived at by methods which are subject to error as high as 5 per cent.

From these results the following deductions may be made:

The basic coal rate for this plant under normal conditions—i.e., 45 deg. fahr. temperature and 50 per cent turbine hours loading on No. 4 unit—is 56 lb. of coal per day average kilowatt, equal to 2.33 lb. of coal per kw-hr.

The basic rate is increased by 6 lb. of coal per day per kilowatt of 1-hr. maximum demand. This amount added to the basic rate gives the total coal rate as follows:

Load factor 100%	0.25	+ 2.33	=	2.58 lb. per kw-hr.
Load factor 50%	0.50	+ 2.33	=	2.83 lb. per kw-hr.
Load factor 33⅓%	0.75	+ 2.33	=	3.08 lb. per kw-hr.
Load factor 25%	1.00	+ 2.33	=	3.33 lb. per kw-hr.

The basic rate is increased or decreased directly 1 per cent for a change in temperature of 5 deg. fahr.

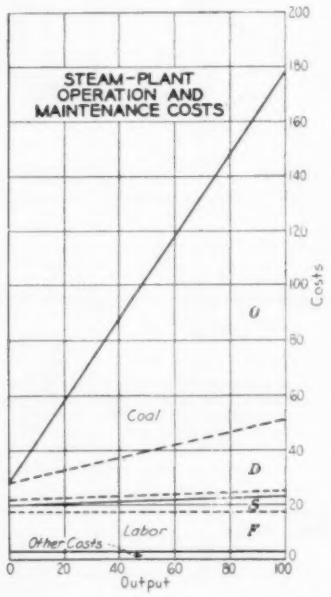

Fig. 7

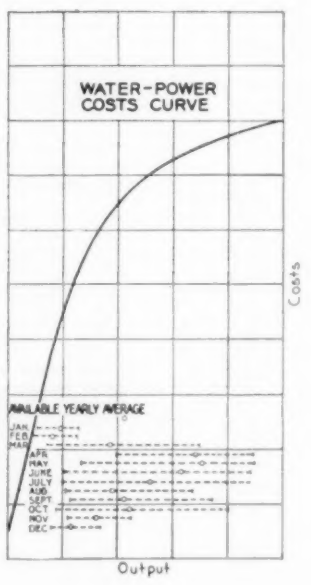

Fig. 8

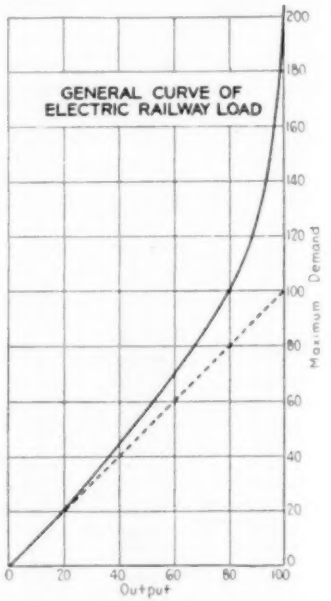

Fig. 9

FIG. 7

(Shows the normal relation, throughout the range of ouput, of the general division of operation and maintenance expense—i.e., fuel, labor, and other costs. These are indicated by the full-line division of the chart. For any output referred to the base scale the expense of each item is indicated by the distance between division lines referred to the vertical scale, and the total expense by the upper line. This chart is plotted from the actual operating data of a plant in which the monthly output varied from point 20 to point 80 of the chart. The secondary subdivision of this chart by the broken lines into parts—F, fixed; S, service; D, demand; and O, output—is for the purpose of illustrating the discussion, at the beginning of the article, on manufacturing costs. The determination of values of subdivisions O and D is the basis of the discussion of the items of expense in the operation of a steam plant.)

FIG. 8

(Shows the variable availability and trend of costs of the water power used on Twin City Electric Railway system. The circles indicate for a period of 10 years the annual and monthly averages of output available. The broken lines indicate the variation of the monthly averages during this period. The vertical ordinates of the full-line curve show the cost of any output.)

FIG. 9

(Shows the general characteristic of an electric railway load. This chart is plotted in terms of the base-load outputs expressed in percentage of total average output for any period to the base scale and the maximum demand of such base load in percentage of total average output to the vertical scale. That is, this chart indicates the peak ratio or inverse-load factor of any base-load portion of the total load, or by differential the load factor of any portion of the total load. The extended broken line indicates a condition of 100 per cent load factor for the total output. From this chart may be determined approximately the characteristics of the loads which may result from a division of load to two or more sources of power.)

The basic rate is increased or decreased inversely 1 per cent for a change of 5 per cent in the percentage of turbine hours of service carried by the preferential turbine unit.

Arriving at the Fuel Costs

A summation of these four factors gives the total coal rate for any character of load under any condition of operation, and this rate multiplied by the current price of coal delivered to the plant gives the fuel costs per kilowatt-hour.

As the rate per kilowatt of maximum demand includes such losses as are entailed by banking of boiler equipment, warming up, and starting and stopping of generating units and main auxiliary units, this item would in great part be eliminated if the plant ran continuously on a 100 per cent load. In this case the continuous coal rate would approach 2.33 lb. per kw-hr. Were the plant equipped fully by generating units such as the No. 4 unit, this rate would be reduced by 10 per cent to 2.1 lb. per kw-hr., which corresponds closely with the estimated performance based on test data of the plant equipment.

Having determined the normal coal rate and costs for any period by the foregoing method, the labor and supplies costs may be added and the total costs for operation and maintenance with relation to output determined as indicated by Fig. 7. The amount and trend of these added costs are based on performance of the plant as modified by variation in wages and prices.

By coordinating the costs thus determined for a varying output of the steam plant with costs as shown on Fig. 8 for a varying water-power supply, the aggregate cost of any load demand is determined, the characteristics of loads on each plant being indicated by reference to Fig. 9.

Other diversion of load to or from the steam plant may be made and the characteristics of load and its influence on cost of output determined by these charts and formulas.

The results of changes in equipment and methods of operating or of the price and quality of fuel may be satisfactorily analyzed and compared by this method.

Description of Power System

This study is based on data collected from the operation and development of the power supply for an electric-railway system comprising approximately 400 miles of single trackage

and operating 1000 cars with an average weight of 24 tons. The development covers a period of 40 years, during which it has passed successively through every phase of electric-railway improvement.

The original power supply consisted of hand-fired boilers and triple-expansion engines belted to small high-speed direct-current generators. About the year 1897 this was supplemented by 10,000 hp. of water power generating alternating-current power which was distributed through rotary converter substations. This water power was leased on a 40-year contract. The payments thereof were on a sliding scale based upon the amount of available power. These powers becoming inadequate, in 1902 a considerable capacity of storage batteries was added as a temporary relief. About 1904 plans for an adequate steam-plant auxiliary were made, and an initial capacity of equipment was installed, consisting of overfeed stokers, water-tube boilers, vertical compound engines direct-connected to 13,200-volt three-phase alternating-current generators. Units of this description were added as required, and the original steam plant and the storage batteries were abandoned. About 1906 two vertical Curtis-type steam turbines of 5000-kw. capacity were added. Following this, overfeed stokers were replaced by chain grates, and additional smoke-stack capacity was provided.

In 1908 an added block of 12,000 hp. of water power was added on a lease, to terminate at the same time as the original water-power lease. The payments on this lease are at a flat rate per year. Neither of these water powers have appreciable pondage for seasonal or daily storage.

From 1909 to 1917 the four 3500-kw. engine-driven units were replaced by three 15,000-kw. vertical Curtis-type turbo-generators, and in 1917 by a 20,000-kw. horizontal Curtis-type turbo-generator. About 1922 a number of chain grates were replaced by underfeed stokers, and increased superheater surface was added in the boilers.

The present continuous rated capacity of this steam plant is 50,000 kw. The combined capacity of the water power has a seasonal variation from 1000 kw. in winter to 16,000 kw. during favorable water supply. The aggregate output of water power available for use on the railway load averages over a period of years approximately 40 per cent of the load demand. This output has a seasonal variation from 12 per cent to 62 per cent and an annual variation from 30 per cent to 60 per cent of the entire load demand. As a result of this variable water power, the auxiliary steam plant is called upon for a very unfavorable load as to economy of operation. The total load demand approximates an average daily load factor of 50 per cent. The load on the steam plant at times is below 20 per cent load factor.

This condition led to a study of the economy of the use of these combined powers, also of the possibilities of replacement of a part or all of these powers by a supply of power from the local light and power company, whose distribution covers the same territory as that covered by the railway system.

A formidable obstacle to such a plan was the condition that the railway power system had been built up on a frequency of 35 cycles, while the power system was at 60 cycles. On the other hand an advantage for the plan existed in the condition that the existing transmission and substation system of the railway was overreached. Car lines were extended beyond the economic distance for trolley-current distribution, and the installation of added substations in such localities would be attended with high costs for extending transmission lines.

The problem therefore includes a study of transmission, conversion, and distribution economy, in addition to costs of generation and supply.

Operation of a Combined Steam and Hydro System

A Discussion of Operating Problems of the Northern States Power Company's System Located in Minnesota and Wisconsin

By JAMES A. COLVIN,[1] MINNEAPOLIS, MINN.

WITH THE growth of the public-utility industry, the responsibility of meeting increased power requirements and providing higher standards of service has presented problems in every system. In an interconnected steam and hydro system which extends over a wide area and which contains a main load center located at some distance from almost one-half of the available energy, and with other scattered load centers, the task of providing continuous and adequate service is quite an undertaking. The maintenance of a continuous supply of power and the regulation of the voltage at substation and point of use constitute the most important of these problems.

To obtain the maximum overall economy consistent with good service is the aim of the operating organization of the system. To do this, full advantage of the diversity of stream flow and of possible reservoir and pondage manipulation must be realized and these operations must be coordinated with the establishment on the steam plants of the most economical load factor that is consistent with the seasonal variations of energy available from hydraulic sources. In order fully to accomplish this aim for high overall economy it is necessary to have centralized control of the system and also communication systems through which the operation of all plants of the system may be properly coordinated.

The general problems of all combined steam and hydro systems are similar, but each system also has certain peculiarities which apply to it alone. These peculiarities result from the method in which the particular system has been developed, the area over which it is spread, the climatic conditions, and the ratio of steam to hydro capacity. The author will endeavor to present some of the problems of operation which obtain on the interconnected system of the Northern States Power Company to which his direct experience has been limited.

Description of Interconnected System

The following brief description, combined with the sketch shown in Fig. 1 in which a small portion of the primary transmission system is shown and certain plants are located, will serve to present a picture of the system under consideration.

The system extends over an irregular area approximately 250 miles east and west and 150 miles north and south. Approximately 75 per cent of the load is concentrated in the small area of Minneapolis and St. Paul.

The heart of the transmission system consists of a 110-kv. loop which encircles the Twin Cities. This loop encloses an area of approximately 200 square miles, and to it are connected two major steam plants (which have a total capacity of 152,000 kw. and which are located inside the loop), and two 110-kv. lines interconnecting 64,000 kw. of hydro capacity from outside the loop. This hydro capacity is obtained from three plants located in middle-western Wisconsin approximately 100 miles east of the loop. The above-mentioned steam and hydro plants, together with one other hydro plant of 21,400 kw. capacity, which feeds through one of the major substations over two 50-kv. lines approximately 40 miles long, constitute the major sources of power of this system. There are, in addition, some eighteen other smaller hydro and steam plants which are connected at various points on the system.

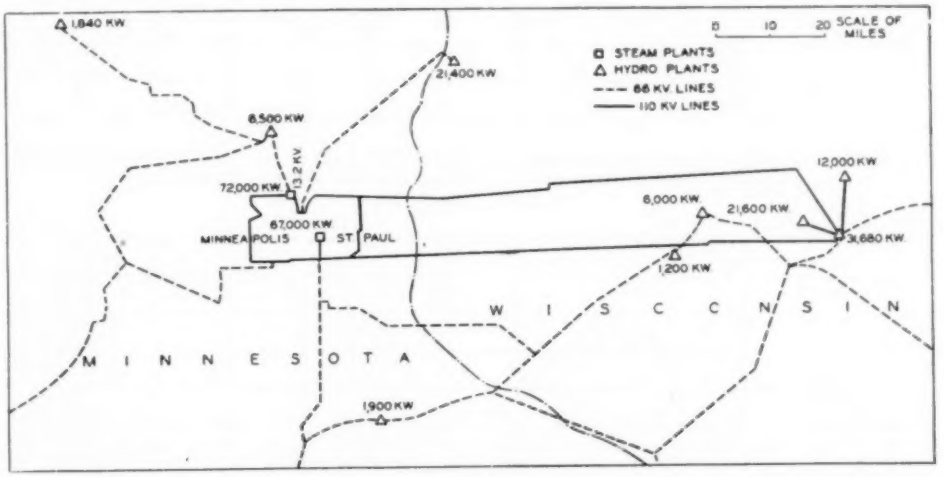

FIG. 1 PRIMARY TRANSMISSION SYSTEM OF THE NORTHERN STATES POWER CO. SHOWING PRINCIPAL TRANSMISSION LINES AND GENERATING STATIONS

Major substations as well as the steam plants, which, in addition to supplying electrical energy, act as major substations, are tapped on the 110-kv. loop. These major substations take care of the entire load of the 110-kv. loop which as mentioned before is approximately 75 per cent of the system load. A little less than one-half of the remainder of the load has for its main source of power a substation connected to the largest of the three hydro plants in Wisconsin, referred to above.

Development of the System

The development and growth of a combination steam and hydro system, where the annual output from the two sources is fairly well balanced, requires a more involved analysis than that

[1] Superintendent of Generation, Northern States Power Company. Mem. A.S.M.E.

Contributed by the Power Division and presented at the Summer Meeting, St. Paul-Minneapolis, Minn., August 27 to 30, 1928, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

required by systems which are mainly hydro or solely steam.

Several years are sometimes required from the time a decision is reached to construct a certain hydro development until the plant is actually complete, on the line, and ready for service. It therefore follows that studies on which decisions are based to develop either additional steam- or hydro-plant capacity must be projected many years in advance, and the predicted outputs of these plants coordinated with reference to the anticipated system load curve. Factors must be applied to adjust for line losses and to compensate for the potential capacity of existing hydro plants, the full utilization of which may not have been realized under existing load conditions because of lack of system absorbing capacity during the off-peak period.

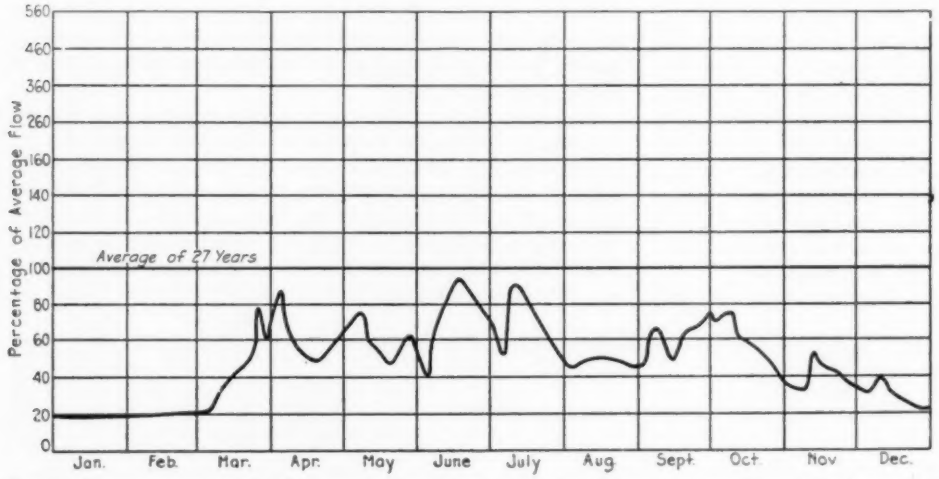

FIG. 2 HYDROGRAPH OF THE MISSISSIPPI RIVER AT COON RAPIDS, MINN., FOR THE YEAR 1925 SHOWING STREAM FLOW IN PERCENTAGE OF AVERAGE FLOW FOR PAST 27 YEARS
(Shows low stream flow.)

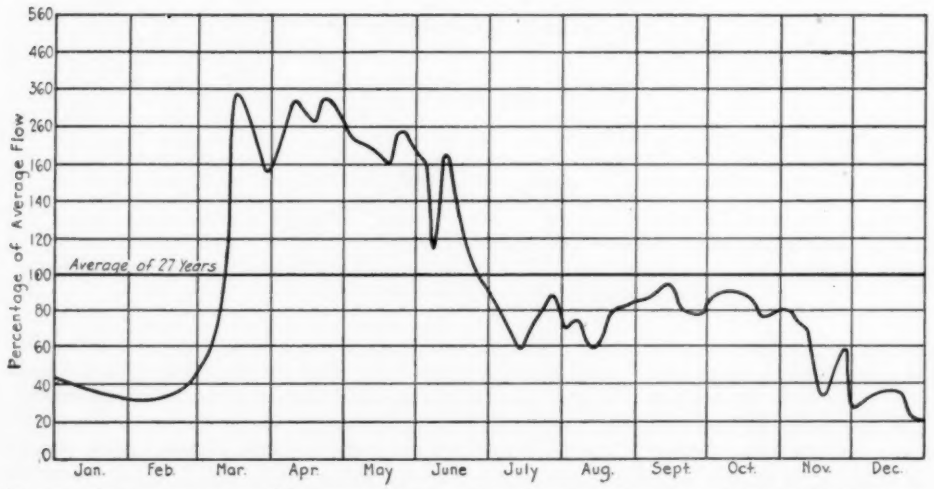

FIG. 3 HYDROGRAPH OF THE MISSISSIPPI RIVER AT COON RAPIDS, MINN., FOR THE YEAR 1927 SHOWING STREAM FLOW IN PERCENTAGE OF AVERAGE FLOW FOR PAST 27 YEARS
(Shows high stream flow.)

The useful capacity of the maximum system requirements must be considered on the basis of anticipated minimum flow conditions as they exist naturally, or when supplemented by discharges from storage reservoirs. Usually when there is a comparatively high proportion of hydro-plant capacity with good pondage facilities and control, the maximum energy output of a projected hydro plant that can be assured during the fourteen to sixteen hours of heavy load of the annual peak day or days will control its economical justification from a capacity standpoint. Under other conditions or stages of development, for instance, where the proportion of steam-plant capacity is greater, the maximum assured capacity of the projected hydro plant during the maximum annual demand period, i.e., the two- or three-hour period of peak demand, will control its justification from a capacity standpoint. Thus, the same plant in a combined steam and hydro system may have entirely different importance, depending upon the period of system development.

The minimum stream flow and the corresponding minimum output of a hydro plant may be fairly accurately predicted from a study of the records over a large number of years, but no accurate forecast can be made of the exact year in which this minimum may occur. In the operation of the system the operating organization must be fully aware of the possible variations in stream flow and also have a good knowledge of the plan on which the system was developed in order to be prepared to meet anticipated load requirements with the equipment available.

In the regulation of reservoirs that control seasonal fluctuations of stream flow, care must be taken so that sufficient storage is retained for maximum system demands—even though losses in power may occur by non-utilization of storage which sometimes might be refilled by subsequent floods. The extent to which stream-flow variations occur, even with limited reservoir control, is best shown in Figs. 2, 3, 4, and 5, which show actual stream flows of two streams for two different years. The average flow over a large number of years is shown by the heavy horizontal line.

In this section of the country maximum flood conditions occur during the months of April and May, and they may occur at any time for short intervals between June 1 and November 15. This period of possible floods is a period when the system load requirements are a little less than average. The maximum system demand period, however, occurs in the early part of December, at which time natural stream flows are usually at very nearly minimum stages. Seasonal variations in system loads are shown in Figs. 6, 7, 8, 9, and 10, which also indicate typical steam and hydro outputs which are obtained during these periods.

VOLTAGE REGULATION

Probably the most important feature of a combined steam and hydro system is the problem of maintaining satisfactory voltage

throughout the system in the face of extreme variations in power flow. In Fig. 1 the two 110-kv. lines, approximately 100 miles long, may at times carry as much as 65,000 kw. to the largest load center. At other times such as periods of low hydro output, even during normal load periods, the power transmitted over the lines is very little. Under night-load conditions the power supply may be actually reversed. In order properly to regulate the transmission voltage under these varying conditions it has been found necessary to carry on the line approximately 75 per cent of the steam capacity normally required for power generation during the seasonal peak period. This is done in order to absorb reactive kva. and maintain voltage within the range of regulation and compensation provided on distribution feeders.

During the excess hydro period it is necessary to generate a comparatively small amount of energy on the steam plants, and at times there is sufficient capacity at the hydro plants to carry the entire system load. Unless special provisions are made for keeping the turbine blading and wheels from overheating, the manufacturers of large turbine units generally recommend carrying a minimum load of not less than 10 per cent of the rated capacity of the unit. On 30,000-kw. units this would require between two and three tons of coal per hour, the majority of which might be saved by arranging a proper supply of cooling steam to the turbine and carefully checking the turbine temperatures. With these precautions the turbo-generator units may be "motored" as synchronous condensers.

The possible number of hours that it would be desirable to "motor" the units would, of course, depend upon the ratio of hydro-plant capacity to the system load. A study of load curves for a system which has a hydro capacity during flood periods of 85 per cent of the system peak at those times indicates that it would be possible to "motor" normal-sized steam units for a total of 1000 to 1500 hours a year. If units are "motored" it is possible to regulate the system voltage as well as to have "on the line" an immediate source of reserve capacity for protection against the failure of transmission lines carrying energy developed at distant hydro plants, and at the same time save 2000 to 3000 tons of coal per year.

Similarly, hydraulic units located at subsidiary load centers are "motored" with gates closed and vented draft tubes, thereby reducing the amount of power required to carry the unit on the line by 50 per cent or more, and thus conserving water for generation of power during peak periods. Steam units are "motored" during periods of maximum hydro output whereas hydro units are normally "motored" during periods of minimum hydro output. In this particular system the use of hydro and steam capacity, combined with certain motor-generator equipment used in the conversion of alternating current for direct-current systems, has provided sufficient synchronous condenser capacity to satisfactorily regulate the voltage of the system within the limits of regulators on distribution feeders, even though there are wide variations in the amount of load carried by the transmission lines. With the continued growth of substation loads and corresponding higher utilization of generating capacity, it is anticipated, however, that the installation of corrective equipment will be necessary.

CHARACTERISTICS OF STEAM-PLANT OPERATION

Wide ranges of loading, seasonal variations of loading, and low-load operation are the outstanding characteristics of the steam-plant operation in a combined steam and hydro system. Generally, the comparatively low annual load factor at which steam plants are operated in such a system will not justify the instal-

lation of equipment producing high thermal efficiencies. More attention must be given to ruggedness of equipment, to its ability to withstand rapid starting and sudden load fluctuations and to provision of equipment that is capable of carrying wide ranges of load with the highest overall economy. Flexibility of operation is more important than high thermal economy.

As stated, no accurate prediction can be made of the hydro output which may be anticipated for any individual year; and this output from a group of hydro plants may exceed the minimum output by 50 per cent during an exceptionally good water year. This deviation from normal stream flow results in a corresponding variation in requirements for energy generated at steam plants. Coal contracts must be based upon minimum hydro conditions, or with sufficient tolerances to take care of the maximum anticipated steam production. In order to obtain favorable contracts, reasonable tolerances are permitted; but with the wide variations in hydro output, the amount of coal contracted for to meet the minimum hydro conditions may exceed actual requirements by as much as 50 per cent. This makes desirable the establishment of substantial storage facilities to eliminate unreasonable tolerances in the coal contracts.

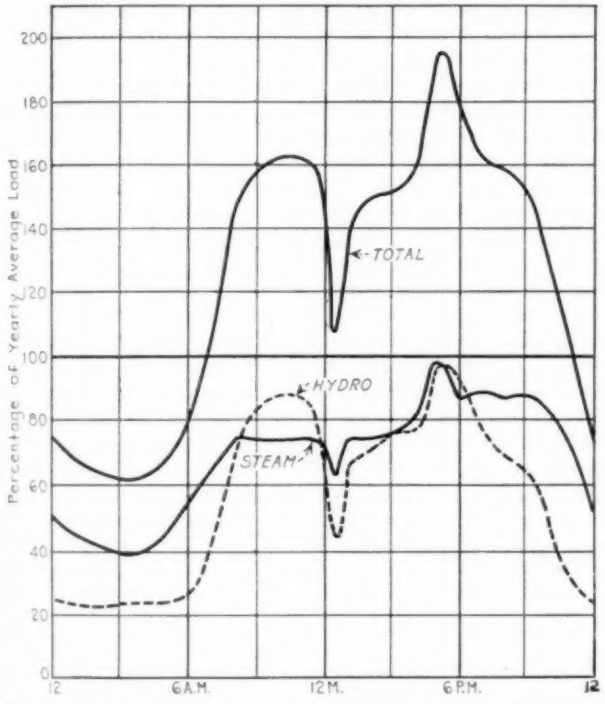

FIG. 10 TYPICAL DAILY SYSTEM LOAD DIAGRAM OF THE NORTHERN STATES POWER CO.'S INTERCONNECTED SYSTEM FOR A WEEK DAY IN DECEMBER SHOWING HYDRO, STEAM, AND TOTAL LOADS IN PERCENTAGE OF YEARLY AVERAGE LOADS
(Shows peak load with hydro and steam approximately equally divided.)

During the summer months changes of scheduled operations will vary on extremely short notice following sudden rains, and make it absolutely essential for the steam supervisory organization to be kept in constant touch with the system operating conditions in order to establish economical operating schedules to meet the different requirements.

During the normal excess-water period it is necessary to carry sufficient capacity in service to protect against transmission-line failures, and to regulate properly the voltage of the system. The operation of the boilers during this period was analyzed, and it was found that by applying the same careful study to this low-load operation as was applied to heavy load conditions, startling economies could be obtained. Not many years ago it was considered that a plant must be resigned to poor boiler efficiency when operating with banked fires or at very low ratings. It was found, however, that efficiencies above 75 per cent could be maintained for long periods when operating with "live-banked" boilers at about 25 to 30 per cent of rating. Efficiencies as high as 78.0 per cent have been maintained at a station over a period of four months, during which time the average rating of boiler capacity in service was approximately 25 per cent. Very substantial savings in fuel resulted from this system of "live-bank" operation and discontinuance of the former procedure of carrying whatever small load there was on the station on one or two boilers and "dead" banking the balance of the boilers.

Probably the most decided advantage that a steam plant enjoys in a combined system is the period available for maintenance and overhaul of large units during the flood period in the spring. Two months can be definitely relied upon for this period. In emergencies, at almost any time of the year, the power supplied normally by a large steam unit may be taken care of for very short periods by pondage draw-downs, thus making it possible to take care of minor repairs of an emergency nature at once before they develop to interfere seriously with service. During the winter months when the bulk of the power is carried on the steam plants, the hydro plants can take the swing of the system load, thus making it possible to establish extremely economical load factors on the steam plants at a time when circulating-water temperatures are low. This partially offsets the low thermal economy which accompanies low load and poor load factor at which the steam plants have had to operate during periods of excess hydro output.

GENERAL SYSTEM OPERATING CONDITIONS

The responsibility for properly operating the system and establishing load schedules is placed in the hands of a centralized dispatching organization and a production engineer. The active work of dispatching requires a centralized office from which the loading of all plants on the system may be controlled by means of suitable communication facilities between dispatchers and plants. For this purpose line telephones, carrier current, and radio are used, and properly trained crews are provided for inspection and maintenance of these communication facilities. The dispatching organization is guided in the loading of the system by fairly well established instructions for operation of plants under normal conditions. These instructions are prepared by the production engineer, whose duty it is to study carefully the operation of the plants and their relation to the system, analyze test curves of both hydro and steam plants, and from this information determine the best schedule for overall system economy. These instructions must be arrived at with the cooperation and complete understanding of the steam and hydro supervising crews. Such instruction must be provided not only for daily but also for seasonal operations, and during normal conditions set up for as long a period in advance as can safely be predicted for the convenience and clear understanding of plants which are located some distance away and which are controlled through subsidiary dispatching centers. Successful results depend largely upon the teamwork of these organizations.

It is true that the operation of a combined steam and hydro system requires a great amount of detailed analysis, complicated study, and careful planning, but since stream-flow and system-load conditions are seldom similar to those previously encountered, the variety which is introduced into the work, and the prompt action which is required when uncontrollable changes in conditions spring up, add ample spice to the drab routine of daily operation and make this work one of the most interesting phases of the public-utility business.

Discussion

H. G. Roby.[2] There is one point that Mr. Colvin's paper did not bring out that might be touched upon, and that is the different ways in which the water powers are operated in the system at different periods of the year. When there is plenty of water, the water powers are operated 24 hours per day, up to plant capacity. The steam plants come in on the short daily peak loads. This happens in the spring and early summer and occasionally in the fall. Ordinarily in the fall and early winter the reverse takes place, and the water-power plants are then operated on the peak and the steam plants carry the base load. The water powers are then deficient in the ability to turn out kilowatt hours, but have considerable plant capacity available. The water is ponded during the off-peak periods and the capacity of the hydro plants is brought into use at the time when the additional capacity is required. By doing this the water-power plants get their maximum use. During the spring of the year the water-power plants are turning out kilowatt hours at their full installed capacity, and in the fall and winter they are turning out kilowatt hours to the full value of the stream flow. It is only by combining steam and water-power plants that such economy is possible.

R. L. Goetzenberger.[3] I have read Mr. Colvin's paper with considerable interest. One question I would like to put is regarding frequency control. No reference appears to have been made to it. However, I would suppose, with the diversified power requirements of a system such as the Northern States Power, that frequency control would be an item of great importance. It would be interesting to know what weight is given to frequency control, as well as something about its accomplishment.

[2] Byllesby Engineering & Management Corp., Chicago, Ill.

[3] Minneapolis-Honeywell Regulator Co., Philadelphia, Pa. Assoc. Mem. A.S.M.E.

Author's Closure

I presume that what Mr. Goetzenberger would like to know is what we think about the problem of frequency control. Frequency control, in a combined steam and hydro system such as ours, is a matter which must be taken care of in a different way each day, each hour, and sometimes each minute. Thus far we have not felt it practicable to consider automatic control, for the simple reason that there are so many plants which have the responsibility of maintaining speed regulation that it would require a large number of control equipments to do this.

We endeavor to maintain a reasonably economic load factor on our steam plants, and during the loading-up period the system frequency control is transferred to the hydro plants after the steam plants have been loaded up. This is done in successive order as we desire the hydro plants to take on the load. As soon as each plant is loaded, the dispatcher is notified and the frequency control is transferred to the next plant. Finally a stage is reached where the balance of the load of the system is within the capacity of the last plant concerned, and this plant watches speed for the two or three hours in the morning, afternoon, and evening. The time of these periods varies with the seasons of the year.

You can see from the system load diagrams for the month of January there is a long period of flat load excepting for a time during the noon hour. In the spring and fall there are three peaks, in the morning, afternoon, and evening. The frequency control must be watched by each individual plant, and it is transferred so frequently we cannot see at the present time any method of automatically regulating frequency control. On our system we have relatively complicated operation, but we endeavor to maintain a time control within a few seconds on standard Western Union or observatory time. So far, we have been successful in doing this.

It is doubtful whether any automatic frequency control could be developed which would be fully applicable to our system.

FSP-51-31

Refractories Service Conditions in Furnaces Burning Anthracite on Traveling-Grate Stokers[1]

Progress Report of the A.S.M.E. Special Research Committee on Boiler Furnace Refractories

By R. A. SHERMAN,[2] EDMUND TAYLOR,[3] and H. S. KARCH,[3] PITTSBURGH, PA.

THIS report presents data which pertain to furnace conditions that affect the life of refractories in furnaces burning anthracite on traveling-grate stokers. The investigation, which was made at the Nanticoke, Pennsylvania, power plant of the Glen Alden Coal Co., is the last of a series of nine in the study of service conditions that govern the life of refractories in boiler furnaces conducted by the Bureau of Mines in cooperation with the Special Research Committee on Boiler-Furnace Refractories of The American Society of Mechanical Engineers. The study of the properties of refractories which affect their life is being continued by the Bureau of Standards and the University of Illinois. A list of the previously published reports of the field investigation is appended to this report.

The size of anthracite now burned in power plants is largely buckwheat and smaller, or that passing a $^{9}/_{16}$-in. round-hole screen. It is generally burned on forced-draft, traveling-grate stokers. A front arch is placed over the stoker to secure and maintain ignition of the coal, and a rear arch is provided in modern design to bring the excess air, which comes through the back of the fuel bed, forward to mix with and burn the combustible gases from the front of the fuel bed. In order to obtain complete combustion of the small particles of fuel it is desirable to maintain such pressures in the air compartments under the rear arch that will lift the coal from the grate; it is then carried forward in the current of gas passing toward the front of the furnace under the arch and again deposited on the grate, so that it is kept in the furnace for a longer time and more complete combustion is obtained.

Although the ash content of the small sizes of anthracite may be as high as 20 or 25 per cent, its softening temperature is also generally high, and normally little difficulty is occasioned by the formation of slags which erode the refractories or adhere to the boiler tubes. The life of the refractories used to line these furnaces is therefore relatively long normally, and failure results more from general weakening of the wall structure and, to some extent, from spalling rather than from slag erosion. However, the operators of this plant reported and inspection showed that erosion by slag was a cause of failure of refractories of equal importance to spalling or structural weakness, and that the accumulation of slag on the exposed boiler tubes was a source of considerable difficulty in the operation of the furnace and boilers.

OBJECT AND SCOPE OF INVESTIGATION

The general object of this investigation was to obtain data on the service conditions which govern the life of refractories in these furnaces, and in particular to study the nature of the slag action. The conditions investigated were:

1 Temperature of furnace gas
2 Composition of furnace gas
3 Velocity of furnace gas
4 Temperatures of refractories
5 Amount and composition of the solids carried in the furnace gas.

Data were obtained on these conditions over the full range of boiler load with the furnace as originally designed and built.

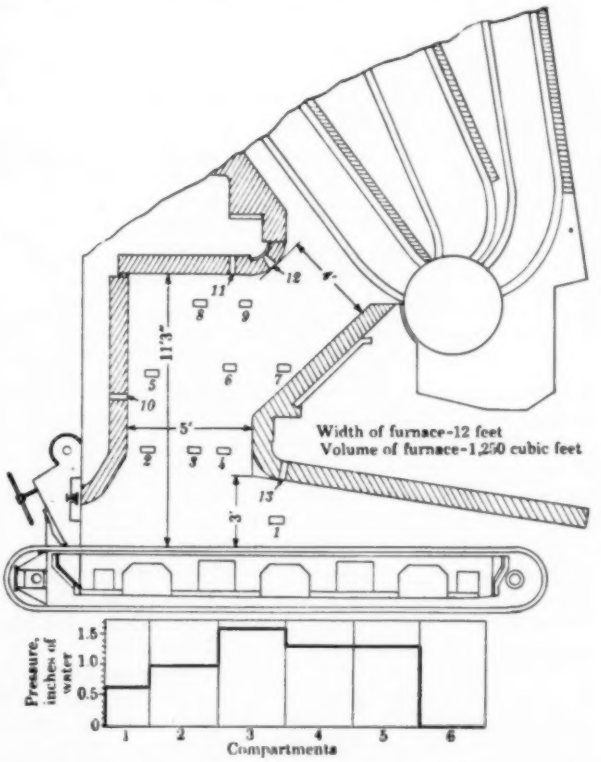

FIG. 1 SECTION OF FURNACE SHOWING PRINCIPAL DIMENSIONS, LOCATION OF BRICKS CONTAINING THERMOCOUPLES, AND TYPICAL DISTRIBUTION OF AIR PRESSURES. FURNACE BURNING ANTHRACITE ON TRAVELING-GRATE STOKER, NANTICOKE, PA.

The company engineers then decided to make a change in the front arch; after this change was made data were taken at one boiler load.

PARTICULARS OF FURNACE

The steam demands of this plant, which furnished power to several collieries of the Glen Alden Coal Co., were supplied by 25 boilers; 20 were horizontal, straight-tube boilers, each with 3030 sq. ft. of heating surface; 5 were inclined, bent-tube boilers, each with 6680 sq. ft. of heating surface.

This investigation was carried on in the furnace of one of the

[1] Published by permission of the Director, U. S. Bureau of Mines. (Not subject to copyright.)

[2] Fuel Engineer, Pittsburgh Experiment Station, Bureau of Mines.

[3] Assistant Fuel Engineer, Pittsburgh Experiment Station, Bureau of Mines.

larger boilers, known in the station as No. 25. Fig. 1 shows a side sectional elevation of the furnace and gives the principal dimensions. The numbered rectangles on the figure mark the position of the bricks in which temperatures were measured.

The design of this furnace differed from others burning small size of anthracite in that the front arch was at a considerable height above the grate. The front and rear arches were of the

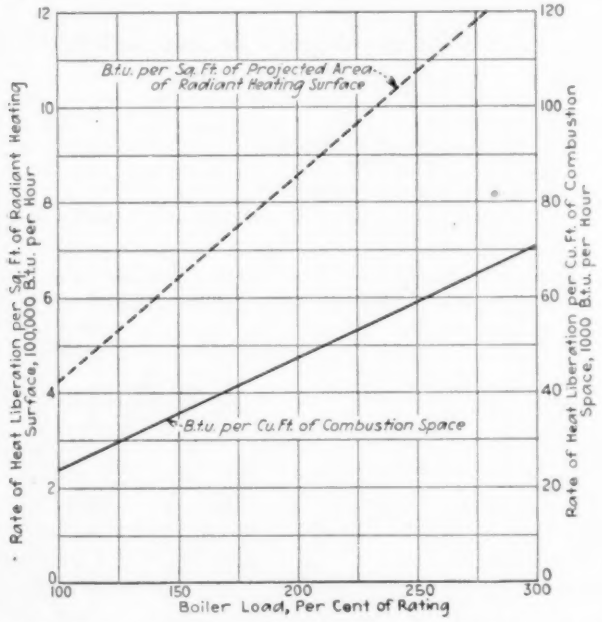

FIG. 2 RELATION OF BOILER LOAD IN PERCENTAGE OF RATING TO RATE OF HEAT LIBERATION, FURNACE BURNING ANTHRACITE ON TRAVELING-GRATE STOKER, NANTICOKE, PA.

flat suspended type; the front wall was of the sectional supported construction in which each section, $10^1/_2$ by 30 in., was independently supported on vertical iron hangers. The tiles in the arches and front wall were 10 in. in thickness, with no covering or insulation on the outside. The total thickness of the side walls was 27 in., of which 18 in. were of firebrick and the remainder face brick. The lining for the first three courses above the grate line was of silicon carbide bricks. There was no air or water cooling in the furnace other than the exposed boiler tubes whose projected area, computed as all that which could "see" any part of the furnace or fuel bed, was 68 sq. ft.

The stoker was fitted with six air compartments in which the air pressure could be separately controlled. The graph in the lower part of Fig. 1 shows a typical distribution of air pressure in the compartments when the boiler was operating at 200 per cent of rating. The area of air space in the grate was about 5 per cent of the total grate area. The normal depth of fuel bed carried was 4 in.

THE COAL BURNED

The coal burned at this plant was from the several collieries of the Glen Alden Coal Co. in Luzerne County, Pennsylvania. As more coal was received from the Truesdale than from the other collieries, this coal was burned during the investigation in the furnace tested except on a few days when none was available.

The size of the coal burned was known as buckwheat No. 4, or barley No. 2, which is that passing through a $^3/_{32}$-in. round-hole screen. Table 1 gives the proximate and ultimate analyses, and calorific value of a composite of a number of samples of this coal on the moisture-free basis, and the range of ash softening temperatures.

PRESENTATION OF RESULTS

The plan for this investigation was to obtain data at three specified boiler loads. It was found difficult, however, to fix the boiler output at a given value and maintain it constant long enough to secure the desired data. The inability to maintain a constant given load was due to rapid changes in the fuel bed which were beyond the control of the fireman. Therefore data were obtained at a number of different boiler loads, and no attempt has been made to present the results individually, but they are arranged and presented in the curves and tables according to three rating bands, 120–150, 175–200, and 210–225 per cent of rating. The corresponding range of rate of heat liberation per cubic foot of combustion space is also indicated on figures. As it may be desired to compare conditions on the basis of the rate of heat liberation per square foot of exposed radiant heating surface, Fig. 2 shows the relation of the boiler load in percentage of rating to this rate and also to the rate of heat liberation per cubic foot of combustion space.

TEMPERATURE OF FURNACE GAS

Fig. 3 shows the temperature of the furnace gas at 6 in. and 36 in. from the side wall at each of the 11 positions of sampling and for the three ranges of boiler load. The positions are indicated by the numbered circles on the outline of the furnace. The temperatures for positions 2 to 10 are presented graphically; those for 1 and 11 are indicated numerically near the circles which mark the positions. From two to five determinations were made in each range of rating, and all are presented.

There was considerable variation among separate determinations at the same position and similar rating, which was to be expected because of the frequent changes in the condition of the fuel bed. Although the coal gate was set to give a 4-in. depth of coal, accumulation of slag on the gate caused variation of the depth; the coal which was carried from the grate at the rear and toward the front by the air blast built up in hummocks on the grate in no consistent or regular order, and holes were sometimes temporarily blown in the fuel bed. Because of these changes in the fuel bed the distribution of the air pressure in the various compartments was sometimes adjusted by the fireman. An attempt was made to correlate the compartment pressures with the temperatures and other data, but it appeared that the variations in other conditions were so great as to mask the effect of the difference in the air distribution under the grate.

The lowest temperature measured in the furnace was 1280 deg. at 6 in. from the wall at position 1, under the rear arch, at the lowest rating, although another determination at the same position and similar rating gave 2330 deg. The highest temperature

measured in the furnace was 2900 deg., which occurred at 36 in. from the wall at position 10, at the rear of the front arch, at both the medium and high ratings, and at position 11, at the nose of the front arch, at the high rating.

The temperatures increased, in general, with increasing height above the grates, but the difference decreased with increase in rating, and the temperatures were quite uniform at the 7 upper positions at the highest range of rating.

The average temperature at position 4, at the nose of the arch, was lower at 6 than at 36 inches from the wall by from 150 to 250 deg., and for most of the other positions the temperatures were somewhat lower at 6 in. from the wall.

Composition of Furnace Gas

Fig. 4 presents the composition of the furnace gas at the 11 positions of sampling for distances of 6 in. and 36 in. from the side wall and for the three ranges of boiler load; they are shown in the same form as were the temperatures in Fig. 3. The nonuniformity of the fuel bed caused a similar lack of uniformity in separate determinations of the composition for one position and rating as of the temperature of the gas.

At the front wall, the CO_2 content was normally high, up to 16 per cent; CO and H_2 were found at all positions at both 6 in. and 36 in. from the side wall and the amounts were greater at ratings above 175 per cent than at 120 to 150 per cent. Toward the rear of the furnace, positions 4, 7, and 10, at 6 in. from the wall the CO_2 was normally somewhat lower than at the front wall and no CO or H_2 was found; at the same positions at 36 in. from the side wall, although the CO_2 in most samples was higher than at 6 in., CO and H_2 were found in only one sample, which was from position 7 at the highest range of rating. Between the front and rear of the furnace, positions 3, 6, and 9, CO and H_2 were found in most of the samples at both 6 in. and 36 in. from the side wall, but the content was, in general, less than at the front wall. Under the rear arch, position 1, appreciable amounts of CO and H_2 were found in only one of the samples taken at 6 in. from the sidewall, but were found in all samples at 36 in. from the wall. At the nose of the front arch where the gas was leaving the furnace, position 11, CO and H_2 were found in but 4 of the 13 samples taken; the maximum total content of the two gases in one sample was 1.6 per cent with 16.1 per cent CO_2. The maximum CO_2 content found without CO or H_2 was 14.6 per cent.

These results indicate that the gases directly above the fuel bed from the front wall to at least the rear arch contained considerable amounts of CO and H_2. Air for their combustion came

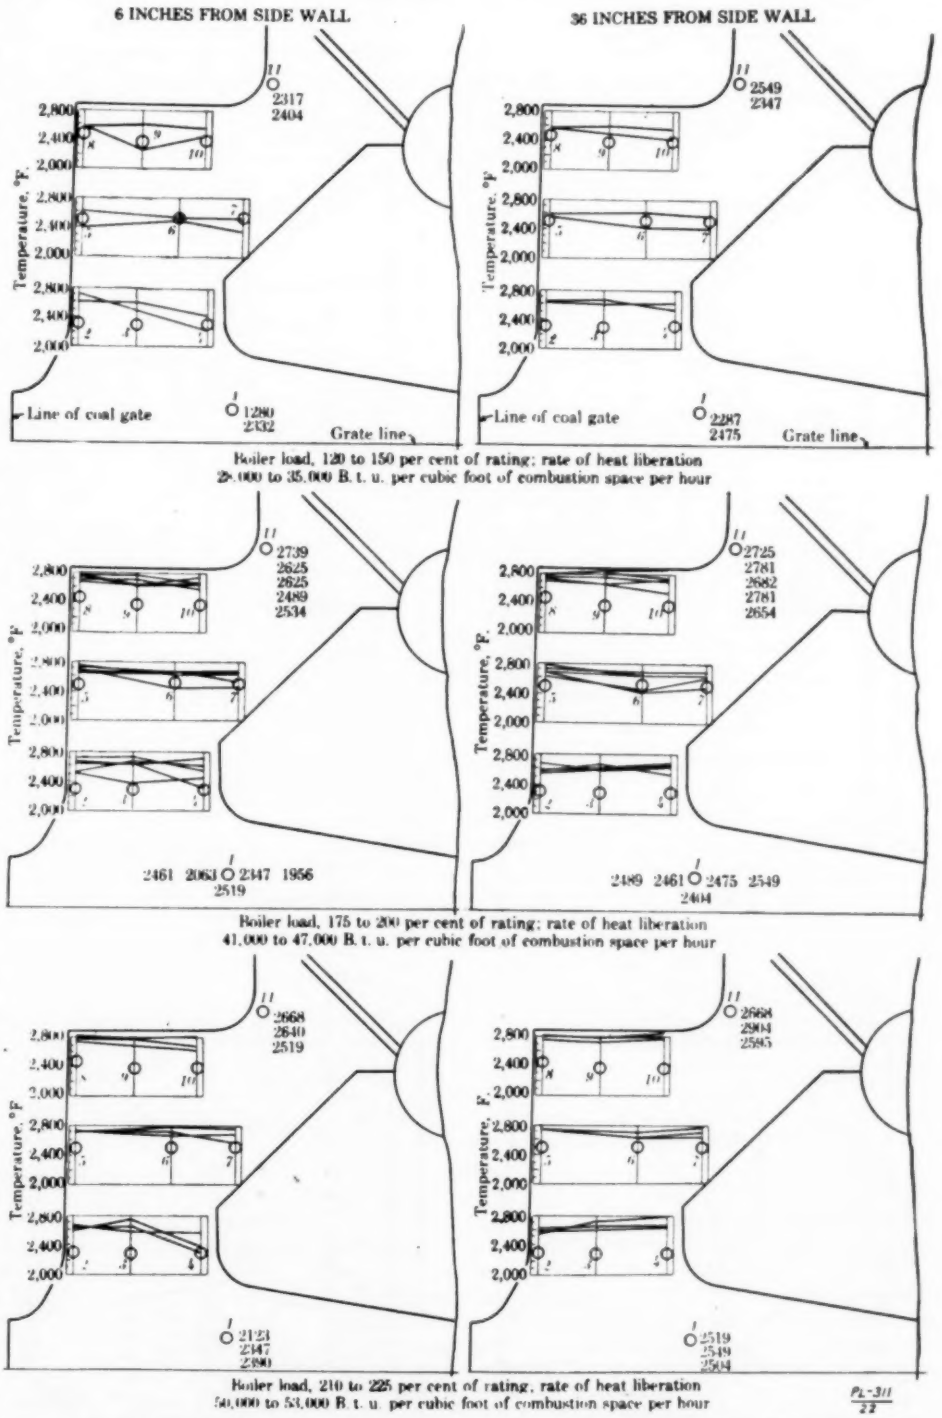

Fig. 3 Temperature of Furnace Gas at 6 In. and 36 In. From the Side Wall at Varying Boiler Loads, Furnace Burning Anthracite on Traveling-Grate Stoker

principally from the rear of the grate, and at the nose of the rear arch no CO or H_2 was found. The air reached to the middle of the throat as the combustible content of the gas was less there than at the front wall, but some combustible remained unburned up to the arch at the front wall; the amount of combustible increased with the rating. Hence the front wall and part of the side walls were in a reducing atmosphere most of the time.

Sulphur Content of Furnace Gas

The sulphur content of the furnace gas, calculated to SO_2, was determined at 6 in. from the side wall at four positions, 3, 6, 10, and 11, at boiler loads of from 140 to 235 per cent of rating. A total of 26 determinations was made. The results varied from 0.024 to 0.088 gram SO_2 per cubic foot or from 0.03 to 0.12 per cent SO_2 by volume, with no relation to position or rating.

The ratio of SO_2 to the total carbon in the gas as computed from its analysis varied from 0.012 to 0.031 and the average ratio for the 26 determinations was 0.022. The ratio of SO_2 to carbon, calculated from the coal analysis, is 0.033. Therefore 67 per cent of the sulphur of the coal was found in the gas at the points of measurement.

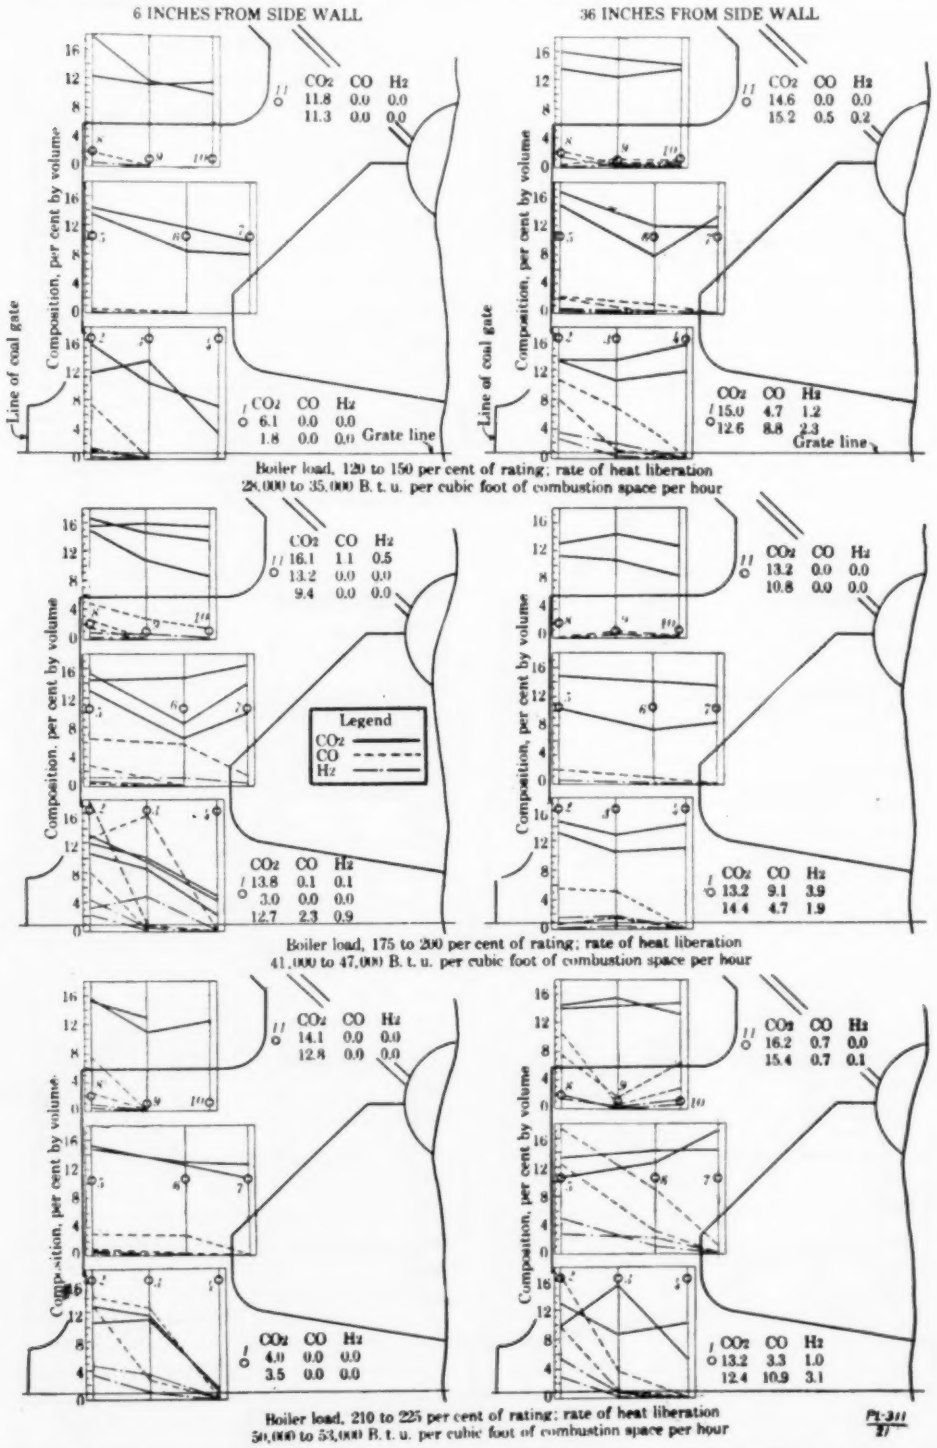

Fig. 4 Composition of Furnace Gas at 6 In. and 36 In. From the Side Wall at Varying Boiler Loads, Furnace Burning Anthracite on Traveling-Grate Stoker

Velocity of Furnace Gas

The velocity at which the gas passes through the furnace determines the amount of ash which will be carried to be deposited on the walls. The velocity was determined at each of the 11 positions in the furnace and at several different boiler loads. Fig. 5 shows typical values obtained at 6 in. and 36 in. from the side wall at a boiler load of 200 per cent of rating. The velocities in feet per second are indicated near the circles which mark the positions. The shading is introduced with its density varied approximately as the velocity in order to assist in the visualization of the path and relative velocity of the gas.

Considering first the velocities at 36 in. from the side wall, that at position 1, under the rear arch, was relatively high, 45 ft. per sec., because this was over the compartment in which the highest air pressure was carried. The velocity was low at the nose of the rear arch; it was approximately the same at the middle of the throat, position 3, as under the arch. The velocities at positions 6, 10, and 11 were of similar order and were higher than at the front or rear of the furnace, which indicates that the main body of gas passed to the furnace outlet in a relatively narrow path at high velocity. The maximum velocity of 50 ft. per sec. was found at the nose of the front arch.

The velocities at 6 in. were of similar order to those at 36 in. from the wall. The principal differences were in a lower velocity

under the rear arch and a higher velocity at the nose of the rear arch. The velocity at both these positions may have been affected by the accumulation of slag on the wall. It is also probable that the measurements made at positions 2, 5, and 8 were affected by their proximity to the front wall; eddy currents were set up, and the direction of flow indicated by the pitot tube was often variable.

Temperature of Refractories

The temperatures of the refractories were measured by means of thermocouples placed in bricks in various parts of the walls and arches. The numbered rectangles in Fig. 1 mark the position of the bricks, of which there was a total of 13; 9 in the side wall, 1 in the front wall, 2 in the front arch, and 1 in the rear arch.

Figs. 6, 7, and 8 show the temperatures measured in six of the bricks over several days of operation; hourly readings are plotted.

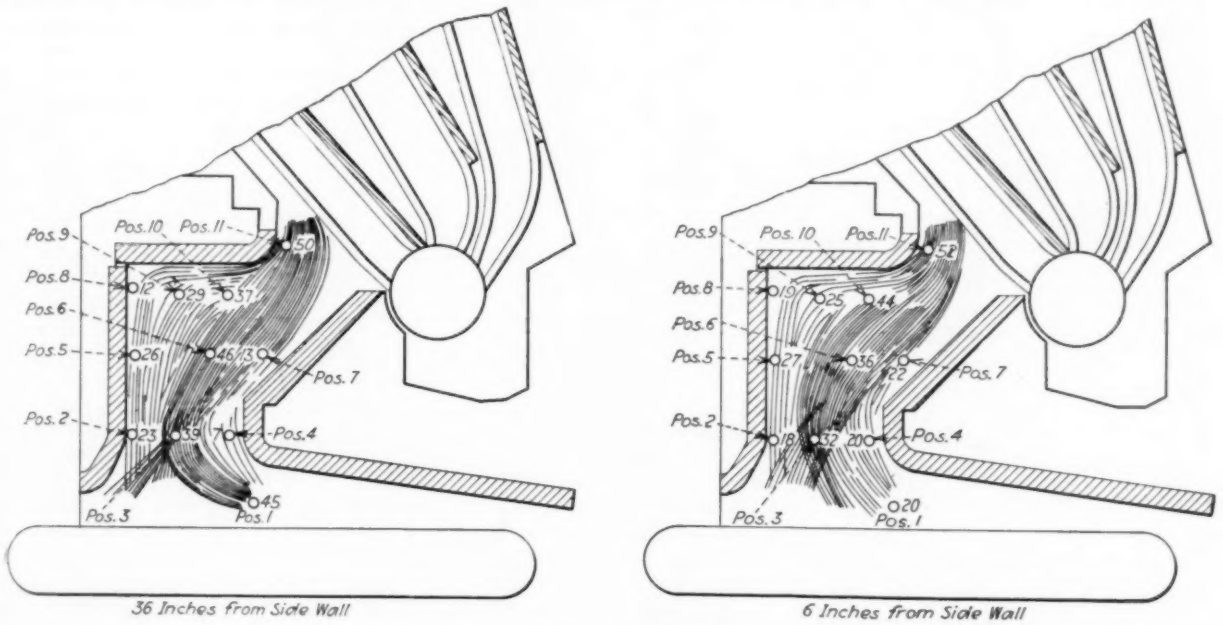

Fig. 5 Velocity of Furnace Gas in Feet per Second, Boiler Load 200 Per Cent of Rating, Furnace Burning Anthracite on Traveling-Grate Stoker

The curve in the upper part of the figures shows the boiler load in percentage of rating, as read on the scale at the left, or the rate of heat liberation in B.t.u. per hour per cubic foot of combustion space as read on the scale at the right.

A low fire, the boiler not steaming, was maintained for 45 hours because there was a relatively large area of new brickwork in the furnace. During this period the temperatures fluctuated widely owing to changes in the low fire carried; the maximum temperature attained at $\frac{1}{2}$ in. from the hot face of any of the bricks was less than 1100 deg.

Following the heating-up period the temperatures were measured over five days of normal operation of the boiler during which it steamed at about 200 per cent of rating and was banked for five hours on one night. The rate of steaming was subject to frequent changes of from 10 to 20 per cent and these changes were reflected in the variations of the temperature of the refractories.

The temperature at 1 in. from the hot face of brick No. 1, in the side wall under the rear arch, which is shown as curve 1-B in Fig. 6, was subject to the most frequent and widest variations. It has been shown that the two determinations of the temperature of the furnace gas at this position were widely different. The temperatures at 3 in. and 6 in. from the surface of this brick, curves 1-C and 1-D, respectively, decreased after the period of banking, although the rate of steaming was, on the average, higher than before. This was undoubtedly due to the insulating effect of an accumulation of slag upon the surface.

After the banking period the temperatures at all points shown in the curves, except 1-C and 1-D, gradually increased through the remaining period of observation. As the average load carried on the boiler did not increase, it would be expected that the temperatures at $\frac{1}{2}$ in. from the face of the bricks would have reached a steady state in less than this time. It is probable that this increase in the temperature of the refractories was due to decrease in the rate of heat absorption from the furnace by the exposed boiler tubes because of the accumulation of slag upon them.

The temperatures at $\frac{1}{2}$ in. from the surface of brick No. 6, in the side wall above the throat of the furnace, and of brick No. 11, in the front arch, shown in Fig. 7, and of brick No. 5, in the side wall, and brick No. 10, in the front wall, shown in Fig. 8, were quite similar during the entire period of observation. The highest temperature measured in any of these bricks was approximately 2600 deg. at $\frac{1}{2}$ in. from the hot face.

Fig. 9 shows the temperature gradients through four of the bricks at 88 hours after lighting the fires when the boiler was operating at 200 per cent of rating or at a rate of heat liberation of 47,000 B.t.u. per cubic foot of combustion space per hour. The temperatures at the surface were obtained by extrapolation of the curves as indicated by the dotted lines. At this time the surface temperatures of the four bricks lay between 2530 and 2600 deg. This uniformity of temperature of the refractories in different parts of the walls above the throat of the furnace was as to be expected from the uniformity of the gas temperatures in this zone.

The gradient through brick No. 10, which was in the front wall, was steeper than through the other bricks which were in the side wall because the front wall was but 10 in., whereas the side wall was 27 in. in thickness.

Quantity of Solids Carried in the Gases

The weight of the solids carried per cubic foot of gas was de-

termined at 6 in. from the side wall at four positions, 3, 6, 10, and 11. Table 2 presents the average results for from 3 to 6 determinations at each of the positions at 200 per cent of rating. The combustible in the sample was assumed to be and is reported as carbon.

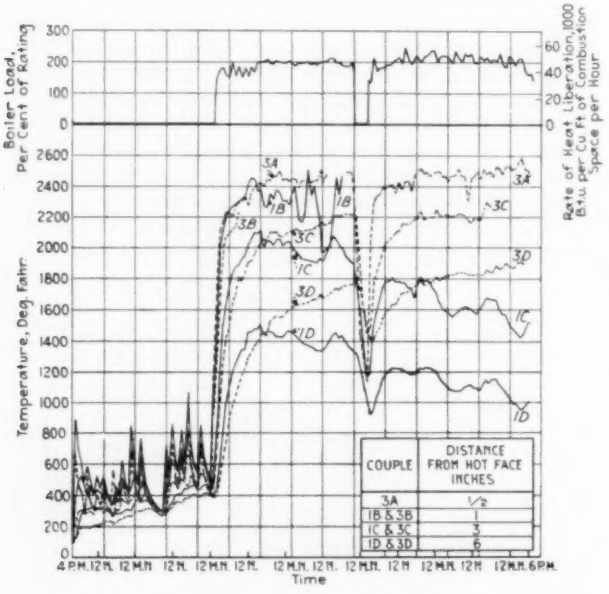

FIG. 6 TIME-TEMPERATURE CURVES IN BRICKS IN SIDE WALL, ANTHRACITE FURNACE, NANTICOKE, PA.

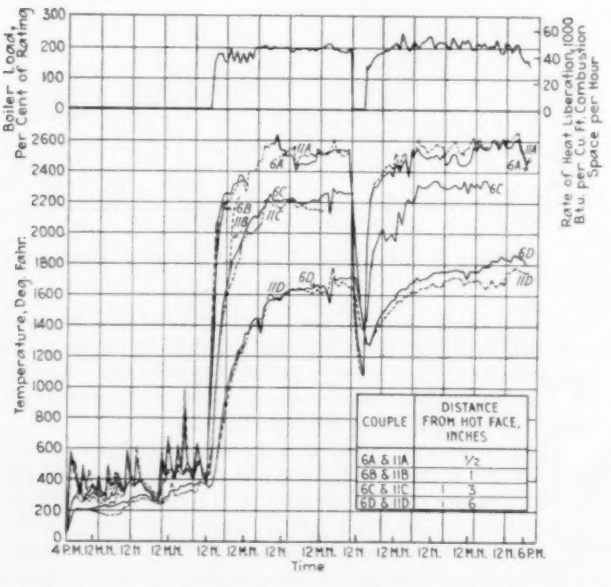

FIG. 7 TIME-TEMPERATURE CURVES IN BRICKS IN SIDE WALL AND FRONT ARCH, ANTHRACITE FURNACE, NANTICOKE, PA.

The weight of solids carried did not decrease with increasing distance from the grate, as might be expected because of particles settling out of the gas stream. Calculation from the equation developed by Blizard[4] from an analysis of Audibert's[5] experimental data on the carrying power of gases for solids shows that gas moving at a velocity of more than 15 ft. per sec. will carry upward particles of anthracite of density 1.5 and of a mean diameter of $^1/_8$ in. or less. As the velocity of the gas at these positions and this rating was not less than 30 ft. per sec., and as all the coal particles were less than $^1/_8$ in. in diameter, any particles which rose from the grate into the stream of gas would be carried and would not be deposited except as thrown out on change of direction of the gas flow. Because some of the ash sintered together on the grates to form large pieces, the amount of ash actually carried out was not as great as would be indicated by this calculation.

It is interesting to note that the percentage of carbon in the sample at the furnace outlet, position 11, 12 ft. from the grates, was not less than at position 3, 4 ft. from the grates, as would be expected if they were in the same stream of gas. There was evidently little combustion of solid carbon in this distance of travel. These values were confirmed by the composition of the dusts taken from the bottom of the second and third pass of the boiler, both of which contained 87 to 88 per cent of combustible.

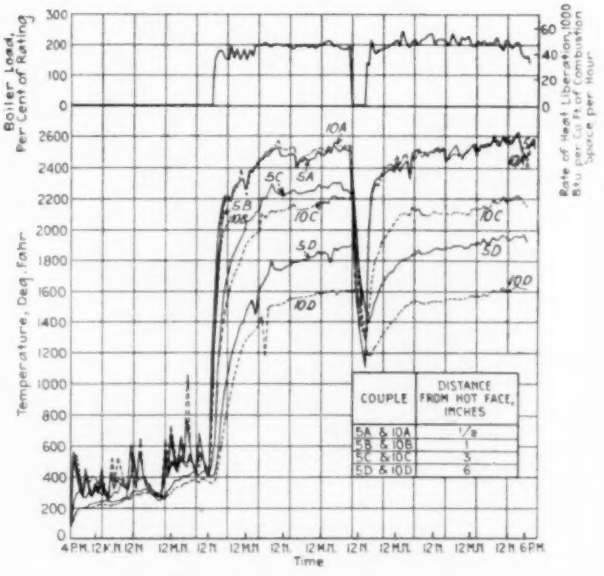

FIG. 8 TIME-TEMPERATURE CURVES IN BRICKS IN SIDE AND FRONT WALLS, ANTHRACITE FURNACE, NANTICOKE, PA.

It is also worthy of note that the dust which passed out of the furnace contained more carbon and less ash than the coal fired to the furnace. The action of the air blast on the coal on the grate was in the nature of a washing process, in which the lighter coal particles were carried by the gas and the heavier slate particles and those fused or sintered together remained on the grate.

The last column but one of Table 2 gives the solid carbon which was carried in the gas stream as a percentage of the total

TABLE 2 AMOUNT AND COMPOSITION OF SOLIDS CARRIED IN THE GAS AT 6 IN. FROM THE SIDE WALL AT 200 PER CENT OF RATING, FURNACE BURNING ANTHRACITE ON TRAVELING-GRATE STOKER

Position	Wt. per cu. ft. of gas, gram		Percentage composition of sample		Carbon, percentage of total carbon(a)	Ash, percentage of total ash(b)
	Carbon	Ash	Carbon	Ash		
3	0.424	0.072	85.3	14.7	16	10
6	0.725	0.106	87.3	12.7	30	16
10	0.228	0.045	83.9	16.1	12	9
11	0.481	0.069	86.8	13.2	21	11

(a) Total carbon is sum of gaseous and solid carbon.
(b) Total ash is that ash which should accompany carbon based on ratio of carbon to ash in coal.

[4] "The Terminal Velocity of Particles of Powdered Coal Falling in Air or Other Viscous Fluid." *Journal of the Franklin Institute*, vol. 197, 1924, p. 199.

[5] "Study of the Entrainment of Powder by an Air Current." *Annales des Mines*, 12th Series, vol. 1, 1922, p. 153.

carbon in the gas, that is, the solid carbon plus that as CO_2 and CO. This ranged from 12 to 30 per cent; at the furnace outlet, position 11, it was 21 per cent.

The last column gives the ash as a percentage of the ash which should accompany the total carbon in the gas on the basis of the ratio of ash to carbon in the coal. From 9 to 16 per cent of the ash fired to the furnace was found in the gas at the points of sampling, and the remainder stayed on the grates.

These samples were taken at only 6 in. from the wall and cannot therefore be definitely taken as representative, but they are indicative of conditions over the entire furnace, and calculations based on these results are of interest. The ash in the gas at position 11 was 11 per cent of the total ash fired to the furnace; the content of ash in the coal on the dry basis was 20.1 per cent. Therefore, the ash carried in the gas was $11 \times 20.1 = 2.2$ per cent of the coal fired. The percentages of carbon and ash at this position were 86.8 and 13.2, respectively. Therefore the carbon was $2.2 \times 86.8/13.2 = 14.5$ per cent of the coal fired. The total material carried in the gas was $14.5 + 2.2 = 16.7$ per cent of the coal fired to the furnace. Because of the high content of combustible this constituted a considerable loss, but a part of this was recovered in these furnaces by returning the dust which collected in the bottom of the second pass to the furnace by gravity through metal chutes.

Composition of Coal Ash and Slag

Table 3 gives the composition and softening temperatures of samples of coal ash, dusts from the furnace gases, and slags from various parts of the furnace.

The first analysis is that of a composite sample of the ash of Truesdale coal which was burned during the tests. The total flux content, the constituents other than silica and alumina, was 17.4 per cent, and the softening temperatures of the ash, as determined on separate samples, varied from 2380 to 2570 deg. Samples 2 and 3 were coals from the Pettibone and Hallstead collieries which were also burned in the plant. Their flux content was 15.1 and 11 per cent, and the softening temperatures of the ash were from 2610 to 2700 and from 2750 to 2810, respectively. The principal difference between the flux content of these two coals and of the Truesdale coal was in the lime content. Although the Hallstead coal would normally be judged as the best of the three coals because of the low flux content and high softening temperature of its ash, it gave the most trouble in the fuel bed, apparently because of clinker formation. As it was not reported to give either more or less trouble from slagging of the refractories, no further analysis of the reason for the action of this coal was attempted.

Sample 4 is the ash of coal burned at the Hunlock Creek station of the Luzerne County Gas and Electric Co., where very little difficulty with slagging or other failure of refractories was reported. The total flux content and the percentage of the various fluxes were very similar to those of the Pettibone coal ash; the content of alumina was somewhat higher than that of any of the three coals from the Nanticoke plant.

Samples 5 to 8, inclusive, are composites of the dust collected from the furnace gases, at positions 3, 6, 10, and 11. Their flux content varied from 18.8 to 20 per cent, which was greater than that of the coal ash; the principal difference was in the somewhat greater content of Fe_2O_3; however, the content of CaO was lower than in the coal ash.

Sample 9, taken from the exposed boiler tubes, was slag whose composition would be expected to be similar to that of the dust carried in the gases. However, its composition was more nearly like that of the Truesdale coal ash, although it was not from the burning of this coal only because, as previously stated, it was occasionally necessary to burn coal from other collieries in this furnace.

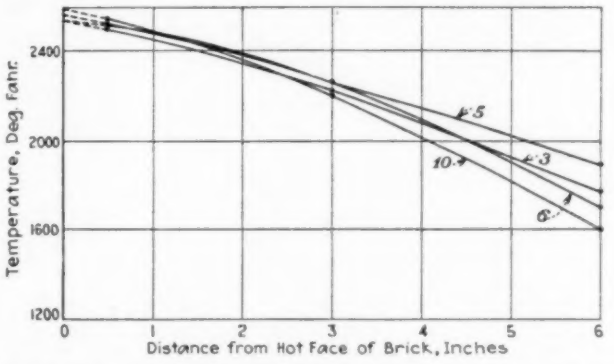

Fig. 9 Temperature Gradient Through Bricks in Walls of Anthracite Furnace at Nanticoke, Pa., 88 Hours After Lighting Fires, Boiler Load 200 Per Cent of Rating, Rate of Heat Liberation 47,000 B.t.u. per Hr. per Cu. Ft. of Combustion Space

Samples 10 and 11 were dusts from the second and third pass; these represented the burning of Truesdale coal only. The content of both the Fe_2O_3 and CaO in the dusts was greater, and the total flux content was about 5 per cent greater, than in the dusts collected from the furnace gases. The material at the bottom of the passes was probably the heavier particles of the dust which were deposited from the gas stream as it changed direction on passing around the baffles.

The content of SiO_2 and Al_2O_3 in the ash from the ashpit, sample 12, differed slightly from that of the coal ash, but the content of the several fluxes and the total flux content was practically the same as of the ash of the coal fired to the furnace.

Sample 13 is that of the dust from the rear door of the furnace which consisted of the small, light particles which rose from the ashpit and grate as the ash fell from the grate; it was largely the unfused or slightly sintered portions. The content of SiO_2 was 7 per cent less, the Al_2O_3 content 7 per cent more, the Fe_2O_3

TABLE 3 COMPOSITION AND SOFTENING TEMPERATURE OF COAL ASH, DUST, AND SLAG SAMPLES, FURNACE BURNING ANTHRACITE ON TRAVELING-GRATE STOKER

Sample number	Description of sample	Composition, per cent: SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	Na_2O(a) K_2O	$\frac{SiO_2}{Al_2O_3}$ ratio	Softening temp., deg.	Softening interval, deg.	Fluid interval, deg.

(a) Alkalis by difference.

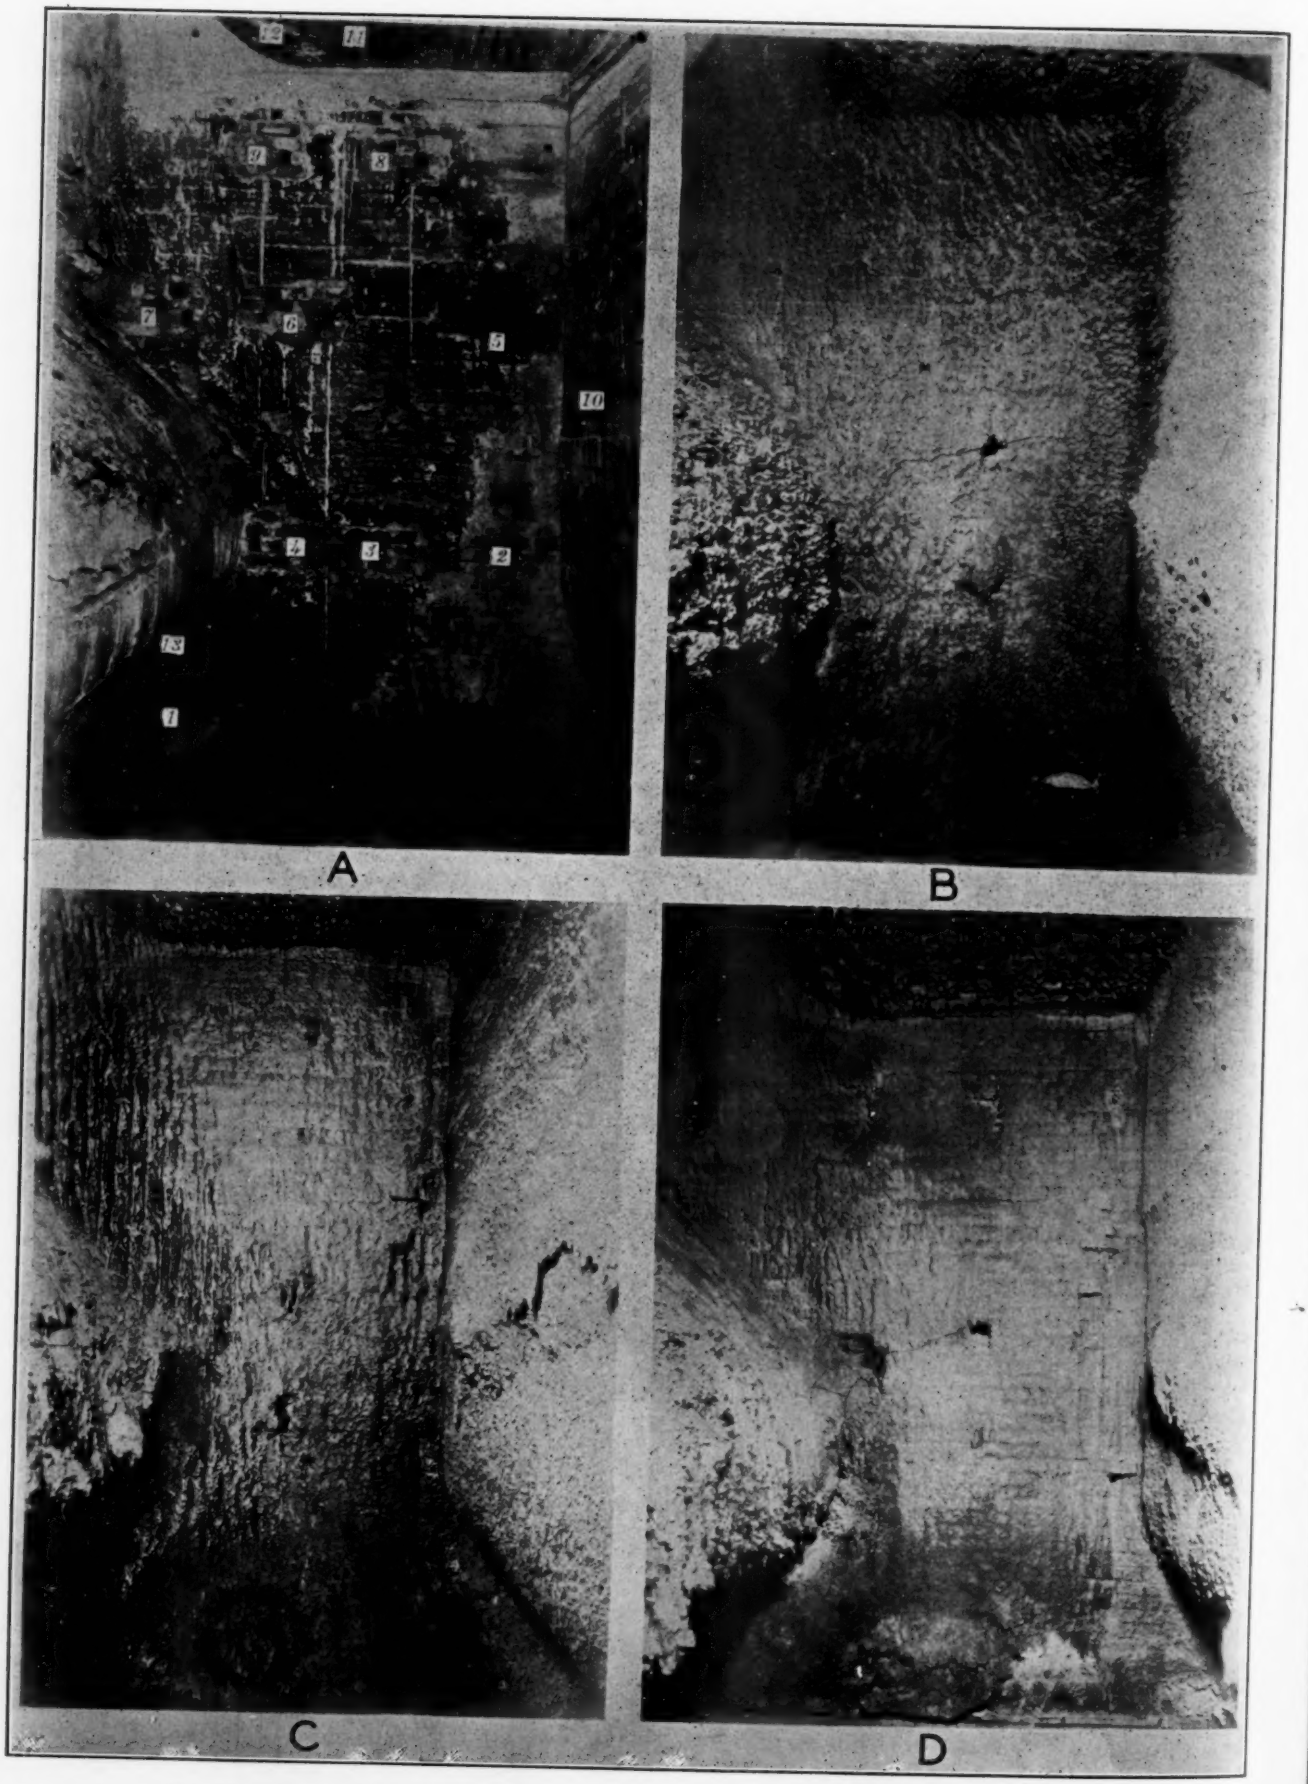

FIG. 10 VIEWS OF INTERIOR OF FURNACE BURNING ANTHRACITE ON TRAVELING-GRATE STOKER

content 1 per cent more, and the lime content 1.5 per cent less than in the ash from the ashpit. The softening temperature of this dust was 2700 deg., 130 deg. higher than the highest for a sample of the Truesdale coal ash.

The softening temperature of the dust from the passes and the slag from the boiler tubes was lower than that of the coal ash. The softening temperatures of eight samples of slag taken from the side walls, arches, coal gate, and front wall of the furnace ranged from 2190 to 2330 deg., all lower than the lowest softening temperature of the coal ash; this is as has been found in other furnaces investigated.

The SiO_2/Al_2O_3 ratio in the Truesdale coal ash was 1.95; it was lower in the dust and slag samples, ranging from 1.47 to 1.71; and it was 2.2, somewhat greater, in the ash from the ashpit. Therefore a somewhat greater percentage of alumina than silica left the grates.

Refractories Service

View A in Fig. 10 shows the side wall and portions of the front wall, front arch, and rear arch at the time the tests were started. The front arch and the nose of the rear arch had just been rebuilt for the second time since the furnace went into service 12 months before. The side wall had been rebuilt once and was still in good condition except for the arch of the observation door which was rebuilt. The patches of new brickwork in the side wall surround the bricks in which thermocouples were placed to measure the temperature of the wall. These bricks are numbered in the photograph as in Fig. 1. The holes in the side wall for the sampling of gases and the measurement of temperature may also be seen.

The tiles in the arches and front wall were hand made of Pennsylvania clay; the inner 9-in. lining of the side walls was of Georgia kaolin, the next 8 in. were of Pennsylvania bricks, and the remainder of buff face bricks. The bricks in which thermocouples were placed and those surrounding them were of Pennsylvania clay. The first three courses above the grate were of silicon carbide bricks. Several silicon-carbide bricks were also placed in other parts of the furnace for this run.

Views B, C, and D in Fig. 10 show the furnace at the end of two, four, and ten weeks of service, respectively, during which the boiler steamed at an average rating of approximately 190 per cent. After the first two weeks of service, view B, the front wall, and the nose of the rear arch were covered with a layer of friable, granular ash. This layer had a maximum thickness of 7 in. on the front wall at about 4 ft. above the grate. This was evidently the coal and ash which were thrown from the stream of gas from under the rear arch as it changed direction to pass up toward the tubes.

The heavy accumulation of slag on the lower part of the side wall and on the front wall had been removed before the photograph of view C was taken at the end of four weeks of service. The slag on the side wall was harder and more glassy than before, and congealed streams of slag may be seen on the upper part of the wall above the rear arch.

At the end of a total of 10 weeks of service, view D, the slag, except in the thick deposit on the lower part of the front wall, was relatively thin. The outlines of the individual bricks and tiles may be seen in the photograph. The differences in the appearance of the walls in these three photographs do not necessarily indicate different conditions of service over the entire period of service. The condition of the slag of the walls when the boiler is taken out of service is governed by the conditions of operation the last day, or even the last few hours of steaming.

The most severe erosion of the refractories by slag was in the corners of the side and front walls; the maximum depth of erosion was 2 in. at position 2. Considerable erosion had occurred on the upper part of the front wall, but the lower part had not eroded because of the protection of the accumulation of slag.

A course of bricks may be seen to project from the rest a little more than half-way up the front wall and others project on the side wall; these were the silicon carbide bricks. The maximum loss from these bricks in the 10 weeks of service was $^1/_8$ in. from a brick near position 5.

Considerable loss from spalling had taken place on the front arch; the greatest loss was in the nose blocks. Reference to Fig. 9 shows that the rate or frequency of change of temperature at $^1/_2$ in. from the face of brick No. 11, which was in the front arch, was little if any greater than at the same distance in brick

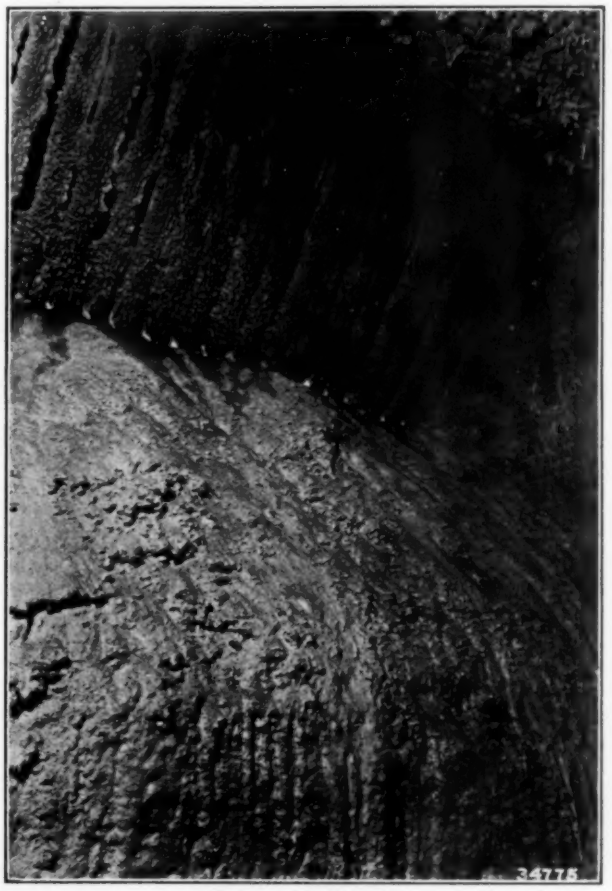

Fig. 11 View of Boiler Tubes With Slag Accumulation, Furnace Burning Anthracite on Traveling-Grate Stoker, Nanticoke, Pa.

No. 6 which was in the side wall where spalling was not a cause of failure. It is probable that pinching was a major cause of the spalling, as many of the blocks were oversize and there was not enough room for expansion.

Fig. 11 shows the boiler tubes at the end of the ten-week period. The tubes were partly cleaned of slag by air pressure through a hand lance once every eight hours and were thoroughly cleaned each time the boiler was down for inspection, which was approximately every two weeks. All of the exposed surface of the tubes was covered with slag and a large portion of the area between adjacent tubes was covered.

Summary of Service Conditions

Although, as has been pointed out, the temperature, composition, and velocity of the furnace gases at any given position and

rating were subject to wide variations due to changes in the fuel bed, the conditions in this furnace may be generally summarized as follows:

The gases arising from the front part of the fuel bed had a high content of CO and H_2. The air for the combustion of these gases came principally from the back of the fuel bed. This air did not penetrate to the front wall, so that this wall and a considerable portion of the side walls were maintained in a reducing atmosphere. Combustion continued throughout the furnace above the throat, and because the area of surface of the boiler tubes exposed for heat absorption was small the heat was absorbed at a lower rate than it was released by combustion; hence the highest temperatures were found in the upper part of the furnace.

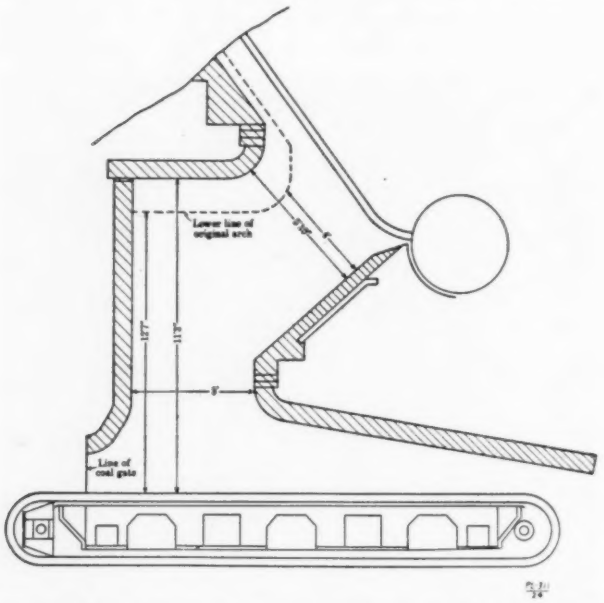

FIG. 12 SIDE SECTIONAL ELEVATION OF FURNACE AFTER FRONT ARCH WAS RAISED, SHOWING LOWER LINE OF ORIGINAL ARCH WITH PRINCIPAL COMPARATIVE DIMENSIONS, FURNACE BURNING ANTHRACITE ON TRAVELING-GRATE STOKER, NANTICOKE, PA.

As the particles of coal were small in size and the gases moved at a high velocity a large amount of coal and ash was carried by the gases to be deposited on the walls, on the tubes, and carried out of the furnace.

As the area of the outlet of the furnace at the boiler tubes was the smallest area in the furnace for the passage of gases, and because the main stream of gases passed upward toward the nose of the arch in the shortest path, the velocity of the gases reached a maximum at the furnace outlet. The high velocity with which the softened particles of ash and slag struck the boiler tubes probably increased their tendency to adhere to the tubes. As the tubes became covered by slag the rate of heat absorption decreased, the temperature in the upper part of the furnace increased, and the slagging of both the refractories and the tubes increased.

The bridging of the slag over the spaces between the tubes increased the pressure drop through the boiler and thus decreased the rate at which the boiler could be operated with the available draft.

COMPARISON WITH CONDITIONS IN OTHER FURNACES BURNING ANTHRACITE

Refractories service conditions have been observed in five other power plants burning the small sizes of anthracite on forced-draft, traveling-grate stokers, although no data were taken as in this furnace. The failure of the refractories in the furnaces of these plants was due to general weakening of the structure after a prolonged period because of repeated expansion and contraction of the walls, and to spalling. Ash was deposited on the refractories in conditions varying from a deposit which could be brushed from the wall with the hand, toi a sintered spongy deposit which adhered rather firmly but whech had not apparently harmed the refractories. Congealed strbams of slag or thin glassy coatings with evidences of erosion by slag were not seen.

The two major differences between the Nanticoke and the other furnaces were the size of the fuel and the design of the furnace.

Whereas the coal burned at the other plants was largely buckwheat No. 3 or barley No. 1, that burned at Nanticoke was almost entirely buckwheat No. 4 and smaller. This difference in the size of the coal may have been an important factor in the difference in the slagging in that a greater amount of material might have been carried in the gases with the smaller size. It was probably not a major factor, however, as there was enough ash on the walls in all furnaces to have caused serious erosion had it been fused.

The designs of the furnaces differed from those at the Nanticoke plant, in that there were front arches over the grates at about the same height as the rear arch. Mixing of the gases and complete combustion was probably accomplished at a greater distance from the boiler tubes, and the furnaces above the throat were exposed to a larger area of boiler tubes so that in the passage of the gases from the throat to the tubes heat was being absorbed faster than it was liberated. Hence it is considered probable that a smaller area of the walls was in a reducing atmosphere, and that the temperatures of the gases and the refractories were not as high as in the Nanticoke furnace.

The softening temperature of the ash of the Truesdale coal which was used in largest amounts at Nanticoke was lower than that of the coal used at the other plants and also than of the other coals at the same plant by from 200 to 300 deg. The operators at Nanticoke did not report, however, that the coals whose ash had high softening temperatures gave less slagging than the Truesdale coal with the ash of low softening temperature. This was probably because the temperatures reached in the furnace at normal boiler loads were well above the softening temperature of the ash of any of the coals.

POSSIBILITIES OF CHANGES

The slagging of the refractories in this furnace might be decreased by decreasing the velocity of the gases, the temperatures, and the content of reducing gases.

It has been stated that calculation, based on available experimental data, shows that a gas velocity of above 15 ft. per sec. will carry upward anthracite particles $^1/_8$ in. in diameter. As all the coal was less than this size and the ash particles still smaller, and as the velocities were well above 15 ft., it would not appear feasible to reduce the velocity by change in furnace design enough to decrease appreciably the amount of solids carried in the gases.

The temperature of the gases in the upper part of the furnace could be reduced by increasing the area of tubes exposed for heat absorption, or by obtaining complete combustion earlier in the path of the gases so that they would have more time for radiation to the absorbing surface.

The area of tubes exposed to radiation could be increased by raising the front arch. This would also serve to decrease the pressure drop through the furnace and boiler, for the area of this section was the least in the furnace. It would also decrease the

mean velocity of the gases at the outlet, but the gases would tend to take the shortest path, and therefore the main stream of gas would pass directly under the nose of the arch as before. Inclination of the arch by raising it more at the nose than at the front wall should also aid in decreasing the temperature of the arch as it would expose the surface at a more favorable angle for radiation to the tubes.

If more complete combustion could be obtained earlier in the path of the gases, the temperature in the upper part of the furnace would be decreased because of the greater time for radiation and also a lesser area of walls would be maintained in a reducing atmosphere. Such mixing as was effected by the high front arch took place so late that little space remained for combustion. Mixing might be effected earlier by a front arch nearer the grate or by the introduction of secondary air in jets at high velocity along the front wall at the height of the nose of the rear arch.

Change Made in the Furnace

It would have been impossible to introduce a front arch near the grate without extensive changes in the furnace. The operators of the plant had previously considered raising the present front arch, and, as the desirability was confirmed by the data taken in this investigation, the change was approved.

Fig. 12 is a side sectional elevation of the furnace after the arch

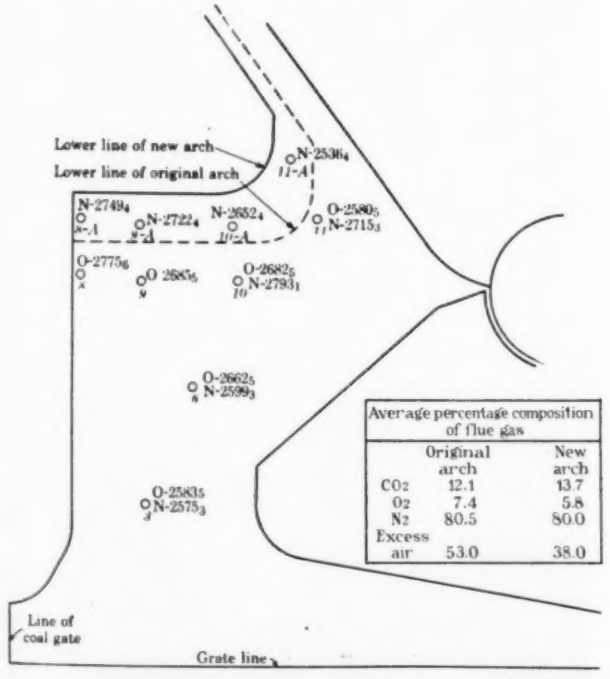

Fig. 13 Temperature of Furnace Gases at 6 In. From Side Wall and After Front Arch Was Raised, Boiler Load 200 Per Cent of Rating, Furnace Burning Anthracite on Traveling-Grate Stoker, Nanticoke, Pa.

(Letter "O" before temperature denotes original arch; letter "N" before temperature denotes new arch; subscript following temperature shows number of determinations averaged.)

was raised and shows the lower line of the original arch in dashed lines and the principal comparative dimensions. The arch was raised 16 in., which made the area of the furnace outlet greater than that of the throat between the front wall and rear arch instead of less as it had been before. The volume of the furnace was now 1380 cu. ft., an increase of 130 cu. ft., and the projected area of boiler tubes was 104 sq. ft., an increase of 36 sq. ft.

Four sampling holes were placed in the side wall at the same position relative to the new arch as the four positions 8 to 11 had to the original arch; these were numbered 8A to 11A. The temperature, composition, and velocity of the gas and the quantity of solids carried in the gas were determined at these and other positions at a boiler load of approximately 200 per cent of rating.

Figs. 13 and 14 show the average temperatures measured at 6 and 36 in., respectively, from the side wall after the arch was

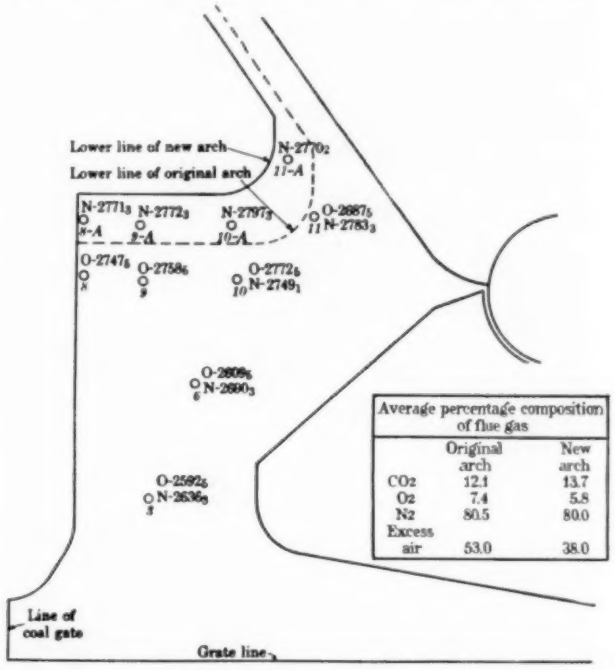

Fig. 14 Temperature of Furnace Gases at 36 In. From Side Wall Before and After Front Arch Was Raised, Boiler Load 200 Per Cent of Rating, Furnace Burning Anthracite on Traveling-Grate Stoker, Nanticoke, Pa.

(Letter "O" before temperature denotes original arch; letter "N" before temperature denotes new arch; subscript following temperature shows number of determinations averaged.)

raised, together with those at similar positions before it was raised. The values for the original arch are prefixed by the letter O, and those for the new arch by the letter N; the subscript denotes the number of determinations averaged.

At 6 in. from the side wall the average temperatures with the new arch were from 63 deg. lower to 135 deg. higher than with the original arch. At 36 in. from the wall, however, the average temperatures at all positions, except position 10 where only one determination was made with the new arch, were from 14 to 101 deg. higher than with the original arch. This was contrary to what was to be expected with the increased area of radiant-heat-absorbing surface. It will be noted, however, that the CO_2 in the stack gas averaged 13.7 per cent, equivalent to 37.5 per cent of excess air, after the arch was raised, whereas it was 12.1 per cent, equivalent to 51 per cent of excess air, before the arch was raised. This difference in excess air was probably enough to account for the differences in temperature found, but enough data are not available to allow an accurate calculation of the temperatures for equal percentages of excess air.

The composition of the gas at the various positions is not shown as it was relatively similar to that before the arch was raised except that the CO_2 content, and likewise the CO content, was generally higher in the furnace as it was in the stack gas. This relatively small change in the height of the arch could scarcely account for the lower excess air; it was more probably due to difference in the manipulation of the fire.

Fig. 15 gives the velocities at the positions under the front arch and at positions 3 and 6 in the lower part of the furnace; the values for the original and new arch are prefixed by the letters O and N, respectively. The velocities in the lower part of the furnace were appreciably lower with the new than with the original arch, which was probably due to a change in the position of the main gas stream with the new arch so that it did not pass the points of measurement. At positions 10 and 11 the velocities were lower with the new arch, but at positions 10A and 11A they were practically the same as at the corresponding positions under the original arch.

These data confirm the expectation that, although the increased height of the arch would decrease the mean velocity of the gases at the outlet of the furnace, it would probably not decrease the velocity at the nose of the arch due to the tendency of the gas to flow out of the furnace in the shortest path.

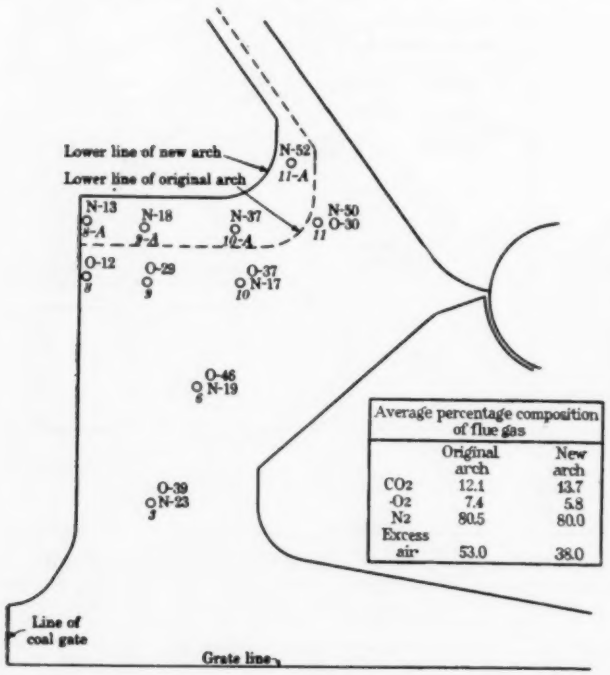

FIG. 15 VELOCITY OF FURNACE GASES IN FEET PER SECOND AT 36 IN. FROM SIDE WALL BEFORE AND AFTER FRONT ARCH WAS RAISED, BOILER LOAD 200 PER CENT OF RATING, FURNACE BURNING ANTHRACITE ON TRAVELING-GRATE STOKER, NANTICOKE, PA.
(Letter "O" before velocity denotes original arch; letter "N" before velocity denotes new arch.)

Table 4 presents the average results of the determination of the solids carried in the gases at positions 11 and 11A with the new arch together with the results at position 11 with the original arch as taken from Table 2; from 4 to 6 determinations at each position were averaged. At position 11 with the new arch, which was at the nose of the original arch, the weight of carbon per cubic foot of gas was greater and the weight of ash was nearly the same as at this position with the original arch; however, the solid carbon as a percentage of the total carbon, and the ash as a percentage of the total ash, were approximately the same with the two arches.

At the nose of the new arch, position 11A, although the percentages of carbon and ash in the sample were not greatly different from those at position 11 with either arch, the weight of both the carbon and ash per cubic foot of gas was about one-third, and the solid carbon and the ash as percentages of the total carbon and ash were about one-half of the values found at position 11. This was not to be expected as the velocity of the gas at 11A was higher than at 11. The probable explanation is that the flow of gas around the nose of the arch after it had been raised was not the same as before, and that the gas passing position 11A was not of the same stream as that passing position 11, but was that which turned upward after passing horizontally under the arch from which a large part of the solids had been deposited either on the arch or by having been thrown out as the stream changed direction.

TABLE 4 AMOUNT AND COMPOSITION OF SOLIDS CARRIED IN THE GAS AT 6 IN. FROM THE SIDE WALL BEFORE AND AFTER THE ARCH WAS RAISED, BOILER LOAD 200 PER CENT OF RATING. FURNACE BURNING ANTHRACITE ON TRAVELING-GRATE STOKER

Position	Arch	Wt. per cu. ft. of gas, gram Carbon	Wt. per cu. ft. of gas, gram Ash	Percentage composition Carbon	Percentage composition Ash	Carbon, percentage of total carbon(a)	Ash, percentage of total ash(b)
11	Original	0.481	0.069	86.8	13.2	21	11
11	New	0.557	0.062	89.8	10.2	26	10
11A	New	0.161	0.023	84.7	15.3	9	5

(a) Total carbon is the sum of gaseous and solid carbon.
(b) Total ash is that which should accompany the total carbon, based on ratio of carbon to ash in the coal.

FIG. 16 VIEW OF SIDE WALL OF FURNACE AFTER 12 DAYS OF OPERATION WITH ARCH RAISED, FURNACE BURNING ANTHRACITE ON TRAVELING-GRATE STOKER, NANTICOKE, PA.

Fig. 16 shows the side wall of the furnace after the boiler had operated for 12 days at approximately 200 per cent of rating with the raised arch. The entire front arch and the upper 16 in. of the side and front walls were new at the beginning of this period, but the remainder of the walls were the same as those in the views of Fig. 10 two months before. The walls have the same general appearance as in the other photographs. The

accumulation of slag on the walls was, perhaps, somewhat heavier in parts, but there were similar evidences of fluid slag and erosion.

Fig. 17 shows the boiler tubes at the same time. Comparison of this view with Fig. 11, which was of the tubes at the end of a similar period before the arch was raised, shows that the accumulation was somewhat lighter, the spaces between the tubes were not as completely covered, and the slag had fallen from some of the tubes. It cannot be definitely concluded that this improvement in the condition of the tubes was entirely due to the increased height of the arch. The amount of slag on the tubes when the boiler comes out of service must vary with the thoroughness of the cleaning by hand lancing during operation, particularly of the last time before taking the boiler out of service.

The increase in the height of the arch did, however, result in marked improvement in the operation of the boiler in that higher loads could be maintained. With the original arch the limit of maintained output of the boiler was about 50,000 lb. of steam per hour, equivalent to about 225 per cent of rating; after the arch was raised an output of 56,000 lb. of steam per hour, equivalent to about 255 per cent of rating, could be easily maintained. This was largely because of the lessened resistance of the larger outlet of the furnace. The average pressure drop from the furnace to the stack at 200 per cent of rating was 0.74 in. of water before and 0.66 in. after it was raised.

The possibility of increased boiler output on these boilers was of a particular advantage in this plant for two reasons: (1) The older and smaller boilers operated at much lower efficiency than the newer and larger boilers; therefore increased output from the latter would result in a lesser number of the former in service and a great overall plant efficiency. (2) As the coal cost was low the investment costs were a large percentage of the total cost of current; therefore increased output per boiler reduces the investment cost per unit of current generated.

GENERAL SUMMARY OF THE INVESTIGATION

The range of values of the refractories service conditions, namely, the temperature, composition, and velocity of the furnace gases, the temperatures of the refractories, and the amount and composition of the solids carried in the gases when burning the small sizes of anthracite on a traveling-grate stoker has been determined and recorded.

The slagging of the refractories and the boiler tubes was more severe than is normal for furnaces burning anthracite. The factors which caused the slagging were the small size of the fuel, the high velocity of the gases, the reducing atmosphere, and the high temperatures.

The velocity of the gases was high because of the restricted area for gas passage and because the gases passed upward in a narrow stream toward the furnace outlet. Because of the high velocity and the fine size of the fuel a large amount of coal as well as ash was carried and deposited on the walls, arches, and boiler tubes.

A reducing atmosphere was maintained over the front wall and a part of the side walls because complete mixing of the combustible gases with air for their combustion was not effected until near the boiler tubes.

The temperatures were high because of the delayed combustion, because the area of exposed boiler tubes was small, and because the heat-absorbing surface became less effective as it was covered with slag.

The data taken after the arch had been raised did not show conclusively that the service conditions were less severe because a lower excess of air was maintained during the period of observation. At the end of a 12-day period, however,[6] it appeared that the boiler tubes were not as badly slagged as before, and it was definitely shown that higher loads could be carried on the boiler because of the lower pressure drop from the furnace to the stack.

This investigation disclosed no reason why, with the proper design of furnace to obviate the extremely high temperatures and high content of reducing gas, the burning of anthracite of the sizes smaller than buckwheat No. 3 should be accompanied by more difficulty with refractories than the burning of the larger steam sizes.

ACKNOWLEDGMENTS

This investigation has been carried on under the general direction of the Special Research Committee on Boiler Furnace Refractories of the A.S.M.E., of which C. F. Hirshfeld is chairman, and under the direct supervision of P. Nicholls, supervising fuel engineer, Bureau of Mines.

The study covered in this report was made possible by the cooperation of H. M. Warren, consulting engineer, C. R. Seem, electrical engineer, and R. B. Allbee, chief engineer, Nanticoke power plant of the Glen Alden Coal Co., Scranton, Pa., and the operating force of the plant.

The analyses of coal ash and slag were made in the general analytical laboratory of the Bureau of Mines at Pittsburgh under the direction of W. A. Selvig, and the coal analyses and softening-temperature determinations in the coal-analysis laboratory under the direction of H. M. Cooper.

[6] The engineers of the plant reported after five months' operation with the arch raised that the slagging of the tubes was less than before.

Design and Test of a Venturi Stack

Result of Tests on a Stack Operating on the Venturi or Ejector Principle, Through Which the Gaseous Products of Combustion Are Discharged for the Purpose of Inducing the Proper Draft

By ALEXEY J. STEPANOFF,[1] SAN FRANCISCO, CALIF.

IN ONE form of induced-draft system the gaseous products of combustion are discharged through a venturi-shaped stack, using the ejector principle to obtain the proper draft. The venturi stack was originated in France about 1913 and was adopted in European countries during the war, but is not widely used in America. Herewith is presented a résumé of the results of a study and tests on a stack operating upon the venturi or ejector principle.

The stack tested was designed for use in connection with a vertical fire-tube boiler (Main Iron Works) 42 in. in diameter and 9 ft. high, with 358 sq. ft. of heating surface. The boiler is located in the Mechanical Laboratories of the University of California at Berkeley. Because of a structural change in the original stack involving the addition of two 45-deg. bends, the natural draft was reduced from 0.5 in. to 0.2 in. of water. The venturi stack was installed to provide additional draft. The boiler is equipped with a Ray mechanical oil burner, and since about one-third to one-half of the air required for combustion at full load is furnished by the burner blower, the draft system of the boiler is a combination forced- and induced-draft one, tending toward the balanced-draft type.

A study of the literature available on venturi stacks revealed the lack of design data for the proper proportioning and arrangement of this stack. The two arrangements possible are the "in circuit" and "out circuit;" in the former, hot gases are drawn from the breeching by a blower and discharged through a nozzle into the venturi-shaped stack (see Fig. 1), and in the latter, cold air is discharged through the nozzle and into the stack by the blower.

Contradictory information with regard to venturi stacks may be found in several articles appearing in American technical journals during the period from 1913 to 1926.[2]

The advantages which were claimed for these stacks are that the capacity of the blower need only be 20 per cent of that for the direct induced draft (i.e., a system of draft where all of the stack gases are handled by the fan), and a saving of power of 4 per cent. These statements were confirmed by long theoretical deductions. But later these figures were considerably reduced and practically nullified in the published account of an actual test (*Power*, Mar. 19, 1925). The results of this test showed an increased power consumption of about 40 per cent as compared with the direct induced-draft system operating under the same conditions.

The dimensions of the stack are shown in Fig. 1. The proportioning of different parts of the stack was a matter of judgment with respect to best practice as exemplified in the design of existing apparatus for fluid flow. The final arrangement of parts, the choice of type and size of nozzle and fan, and the position of the nozzle were made after preliminary tests of the stack as an air-jet pump. The stack was placed in a horizontal position and cold air used as the working fluid.

The investigation with cold air covered the following problems: (1) Performance of the stack for different locations of the jet and the determination of the best position; (2) the performance characteristics for different back pressures (corresponding to different stack resistances) and for different driving air (nozzle) pressures, involving the calculation of the ratio of induced to driving air; (3) the performance of the jet pump with different forms of nozzles: namely, (*a*) single-jet type (Fig. 2); (*b*) annular type; (*c*) circular single jet with spiral guide vanes; (*d*) single jet with a diffuser; and (*e*) multi-jet type.

The quantity of air discharged was measured by means of a standard pitot tube. The differential pressures, in some instances as low as 0.0005 in. of water, were measured by a special inclined manometer developed at the University of California and shown in Fig. 3.[3]

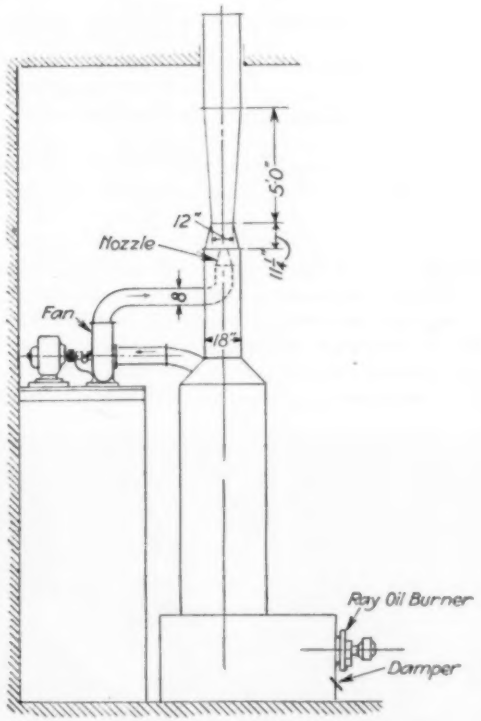

FIG. 1 ARRANGEMENT OF VENTURI STACK

The general conclusions from these tests are as follows:

1 The best position for the nozzle in the stack is found to be near the base of the converging cone; the change in position in close neighborhood to this point has very little effect upon the efficiency of the stack, while as the nozzle approaches the throat, the effect of the change in position becomes more pronounced. The reason for this lies in the fact that near the throat of the

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] A detailed description of this manometer is given in "Ventilation of Mines," by W. S. Weeks, McGraw-Hill, 1926.

stack the nozzle presents more obstruction to the flow of induced air than when it is near the base of the cone.

2 The nozzles may be listed in the following order when considered from the point of view of efficiency—that is, the ratio of induced to driving air—the first being the best, after which come the circular nozzle with spiral vanes, multi-jet nozzles, plain circular, annular, and circular with diffuser. The best performance was obtained by using the nozzle equipped with spiral vanes, because the rotation of the entering stream caused a uniform velocity distribution throughout the cross-section of the stack, while with the other nozzles higher velocities were observed in the upper half of the stack. This condition was probably due

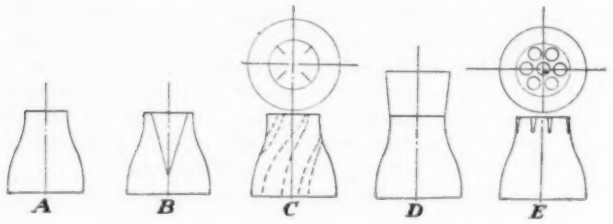

FIG. 2 AIR-JET PUMP WITH DIFFERENT FORMS OF NOZZLES

to the position of the stack near the floor, with obstructed flow of air into the intake. When used in a vertical position the spiral-vane nozzle has no advantage over the circular nozzle. The low efficiency of the annular nozzle is probably due to the large angle of the central cone. The addition of the diffuser to a nozzle approximately doubles the discharging capacity for the same nozzle pressure.

For all nozzles it was observed that the low driving heads were more efficient than the higher ones. The same was found to be true for hydraulic jet pumps recently tested by the author. The draft produced increased with an increase in pressure of the driving air or with an increase of the area of the nozzles; i.e., with an increase in the quantity of driving air in both cases. But it was found to be more economical to increase the quantity of driving air by

FIG. 3 SPECIAL INCLINED TYPE OF MANOMETER USED

increasing the nozzle area rather than by increasing the pressure back of the nozzle.

A Sturtevant fan (Monogram No. 3) was chosen for the installation of the stack on the boiler. This unit is rated to deliver 700 cu. ft. of gases per minute against a static pressure of 3.6 in. of water at 65 deg. fahr. at 1750 r.p.m., or 700 cu. ft. of gases against a static pressure of 2 in. of water at 500 deg. fahr. at the same speed. The ratio of the fan pressure to the required draft in this particular case is about 4, and the ratio of the fan capacity to the total quantity of boiler gases is about 0.7. A direct-current motor was used to drive this fan. The general arrangement is shown in Fig. 1. The furnace was equipped with a Ray burner, size No. 5, capacity 20 gal. of oil per hour. Three dampers were in the path of the gases through the stack: one in the pit below the burner, which was closed during these tests; the second just above the hood of the boiler; and the third on the top of the stack. The last two dampers were wide open for all runs. The

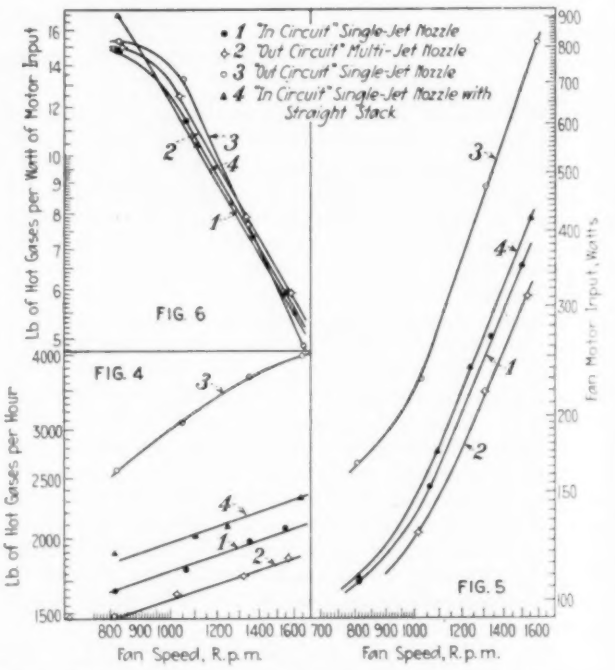

FIG. 4 WEIGHT OF HOT GASES DISCHARGED PER HOUR AT VARIOUS SPEEDS

FIG. 5 FAN-MOTOR INPUTS AT VARIOUS SPEEDS

FIG. 6 WEIGHT OF HOT GASES PER WATT OF MOTOR INPUT AT VARIOUS SPEEDS

necessary air for combustion was delivered by the fan of the burner, and through a clearance between the burner and the firebox door. The lower damper was kept closed because the quantity of air produced in this way was sufficient to support a good combustion of about 12 per cent of CO_2 content, and to obtain a boiler output up to 25 per cent overload. The rated capacity of the boiler is 25 boiler hp. From the preliminary runs it was found that with the lower damper open, double the rated capacity of the boiler could be obtained.

The following arrangements were tested on hot gases at different fan speeds: (1) "In circuit" with a single-jet nozzle $4^1/_2$ in. in diameter, area 15.9 sq. in.; (2) "in circuit" with a nozzle having seven jets each $1^1/_2$ in. in diameter, combined area 12.36 sq. in.; (3) "out circuit" with the first nozzle (for these runs the suction of the fan was disconnected from the boiler hood); (4) the same arrangement as (1) but with the venturi-shaped part of the stack replaced by a cylindrical pipe; (5) the same arrangement as (1) but with the fan not running, the draft being produced by steam jets (for these tests a $^3/_8$-in. pipe ring with 20 orifices each 0.052 in. in diameter was placed around the tip of the nozzle and connected to the steam line); (6) the arrangement (1) with the fan not running, the draft being due to the natural draft only. The quantity of hot gases was measured by means of a standard pitot tube, the readings being taken at twenty points.

The results of these tests are plotted in Figs. 4 to 9, and given in Tables 1 and 2. The logarithmic scale has been used on these

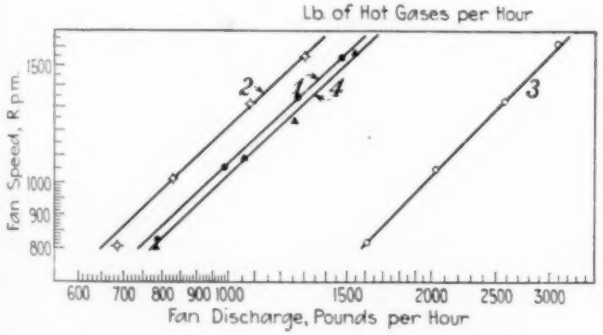

FIG. 8 FAN DISCHARGES AT VARIOUS SPEEDS OF FAN

graphs. Fig. 4 shows that the quantity of boiler gases varied considerably for different arrangements, but the efficiency is approximately the same for all of them, as is seen from Fig. 6, where the quantities of hot exhaust gases per watt of the fan-motor input are plotted against the motor speed. From these curves it is seen that the quantity of gases moved per watt decreases with higher fan speeds and hence higher fan discharge pressures. The same result was obtained from the runs on cold air. The steam consumption for steam-jet draft was on the average 8 per cent of the boiler output. It is evident that this is the least economical system tested and should be used only in the

TABLE 2 STEAM-JET INDUCED DRAFT

Run number	1	2	3
Steam consumed per hour, lb.	83.5	77.6	57.3
Per cent of boiler output	8.97	9.6	7.7
Weight of hot boiler gases, lb. per hr.	2095	1960	1770
Pounds of hot gases per pound of steam used	25.1	25.2	30.8

case of emergency. The substitution of the cylindrical part instead of the venturi-shaped portion of the stack decreased slightly the quantity of gases moved per watt (see Fig. 6). The quantity of hot gases moved by natural draft was found to be 1290 lb. per hour, the draft being 0.125 in. of water.

It should be noted that the out-circuit arrangement (3) is the most effective. The quantity of hot gases handled in this arrangement is approximately twice that for the in-circuit system. The reasons for this are the greater density of cold air, and hence the greater quantity of air discharged by the fan.

It has been mentioned that the venturi stack using the ejector principle for producing draft is less economical than the direct induced-draft system. The same conclusion may be based upon experimental data available on water-jet pumps. It is evident that it is more economical to use one low-pressure centrifugal pump to raise a certain quantity of water to a definite level than to use a smaller high-pressure pump for a portion of water to be raised and use the discharge of this pump to drive a jet pump to raise the remainder of the water. This is true because the efficiency of the jet pump is about one-half that of the centrifugal pump.

But the venturi stack with the jet method of producing draft has the following advantages: (1) To move the same quantity of boiler gases the size of the fan is considerably smaller; (2) a high-speed motor can be used, as the fan discharge pressures are higher in this system; and (3) the space occupied is smaller and the support can be lighter than for a large fan with a slow-speed motor. All three items result in a lower first cost of installation. For intermittent service, such as in the case described, and also to meet high peak loads for a short time, this system of draft will be found more convenient and economical than any other. It is possible to install it with an existing cylindrical stack, and to start the fan for peak loads and run on natural draft for normal loads. The "out circuit" arrangement is simpler to connect, though no trouble was experienced in running the fan on hot gases at temperatures up to 650 deg. fahr., the fan being equipped with plain bearings without water cooling

A Graphical Treatment of Heat-Exchange Problems

By JOS. S. STEPANOV,[1] HARRISON, N. J.

In this paper the author points out that the graphical method has been an important tool in engineering calculations and investigations. Applying this method to the investigation of certain heat-transfer problems, he finds it convenient to introduce some new relations between the variables involved in heat transfer and to give them corresponding mathematical expression, thus simplifying the graphical presentation of the heat-transfer equations. An arrangement of interconnected diagrams around the origin of a coordinate system furnishes the numerical values of the variables pertaining to the given set of heat-transfer equations and simultaneously satisfying them. Picturing the change of variables for different conditions, these diagrams can be used for calculations as well as for investigations and for analysis of experimental data.

In the paper are given and explained equations and diagrams for handling the heat-transfer problems pertaining to surface heat exchangers and direct-contact heat exchangers, using countercurrent and parallel flow of substances, and their applications in general calculations and investigations, and in the analysis of experimental data.

THE problems confronting the modern engineering art are becoming more and more complicated. The number of factors involved in certain engineering problems and affecting their final solution is so great that it becomes impossible to visualize the character and value of the influences they exercise upon the sought-for solution.

In the experience of the author, the graphical method of handling such problems has proved to be a helpful tool in the hands of designers or investigators.

Heat-transfer problems no doubt belong to this class of problems, and the author believes it worth while to develop for their treatment a graphical method which he devised many years ago,[2] for the calculation and investigation of ship propellers and which was found useful. Its general idea may be applied also in the solution of other engineering problems.

For convenience in locating desired material, the author has adopted the following sequence treatment of the subject:

I Transformation of Heat-Exchange Equations
  (*a*) Surface Heat Exchangers
  (*b*) Direct-Contact Heat Exchangers
II Graphical Representation of Equations
III Logarithmic Curves
IV General Properties of the Diagrams
V Applications of the Diagrams

I—TRANSFORMATION OF HEAT-EXCHANGE EQUATIONS

(*a*) Surface Heat Exchangers

Fundamental Equations. The amount of heat transferred per hour in surface heat exchangers from one substance to another at a lower temperature is usually expressed in the following ways:

1 In terms of the properties of the hot substance:

$$H = G_h c_h \Delta T \quad \ldots\ldots [1]$$

2 In terms of the properties of the cold substance:

$$H = G_c c_c \Delta t \quad \ldots\ldots [2]$$

3 In terms of the heat-transmitting surface:

$$H = SU\theta_m \quad \ldots\ldots [3]$$

where

$$\theta_m = \frac{\theta_1 - \theta_2}{\log_e \frac{\theta_1}{\theta_2}} \quad \ldots\ldots [4]$$

in which H = B.t.u. per hr. transmitted from the hot substance to the cold one through the total heat transmitting surface under consideration

G_h, G_c = weight of the substance, in lb. per hr. (Subscript h for hot substance, c for cold substance.)

c_h, c_c = mean specific heats at constant pressure, in B.t.u. per lb. per deg. fahr.

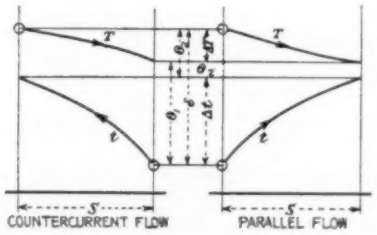

FIG. 1 SCHEME OF TEMPERATURE NOTATION EMPLOYED

T = temperature of the hot substance, deg. fahr.

t = temperature of the cold substance, deg. fahr.

ΔT, Δt = corresponding temperature drops, deg. fahr.

θ_1, θ_2 = temperature differences at the ends of the heat-transmitting surface, deg. fahr.

θ_m = mean temperature difference along the total heat-transmitting surface, deg. fahr.

U = heat-transfer coefficient, in B.t.u. per hr. per sq. ft. per deg. fahr.

S = heat-transmitting surface, in sq. ft.

δ = available temperature drop, in deg. fahr., i.e., the difference between the highest temperature of the hot substance and the lowest temperature of the cold substance.

The temperature notations are given also in Fig. 1.

The Specific Heats c_h and c_c for any substance are beyond the control of designers, and therefore can be conveniently considered together with the weight of the substance as single variables $W_h = G_h c_h$ and $W_c = G_c c_c$, which represent the heat capacities of the interacting substances and which, according to German investigators,[3] may be called "water values" of the substances. These express the amount of heat given out or absorbed by a temperature change of the substance of 1 deg. fahr., and are obviously equal to such an amount of heat in W lb. of water, hence the name "water values."

[1] Worthington Pump & Machinery Corporation. Mem. A.S.M.E.

[2] Published in *Viestnik Ingenerov*, 1915, Petrograd.

Contributed by the Power Division and presented at the Annual Meeting, New York, December 3 to 7, 1928, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

[3] Grober, Nusselt, ten Bosch and others.

The Temperature Drops ΔT and Δt as well as the *temperature differences* θ_1, θ_2, and θ_m, can be expressed in common terms of the available temperature drop δ as follows:

$\frac{\Delta T}{\delta} = e_c$ shows to what extent the hot substance is cooled, and may be called the "cooling efficiency" of the heat exchanger.

$\frac{\Delta t}{\delta} = e_h$ shows to what extent the cold substance is heated, and may be called the "heating efficiency" of the heat exchanger.

$\frac{\theta_m}{\delta} = e_m$ shows to what extent the available temperature drop δ is used to provide the thermomotive force causing the heat transmission, and may be called "thermomotive coefficient" of the heat exchanger.

Hence

$$\Delta T = e_c\delta$$
$$\Delta t = e_h\delta$$
$$\theta_m = e_m\delta$$

For countercurrent flow, Fig. 1,

$$\theta_1 = \delta - \Delta T = \delta - e_c\delta = \delta(1 - e_c)$$
$$\theta_2 = \delta - \Delta t = \delta - e_h\delta = \delta(1 - e_h)$$

and for parallel flow,

$$\theta_1 = \delta$$
$$\theta_2 = \delta - (\Delta T + \Delta t) = \delta - \delta(e_c + e_h) = \delta[1 - (e_c + e_h)]$$

The Transformation of Equations [1]–[4] may be effected by substituting the heat capacities W_h and W_c and the values e_h and e_c for the corresponding variables of these equations. This gives

$$H = W_h e_c \delta \quad [1a]$$
$$H = W_c e_h \delta \quad [2a]$$
$$H = SUe_m\delta \quad [3a]$$
$$\theta_m = e_m\delta \quad [4a]$$

or, dividing all members by δ,

$$\frac{H}{\delta} = W_h e_c \quad [1b]$$
$$\frac{H}{\delta} = W_c e_h \quad [2b]$$
$$\frac{H}{\delta} = SUe_m \quad [3b]$$
$$\frac{\theta_m}{\delta} = e_m \quad [4b]$$

where Equation [4b] is given in general form and may be developed by using [4] and the foregoing assumptions as follows:

For countercurrent flow,

$$e_m = \frac{e_c - e_h}{\log_e \frac{1 - e_h}{1 - e_c}} \quad [5]$$

for parallel flow,

$$e_m = \frac{e_c + e_h}{\log_e \frac{1}{1 - (e_h + e_c)}} \quad [6]$$

or in general form for both flows,

$$e_m = \phi\,(e_c, e_h) \quad [7]$$

The fraction H/δ in Equations [1b], [2b], and [3b] expresses the mean amount of heat transferred per hour and per degree fahrenheit of the available temperature drop δ, i.e., the intensity of the utilization of this drop.

To avoid having more than three variables in Equation [3], a new one is introduced, namely, $h_m = Ue_m = H/\delta S$, which expresses the thermal load of heat-transmitting surface in B.t.u. per hr. per sq. ft. per deg. fahr.

Now the heat-transfer equations appear in the following form:

$$\frac{H}{\delta} = W_h e_c = W_c e_h \quad [8]$$
$$\frac{H}{\delta} = SUh_m \quad [9]$$
$$h_m = Ue_m \quad [10]$$
$$e_m = \phi\,(e_h, e_c) \quad [11]$$

(*b*) Direct-Contact Heat Exchangers

Assumptions. Such heat exchangers as are represented by dry coolers of different kinds of granular material (coke, lime, cement clinker, etc.) or gas coolers by direct contact with water, have no measurable heat-transmitting surface. Therefore the heat-transfer equations should be changed to take care of these cases.

It is assumed that heat transmission takes place on the surface of the particles (whatever size they may be), and some heat-transmitting surface exists, though not readily accessible for measurement and calculations. This surface depends upon the size of the particles, and for a given size it depends only upon the space the material occupies.

Instead of a heat-transmitting surface we may consider a heat-transmitting volume V expressed by the factors cross-sectional area A, perpendicular to the flow of the substance, multiplied by L, the length of the contact; i.e., $V = AL$, for each of these factors has its own function in the heat exchange.

Formation of the Equations. Arranging Equations [8], [9], and [10] as follows:

$$\frac{H}{\delta} = W_h e_c = W_c e_h = SUe_m$$

and replacing S by $V = AL$,

$$\frac{H}{\delta} = W_h e_c = W_c e_h = ALUe_m$$

dividing all members by AL,

$$\frac{H}{\delta AL} = \frac{W_h}{A} \times \frac{e_c}{L} = \frac{W_c}{A} \times \frac{e_h}{L} = Ue_m = h_m$$

In different ways, all members express the same thing, namely, h_m, or the amount of B.t.u. transferred per hour per degree fahrenheit, per cubic foot of heat-transmitting volume ($V = AL$).

U, the heat-transfer coefficient in this case, means the number

of B.t.u. transferred per hour per degree fahrenheit per cubic foot of the heat-transmitting volume.

$\frac{W_h}{A}$ and $\frac{W_c}{A}$ express the heat capacities of interacting substances per hour corresponding to the square foot of the cross-sectional area, and therefore they may be correspondingly indicated by W_h and W_c. Hence

$$h_m = \frac{W_h e_c}{L} = \frac{W_c e_h}{L} = U e_m$$

The products $W_h e_c = W_c e_h$ express the portions of the heat capacities exchanged in the process, in B.t.u. per hr. per deg. fahr. per sq. ft. of cross-sectional area, and may be indicated as one variable by the symbol K.

The following set of equations expressing the heat exchange in the direct-contact heat exchanger may now be offered:

$$K = W_h e_c = W_c e_h \quad [12]$$

$$K = L h_m \quad [13]$$

$$h_m = U e_m \quad [14]$$

$$e_m = \phi\,(e_c, e_h) \quad [15]$$

II—GRAPHICAL REPRESENTATION OF EQUATIONS

Inspection of Equations [8]–[11] and [12]–[15] shows that—

1 Each pair of equations, [8] and [12], are mathematically identical, for the variables have the same range of numerical values.

2 In Equations [11] and [15], developed in [5] and [6], the variables e_c and e_h are interchangeable: the value of e_m does not change if e_c is replaced by e_h, and vice versa. The combined effect of the foregoing permits the determination of both variables, although [8] and [12] have been plotted as one equation.

3 Each equation involves three variables, and any two consecutive equations in arrangement given above have a common variable.

These properties make it possible:

(*a*) To plot each equation in the rectangular-coordinate system as a family of curves, each of them corresponding to the definite numerical value of the variable selected as the variable parameter. Using only the positive values of the variables, each equation will occupy only one quadrant of the coordinate system.

(*b*) To locate all four equations in four quadrants around the origin, plotting any pair of equations with common variables in two adjacent quadrants, so that the common variable may be measured in the same coordinate direction for both equations. The arrangement of both sets of equations is shown in Fig. 2.

After the selection of the variables measured in the directions of the coordinate system, the remaining variables in each equation should be treated as variable parameters.

In this arrangement Equations [8], [9], and [10], and [12], [13], and [14] represent the families of straight lines passing through the origin: each straight line for a definite numerical value of the variable parameter.

Equation [11] or [15] expresses the family of curves, each curve corresponding to a definite value of the variable parameter (e_c or e_h, ad lib.).

The general arrangement of the diagrams is shown in Fig. 3.

Any rectangle around the origin like that shown in Fig. 3, with sides parallel to the coordinate axis, gives, in its intersections with the axes and curves or straight lines in the quadrants, the numerical values of eight variables simultaneously satisfying all four equations plotted in the quadrants.

In addition, taking the given or the first selected value of e_h (or e_c, ad lib.) along the axis, the value of e of another substance is found at the point of intersection with the e-curves (e_c or e_h, correspondingly); taking this value along the e_h-axis and dropping a perpendicular to its intersection with the horizontal line SW_c projected, the heat capacity W_h of the other substance is determined.

The same diagrams can be used for both sets of equations, i.e., for investigations of both surface and direct-contact heat exchangers, bearing in mind that some of the variables have different meanings and ranges of numerical values, and therefore that the scale for such variables on the same diagrams should be correspondingly different for each case.

For convenience in further development, the quadrants may be distinguished according to the variable parameters as follows:

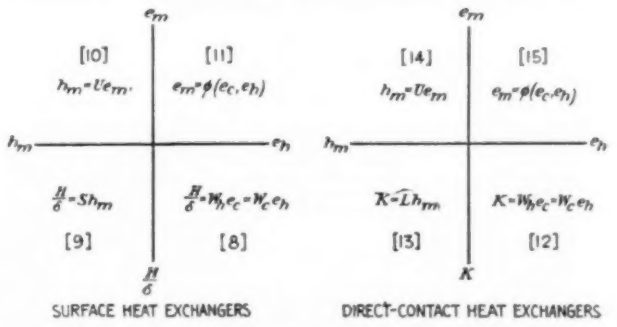

FIG. 2 ARRANGEMENT OF EQUATIONS AROUND ORIGIN OF COORDINATE SYSTEM

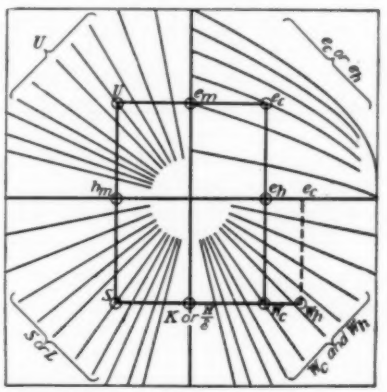

FIG. 3 GENERAL ARRANGEMENT OF FOUR INTERCONNECTED DIAGRAMS AROUND THE ORIGIN OF THE COORDINATE SYSTEM

1 Temperature quadrant, parameter e_c or e_h
2 Heat-transfer-coefficient quadrant, parameter U
3 Heat-transmitting surface (S) or length (L) quadrant, parameter S or L, and
4 Heat-capacity quadrant, parameter W.

III—LOGARITHMIC CURVES

In the temperature quadrant the equation $e_m = \phi\,(e_c, e_h)$ is plotted. The explicit forms of this equation differ for the countercurrent flow and parallel flow as shown by [5] and [6].

The computation, the plotting, and even the use of the logarithmic curves expressed by these equations are much easier if their peculiarities are taken in consideration.

(*a*) *Countercurrent Flow* (Fig. 4)

$$e_m = \frac{e_c - e_h}{\log_e \frac{1 - e_h}{1 - e_c}} \quad [5]$$

1 The numerical range of e_m, e_c, and e_h, as follows from their definitions, is from 0 to +1.

2 All values of e_m are positive for the values of e_c and e_h in the given range.

3 For all values of the parameter e_c in the given range, $e_m = 0$ if $e_h = 1$ (limit value). This means that all curves have a *common end point* on the e_h-axis, at a distance from the origin $e_h = 1$.

4 For all values $e_h = e_c$, values of e_m become indeterminate (0/0). The evaluation of this expression shows that the real values of the function in these points are $e_m = 1 - e_h = 1 - e_c$. All these points are located on the straight line connecting the points of coordinate axis: ($e_h = 1$, $e_m = 0$) and ($e_h = 0$, $e_m = 1$). It is the locus of equal cooling and heating efficiencies ($e_h = e_c$) which correspond to the equal heat capacities

$$W_h = W_c \text{ or } \frac{W_h}{W_c} = \frac{e_h}{e_c} = 1$$

connected with the different values of this ratio. In such cases the heat capacities may change, keeping the same ratio $W_c/W_h = \alpha$. Introducing this condition in [5] and [6], new equations involving the variable parameter α are obtained as follows:

For countercurrent flow,

$$e_m = \frac{e_h(\alpha - 1)}{\log_e \dfrac{1 - e_h}{1 - \alpha e_h}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [16]$$

For parallel flow,

$$e_m = \frac{e_h(\alpha + 1)}{\log_e \dfrac{1}{1 - e_h(\alpha + 1)}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [17]$$

(*c*) *Peculiarities of Curves* expressed by [16] and shown in Fig. 5.

1 If $\alpha = 0$, [16] becomes equivalent to [5]; for $e_c = 0$, curves $\alpha = 0$ and $e_c = 0$ coincide. This means that $W_c/W_h = 0$ only if $W_h = \infty$. Since e_h is finite, W_c is finite, therefore W_h should be ∞ in order that $W_c/W_h = 0$; that is, the heat capacity of the substance changing the state of aggregation is infinite.

2 If $\alpha = 1$, $e_m = 0/0$, that is, indeterminate, and the real values coincide with those of [5] and are graphically represented by the same straight line [case (*a*) par. 4].

3 If $e_h = 0$, $e_m = 0/0$, also indeterminate. The evaluation of the indeterminate form shows that the real value of $e_m = 1$. This means that all curves have a common end point on the e_m-axis at a distance from the origin $e_m = 1$.

4 If $e_h = 1/\alpha$, $e_m = 0$ for any value of $\alpha > 1$. This means that these curves have their end points on the e_h-axis, but each at a different distance from the origin and equal to $e_h = 1/\alpha$.

5 If $e_h = 1$ and $\alpha < 1$, $e_m = 0$ for all values of $\alpha < 1$. This means that part of the α-curves, for $\alpha < 1$, have a common end point on the e_h-axis at the distance $e_h = 1$ from the origin.

(*d*) *Peculiarities of Curves* expressed by [17] and shown in Fig. 6.

1 If $\alpha = 0$, curves $\alpha = 0$ and $e_c = 0$ coincide as in case (*c*), par. 1.

2 If $\alpha = 1$, $e_m = \dfrac{2e_h}{\log_e \dfrac{1}{1 - 2e_h}}$, the curve of equal efficiencies and heat capacities has its end point on the e_h-axis at the distance from the origin $e_h = 1/(\alpha + 1) = 1/2$.

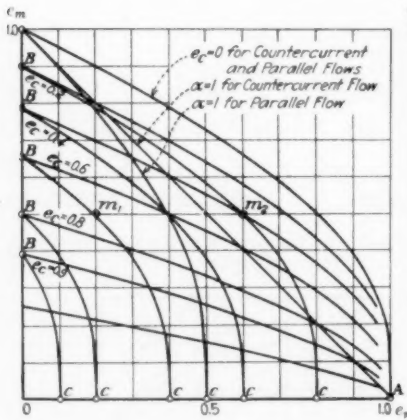

FIG. 4 PECULIARITIES OF THE e_c-CURVES
A = Common end point for countercurrent flow.
B = Common end points of pairs of the e_c-curves, presenting the same value of e_c for both flows.
C = End points of e_c-curves for parallel flow.

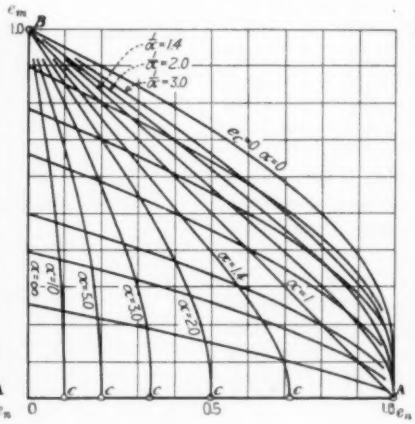

FIG. 5 PECULIARITIES OF THE α_c-CURVES FOR COUNTERCURRENT FLOW
A = Common end point for the α-curves $\alpha < 1$.
B = Common end points for all the α-curves.
C = End points for the α-curves $\alpha \geq 1$.

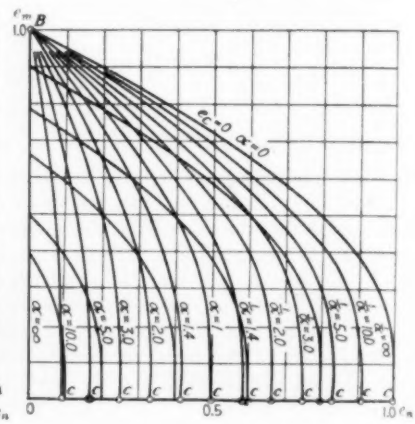

FIG. 6 PECULIARITIES OF THE α-CURVES FOR PARALLEL FLOW
B = Common end point for all the α-curves.
C = End points for different α-curves.

(*b*) *Parallel Flow* (Fig. 4)

$$e_m = \frac{e_c + e_h}{\log_e \dfrac{1}{1 - (e_c + e_h)}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

1 The numerical values e_m, e_c, and e_m are as in (*a*) above. In addition, $e_c + e_h$ lies in the same range, because $\Delta T + \Delta t \leq \delta$.

2 For all values of e_c, $e_m = 0$ if $e_c + e_m = 1$ (limit value). This means that all curves have end points on the e_h-axis, but that each curve starts at a different distance from the origin; that is, the values of e_c and e_h at the starting points should satisfy the condition $e_c + e_h = 1$.

(*c*) *Common Points and Curves* (Fig. 4). Both families of curves [(*a*) and (*b*)] have the following in common:

1 Both Equations [5] and [6] become equivalent and represent the same curve when $e_c = 0$. This means that if one of the interacting substances does not change its temperature as by a change in the state of aggregation, both principles of the heat exchange—countercurrent and parallel flow—are equivalent.

2 Similarly, both equations are equivalent if $e_h = 0$; i.e., for the same values of e_c both curves [for cases (*a*) and (*b*)] have a common end point on the e_m-axis.

Sometimes a definite relation (W_c/W_h) between the heat capacities may be desirable on account of characteristic properties

3 If $e_h = 0$, the properties are the same as in (*c*), par. 3.

4 If $e_h = 1/(\alpha + 1)$, $e_m = 0$ for any value of α.

This means that *all* curves have their end points on the e_h-axis at *different* distances from the origin, i.e., at $e_h = 1/(\alpha + 1)$.

All the foregoing statements concerning the peculiarities of the curves in cases (*a*), (*b*), (*c*), and (*d*) can be readily proved by applying the usual methods of the calculus.

Dividing Lines. All families of curves in the temperature quadrant are divided by the lines $\alpha = 1$ into two fields each possessing equivalent properties, but this afforded an additional convenience to the investigator.

1—Fig. 4, Families of Curves *a* and *b*.

On account of the interchangeability of e_c and e_h the final temperature conditions of the interacting substances may be expressed in two ways: If the investigation is started by the condition $W_c/W_h > 1$, i.e., $e_c/e_h > 1$, the point representing this case will be at the left side of the dividing line on the vertical from the point of *greater* heat capacity W_c (point m_1). But by interchanging e_c and e_h, the same temperature condition will be represented by the point at the right side of the dividing line, on the perpendicular from the *smaller* heat capacity W_h (point m_2), $W_h/W_c < 1$.

Which of these equivalent points is to be used depends upon which heat capacity is given or selected first, the greater or the smaller.

2—Figs. 5 and 6, Families of Curves *a* and *c*, and *b* and *d*.

From the foregoing another conclusion may be drawn: By studying the cases where α = constant, for $\alpha > 1$ the vertexes of the rectangles will be on the α-curves at the left side of the dividing lines.

For $\alpha < 1$ the equivalent rectangles will have their vertexes on the α-curves with reciprocal values $= 1/\alpha$ at the right side of the dividing lines.

When possible, it is more convenient to use the left field of curves, because they are located at greater distances from each other.

IV—GENERAL PROPERTIES OF THE DIAGRAMS

(*a*) *The Coordinate Axes*, in addition to their usual function, represent also the loci of the limiting values of the variable parameters in corresponding quadrants. Thus,

The h_m-axis is the locus for S or $L = 0$ and for $U = \infty$

The H/δ- or K-axis is the locus for S or $L = \infty$ and for $W = \infty$

The e_h-axis is the locus for $W = 0$ and for $e_c = 1$ in countercurrent flow, and

The e_m-axis is the locus for $U = 0$ and for $\alpha = \infty$

(*b*) *The Limiting Rectangles.*

1 $S = 0$ or $L = 0$

Such a rectangle is shown in Fig. 7 as No. 1. Here $e_m = 1$, S or $L = 0$, H/δ or $K = 0$, $e_c = 0$, $e_h = 0$, W_c and W_h may have any value (starting points of all W straight lines are at the origin), U = some real value, and h_m a corresponding one. Both countercurrent and parallel flow have similar rectangles—or identical if the same U is selected for both cases.

2 $S = \infty$ or $L = \infty$ (countercurrent flow).

Such a rectangle is shown in Fig. 7 as No. 2. Here $e_h = e_c = 1$, $e_m = 0$, W_c and W_h = any real value, U = any value (all U straight lines start from the origin), and H/δ or K = real values corresponding to heat capacities.

Note the following inconsistency in the algebraic analysis:

$H/\delta = USe_m = U \times \infty \times 0$ (indeterminate)

$H/\delta = W_c e_h = W_h e_c = W \times 1$ (real value)

This can be explained by assuming that the total ∞-surface cannot be fully utilized for transmitting the heat, because during a part of the time of their contact the substances already have equal temperatures.

3 $S = \infty$ or $L = \infty$ (parallel flow).

Such a rectangle is shown in Fig. 7 as No. 3. Here $e_c + e_h = 1$ and $e_m = 0$, the other variables being as in the preceding case.

(*c*) *Typical Rectangles.*

4 The heat capacities of both substances are equal: $W_c = W_h$, and

$$\frac{W_c}{W_h} = \frac{e_c}{e_h} = 1$$

Such a rectangle is shown in Fig. 7 as No. 4. Its vertex in the temperature quadrant will be always on the dividing line $\alpha = 1$, for countercurrent flow as well as for parallel flow.

5 $W_h = \infty$, W_c = finite value, $e_c = 0$, e_h = finite value, and

$$\alpha = \frac{W_c}{W_h} = \frac{e_c}{e_h} = 0$$

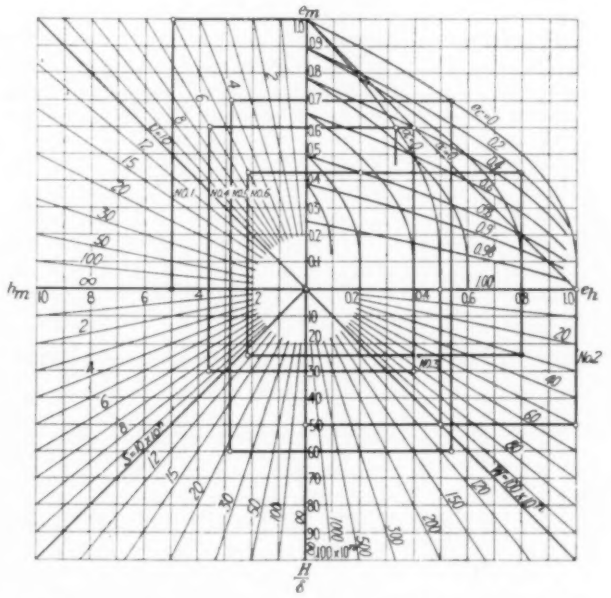

FIG. 7 SHOWING GENERAL PROPERTIES OF DIAGRAMS—LIMITING AND TYPICAL RECTANGLES

One of the interacting substances changes the state of aggregation. Such a rectangle is shown in Fig. 7 as No. 5. Its vertex in the temperature quadrant for any other conditions will be always on the ($e_c = 0$)-curve. The curves $e_c = 0$ and $\alpha = 0$ coincide, therefore for the heat-capacity ratio $\alpha = 0$, the temperature change will be expressed by the same curve ($\alpha = 0$), but for the reciprocal ratio $1/\alpha$, $\alpha = \infty$ and the α-curve coincides with the e_m-axis, thus showing that no temperature change is occurring ($e_h = 0$).

6 $W_h \neq W_c$, e_h and e_c have finite values,

$$\frac{W_c}{W_h} = \frac{e_c}{e_h} = \alpha, \quad \infty > \alpha > 1, \text{ and its reciprocal}$$

$$1 > 1/\alpha > 0$$

The rectangle No. 6 in Fig. 7 is typical for this case. This rectangle shows two vertexes in the temperature quadrant: one for greater heat capacity ($\alpha > 1$), on the left side of the dividing line, and another, for smaller heat capacity, on the right side, on the α-curve having a reciprocal value. This rectangle is characteristic for both countercurrent and parallel flow.

(*d*) *The Scale of Working Diagrams.*

The limiting values of e_m, e_c, and e_A are unity; the range of $h_m = Ue_m$ is narrow, but the variables S, H/δ, and W may vary within an extremely wide range depending on the size of the heat exchanger.

The author used the following scales:

For U-values, the locus of $U = 10$ B.t.u. (for gases) is represented by the diagonal at this quadrant, hence the largest value of h_m on the h_m-axis is $10 \times 1 = 10$.

In the S-quadrant the diagonal expresses $S = 10$ sq. ft., hence max. $H/\delta = 10 \times 10 = 100$.

In the W-quadrant, max. $e_A = 1$; the diagonal of the quadrant expresses 100, hence max. $H/\delta = 100 \times 1 = 100$, corresponding to the S-quadrant.

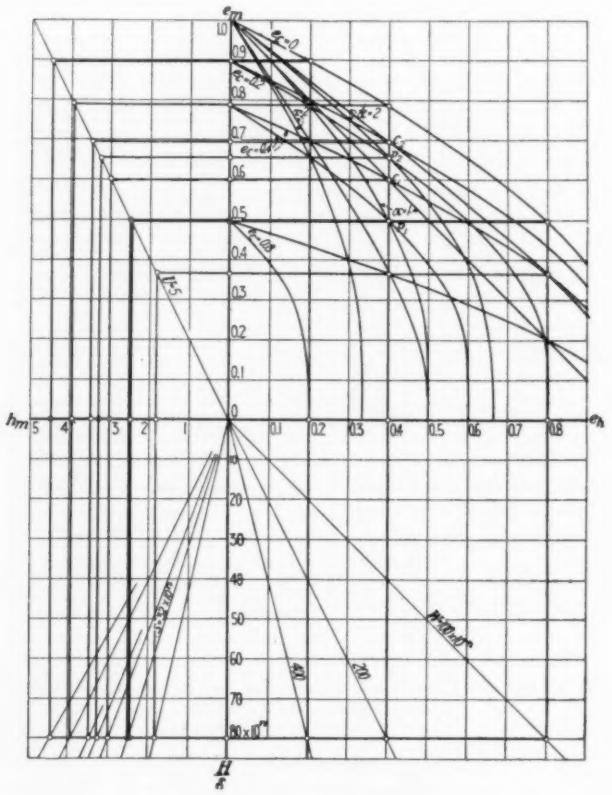

FIG. 8 APPLICATIONS OF THE DIAGRAMS
(Only the lines and curves involved in the examples given are shown.)

To take care of values for S, H/δ, and W greater than these, the figures given on the diagram are multiplied by 10^n, i.e., the figures on the diagram express units, tens, hundreds, thousands, etc., depending on the size of the plant.

In similar way the scales for L, K, and W are chosen (direct-contact heat exchangers).

V—APPLICATIONS OF THE DIAGRAMS

The use of the diagrams for investigations and calculations will be shown by a few examples.

Consider a surface water heater for raising the temperature of 2000 lb. of water from 50 deg. fahr. to 110 deg. fahr. by forcing along the heating surface a gas at 200 deg. fahr. inlet temperature and where $c_p = 0.24$ B.t.u. per lb. per deg. fahr. For these conditions

$W_c = 2000 \times 1 = 2000$ B.t.u. per hr.

$\delta = 200 - 50 = 150$ deg. fahr.

$e_A = 60/150 = 0.4$ where $60 = 110 - 50$

$H/\delta = W_c e_A = 2000 \times 0.4 = 800$ B.t.u. per hr. per deg. fahr.

$U = 5$ B.t.u. per hr. per deg. fahr. per sq. ft. (assumed).

CASE 1: $W_c/W_A = e_c/e_A = 1$, i.e., the heat capacities and efficiencies are *equal*.

The rectangles representing this case for countercurrent flow (No. 1) and for parallel flow (No. 2) are shown in Fig. 8.

The numerical values of the remaining variables as taken from the diagrams are:

	Countercurrent	Parallel
e_m	0.60	0.50
h_m	3	2.5
S	267	320

To transfer the same amount of heat, maintaining the same temperature conditions, the parallel flow requires (320 — 267)/267 = 0.2, or 20 per cent more heating surface than the countercurrent flow.

This difference is caused by the different values of e_m and is expressed on the diagram by the distance c_1-p_1 between the intersections of the rectangle side with the ($e_e = 0.40$)-curve for countercurrent flow (point c_1) and with the same curve for parallel flow (p_1).

The diagram shows that this distance is decreasing with e_A and becomes 0 if $e_A = 0$. This means that the difference between the countercurrent and the parallel flow is negligible if small temperature changes are involved.

CASE 2: $W_c/W_A \neq 1$, $e_c/e_A \neq 1$, i.e., the heat capacities and efficiencies are unequal.

Assume that $W_c/W_A = 1/2$. As before, for $W_c = 2006$ B.t.u. per hr. and $e_A = 0.40$, the values of $W_A = 4000$ and $e_c = 0.20$ result. The rectangles for these conditions are also shown in Fig. 8—for countercurrent flow as No. 3, and for parallel flow as No. 4.

The numerical values of the remaining variables are as follows:

	Countercurrent	Parallel flow
e_m	0.695	0.654
h_m	3.47	3.27
S	230.5	244.2

Again the parallel flow calls for more heating surface, but not to the same extent as at $\alpha = 1$ (case 1), i.e., (244.2 — 230.5)/230.5 = 0.06 or only 6 per cent difference.

Similarly to case 1, this difference is expressed by the distance $c_2 — p_2$. The points c_2 and p_2 are also on the intersections of the e-curves with the α-curves of the corresponding directions of the flow. Therefore the distance $c_2 — p_2$ depends upon the shape of these curves for the same value of α, but for different flows.

All α-curves, for both flows, start from the same point $e_m = 1$, $e_A = 0$ [III, (*c*) and (*d*), Figs. 5 and 6], and each pair of curves for the same α are divergent from the starting point, the divergence being maximum at $\alpha = 1$ and zero at $\alpha = \infty$. The distance $c_2 — p_2$ depends on this divergence, and therefore the conclusion follows that the greater the difference between the heat capacities ($W_c/W_A = \alpha$), the smaller the difference in using countercurrent or parallel flow, which disappears completely if $\alpha = \infty$, i.e., if one of the substances is changing its state of aggregation ($W_c = \infty\beta$).

Assume now that $W_c/W_A = 2$ and that as before $W_c = 2000$ and $e_A = 0.40$; then $W_A = 1000$ and $e_c = 0.80$.

In this case parallel flow is impossible. The rectangle side passing through $e_A = 0.40$ does not intersect the ($e_c = 0.80$)-curve

for parallel flow. The limit for the use of parallel flow is $e_c + e_h = 1$, whereas in this case $e_c + e_h = 0.40 + 0.80 = 1.20$.

For countercurrent flow the case is represented by rectangle No. 5 in Fig. 8.

The numerical values of the remaining variables are as follows:

$$e_m = 3.63;\ h_m = 1.82;\ s = 440.$$

CASE 3: One of the substances (water) is changing its state of aggregation (boiling): $W_c = \infty$, $e_h = 0$, $W_c/W_h = e_c/e_h = \alpha = \infty$.

To make this comparable with the preceding, let us keep the amount of heat transferred H and the available temperature drop δ as before, i.e., $H/\delta = 800$ B.t.u.

The heat capacity W_h and the corresponding temperature change e_c of another substance (gas) may have any values in the limits of given conditions $W_c = \infty$ and $e_h = 0$, but it is interesting to investigate this case with the same values of W_h as in cases 1 and 2, i.e., with $W_h = 2000$, 4000, and 1000.

In this case the interchangeability of e_c and e_h on the diagrams should be made of use, because for the given $W_h = 2000$, 4000, and 1000 corresponding values of $e_c = 0.40$, 0.20, and 0.80 are to be taken on the e_h-axis.

The rectangles representing these conditions are shown in Fig. 8 as Nos. 6, 7, and 8, and express the countercurrent and parallel flow in the following order:

For $W_h = 2000$	No. 6
$W_h = 4000$	No. 7
$W_h = 1000$	No. 8

The values of the remaining variables are as follows:

	No. 6	No. 7	No. 8
e_m	0.783	0.897	0.497
h_m	3.91	4.48	2.48
S	205.5	178.5	322.5

The size of heating surface depends on the location of the rectangle vertex on the ($e_c = 0$)-curve: the nearer the vertex to the e_m-axis, i.e., the smaller the temperature change of the gas (or the greater its heat capacity), the less the surface required to transfer the same amount of heat.

Now compare rectangles Nos. 1, 3, 5, 6, 7, and 8, all representing countercurrent flow (the last three parallel flow as well).

	No. 3	No. 1	No. 5	No. 7	No. 6	No. 8
W_c	2000	2000	2000	∞	∞	∞
W_h	4000	2000	1000	4000	2000	1000
W_c/W_h	1/2	1	2	∞	∞	∞
S	230.5	267	440	178.5	205	322.5

To transfer the same amount of heat to the same weight of a given substance, the surface required will be the less the greater the weight of the second substance, whereby the case of $W_c = \infty$; the effect of the W_h is *smaller* than in other cases because the ($e_c = 0$)-curve has a greater slope than the other e_c-curves.

Making the same comparison for parallel flow it can be seen that the same effect is *greater* for $W_c = \infty$ than in other cases because the others e_c-curves have a greater slope than the ($e_c = 0$)-curve.

In a similar way the influence of other variables can be investigated.

The same method is applicable in the investigation of direct-contact heat exchangers if the process of heat exchange is continuous, but it will be necessary to use a different scale for the diagrams and to bear in mind the different meanings of the variables.

From the application of the diagrams in investigations of heat exchangers in design work, it is clear that the same method can be applied in the investigation of the experimental data taken from existing plants.

In developing these diagrams the author is fully aware that their value is restricted by the same conditions which are involved in the heat-transfer equations: the process of heat exchange is considered continuous and stationary, the heat-transfer coefficient U as well as the heat capacities W being constant along the whole heat-transmitting surface.

The cross-current flow and intermittent process of heat exchange, on account of their two-dimensional change of temperature, are not covered by these diagrams.

The intermediate values of the temperatures of the interacting substances, as well as the proper values of the heat-transfer coefficients to be used in given conditions are highly important for the intelligent handling of heat-transfer problems.

The functional relations of the heat-transfer coefficient U to the heat capacities W, and of the temperature conditions and properties of the substances to the heat-transmitting surface and pressure drop to be expected for the corresponding value of U, as well as the temperature change along the selected heat transmitting surface, permit a similar graphical representation in the diagrams around the origin of a coordinate system, but space limitations prevent the author from dealing with it in the present paper.

Discussion

M. A. STONE.[4] In the diagram on the third page of the paper, the author has given a tool which is of universal application to the solution of all heat-transfer problems.

The writer has had a varied experience with heat-transfer problems in the past, both in connection with the design of apparatus for the transfer of heat and the insulation of furnace walls and of power-plant piping, and he has found a diagram of this same form, which was published by A. Lanstaff Johnson in *The Engineering Magazine* in 1915, of very great assistance in the latter case.

This particular diagram was prepared for the determination of the economic size of steam pipe and thickness of insulation, taking into account the cost of pipe, insulation and steam, the rate of heat transfer, flow of steam, loss of heat, and pressure drop. A glance at the expressions in the text of the paper is sufficient to show for such a problem the superiority of a graphical solution, in which the relation of the many variables can be grasped at a glance, to the tedious solution involved in setting up the algebraic equations with their many variables and exponential functions and then arriving at the correct arithmetical solution by trial and error.

ARTHUR J. WOOD.[5] Has the author used alignment charts to meet the same requirements as indicated in his paper? The quadrant method of plotting the results of certain equations may have advantages, but since the alignment chart has come into such universal use and has greater possibilities in its application, it is suggested that this method be tried out to meet the requirements of the author in presenting to the eye some of the complex relations in order that they may be more clearly interpreted by the average reader.

CROSBY FIELD.[6] This paper requires a great deal of study in order to fully comprehend its many fields of application and to fully realize its great merit. The writer hopes that this splen-

did paper is only a starting point for further papers by Mr. Stepanov on the same subject and would like to see applications of this paper to those many problems arising in the art of refrigeration.

Author's Closure

The advantage of the diagrams developed in this paper consists of not only eliminating the tedious figuring, but chiefly in visualizing how the different variables are affecting each other. The latter property is not represented in alignment charts which chiefly replace the slide rule.

As to the quadrants, with straight lines, representing mere multiplications, they are of value only in connection with other quadrants showing the influence of variables on each other. This property is fully secured only by functional interconnection of all the equations represented around the origin; there are several forms of the diagrams around the origin, with equations functionally disconnected. Such diagrams are deprived of most valuable property for investigations.

In the last page of the paper the author mentioned that the diagrams involve the properties and restrictions hidden in the fundamental equations. Therefore, being represented here in most general form, these equations may be plotted differently according to any special case, as for instance: (1) Only for countercurrent flow, if no problem of using parallel flow exists; (2) only α-curves, if the relationship of heat capacities be of first interest; (3) only ϵ-curves, if the temperature differences are to be specially investigated. Scale and size of the diagrams depend upon the heat exchanger under consideration.

Sometimes the use of logarithmic paper may be of advantage, if a large range should be investigated, whereas the precision of interpolation is not important. From this point of view the author hardly would recommend the reproduction of the full-sized diagrams as they are demonstrated in this paper; they will not conveniently cover the whole variety of the heat exchangers.

As the author mentioned in the last paragraph of his paper, the similar diagrams can be constructed for the investigations of the temperature change along the heat-transmitting surface as well as for selection of the heat-transfer coefficient in function of the pressure drop in the substance forced through the heat exchanger.

The author still hopes to publish these diagrams and to combine them with the diagrams of this paper adding detailed figures and several full-sized diagrams for the most widespread cases.

Low-Temperature Distillation of Low-Grade Fuels, Especially Lignites

By MAX TOLTZ,[1] ST. PAUL, MINN.

This paper is not intended to be a description of the various types of apparatus which are used in low-temperature distillation of low-grade fuels. On the contrary, its main purpose is to point out the advantages which inhere in these processes, and which result in greater usefulness and economies, particularly with reference to the lignite as found in the northwestern portion of the United States.

ABOUT 9 billion tons of lignite are deposited in North and South Dakota and Montana, but very little use is made of it except for domestic purposes at the rate of about 2½ millions of tons per year.

During the past 30 years attempts have been made to briquet this fuel, but these have not been successful because it has been necessary to transport the binding material over a long distance to the supply fields.

The lignites, as found in the above states, differ considerably in quality. This is evident from the facts revealed by the following analysis:

Site	Moisture, per cent	Ash, per cent	Volatile, per cent	Fixed carbon, per cent	B.t.u. as received	B.t.u. dry
Rosebud (Montana)	23.65	9.51	30.00	36.86	8750	11450
North Dakota	36.18	8.70	29.17	25.35	6700	...
North Dakota	32.64	11.42	29.10	26.25	6970	...
North Dakota	43.87	5.82	24.88	25.43	5938	...

Low-Temperature Distillation

On account of the high water content, this lignite cannot be shipped long distances. It has another disadvantage in that it slacks readily when stored, and crumbles into powder. Therefore low-temperature distillation seems to be the only method whereby this fuel may be utilized advantageously and conveyed to the people of the Northwest within a radius of about 600 miles of its source.

The following question arises: What is the nature of low-temperature distillation?

Low-temperature distillation may be defined as a heat treatment, not exceeding 1000 deg. fahr., whereby the decomposition of the tar is prevented, thereby releasing the maximum amount of liquid by-products and at the same time producing a smokeless fuel called semi-coke or char. The yield of tar of course is eliminated when the use of a gas of high thermal value is preferred. It should here be mentioned that tar water constitutes another by-product. The reason why low- instead of high-temperature distillation is preferable may be found principally in the larger yield of liquid fuels.

Although there are many different processes of low-temperature distillation, nevertheless all these types may be broadly segregated into two main classes, viz.:

1 The type in which heat is applied directly to coal in suitable retorts, or, in other words, in which the coal comes in direct contact with the hot gases or superheated steam

2 The type in which the heat required for distillation is applied externally, that is, through the walls of the retorts which contain the coal.

The retorts themselves may be placed in horizontal or vertical positions, they may be stationary or rotating, and the operation may be either continuous or intermittent.

European Progress and Requirements

It may be of interest to discuss briefly what Europe has accomplished and is now doing in the field of low-temperature distillation of fuels. In England the purpose is to obtain a smokeless solid fuel for domestic use. This aim has been achieved. But in Germany the principal needs consist in the production of a motor fuel called benzol which is similar to our gasoline, also other oil substitutes. The coke or char is used either in powdered form in the various power plants or in the form of briquets. Because Germany has no oil wells, oil must be purchased from other countries. Hence the securing of a substitute for crude or natural oils is a vital problem in Germany. Eventually all of the coal used in that country will be treated by this process. Then a sufficient supply of liquid fuel and oil substitutes will become available. In this connection, it should be noted that the benzol which is used for automobile purposes costs, in Germany, from 60 to 85 cents per 4 liters (1.2 U. S. gallons).

The term "braun Kohle" (brown coal) is applied in Germany to this coal. It is less valuable than North Dakota lignite, but it is superior to peat. It contains up to 60 per cent moisture, and has a heating value of from about 3700 to 5000 B.t.u. per pound in the dry state. At present Germany produces about 1,000,000 tons of semi-coke or char from about 3,000,000 tons of brown coal. The yield of tar is about 7 per cent.

In the northwestern part of the United States the problem is entirely different. Here a commercial fuel for domestic and industrial purposes is needed. The char, which is a product of the low-temperature distillation process, consists of distinct small granules or particles which range in size from 1/16 in. to nearly ¾ in. Special grates are required in order to use char of this kind under boilers. In Europe the char is used on chain grates, but the tendency is toward the employment of this fuel in powdered form. In several European plants inspected by the author, pulverized char was used. In one case which came under the author's observation pulverization was temporarily abandoned on account of the danger of producing explosions in the mill. It was hoped, however, that this danger would be overcome in the near future.

The conditions which prevail here require the briqueting of the char. This is easily accomplished by the addition of about 6 per cent of by-product tar, as a binder. It is noteworthy that in one plant located in central Germany experiments have been conducted during the past two years for the purpose of evolving a method of making char briquets without a binder. These efforts proved successful, but the author was unable to learn the details because the process was being protected by pending patents. He was informed that the manager of this plant had been instructed to preserve strict secrecy concerning the nature of this process, but he (the manager) was confident that in the near future complete details would be revealed.

Solution of Northwest Fuel Problem

It is evident that in this discovery lies the solution of the fuel problem of the Northwest. When its use is available here, the

Contributed by the Fuels Division and presented at the Summer Meeting, Minneapolis-St. Paul, Minn., August 27 to 30, 1928, of The American Society of Mechanical Engineers.

problem of the handling of lignite when in the form of char briquets as a domestic, industrial, and railroad fuel will have been solved. Moreover, economical transportation throughout the tributary territory will then be possible. Furthermore, char briquets could then compete with coke or any eastern, Illinois, or other bituminous coal which is now sold in this territory.

Tar and Its By-Products

During the process of distillation, tar as a by-product is obtained through the condensation of the gases. The average yield of tar from lignite is about 9 per cent of the total weight. Its value for chemical purposes increases in proportion to its freedom from dust and other substances.

As pointed out already, in Europe light oils (benzol) and heavy oils (for lubrication) are extracted from this tar. The most valuable product, however, is paraffin. Its consumption is increasing every year, and it has an extensive field of application in the manufacture of electrical appliances and accessories. This tar also contains a small amount of asphaltum which is too small, however, to warrant extraction.

Tar Water and Its By-Products

Ammonium sulphates are distilled from the tar water as by-products. It is well known that ammonium sulphates, $(NH_4)_2SO_4$, are used in the manufacture of fertilizers, smokeless powder, and ice. It is not necessary to give particular consideration to the two last-mentioned uses, but the employment of ammonium sulphates in the manufacture of fertilizers is of high importance, not only in Europe but also in America. In order to bring ammonium sulphate acid, NH_4HSO_4, into the use which its properties so highly warrant, a well-organized educational campaign among the farmers of the Northwest is required. Economical farming will be greatly augmented by the scientific use of suitable fertilizers which will give back to the soil that which has been removed in the growing of crops. At present, however, in United States the market is swamped with ammonium sulphates.

Acetate of lime, in the form of brown or gray lime, is another by-product of tar water. This is used in the distillation of acid salts and pure vinegar.

Indirect Heat Treatment in Germany

Of all the plants which the writer visited, one located in central Germany proved the most interesting. In this plant brown coal is carbonized by the indirect method. Experiments extending over a period of four years showed that the best results were obtained from coal which had been crushed to a size of about $^1/_2$ to $^3/_4$ in. The moisture content of this crushed product is about 55 per cent before drying in a rotary dryer to about 15 per cent. After the moisture content has been thus reduced by the drying process, the brown coal is deposited in retorts, similar in design to the Koppers coke ovens, the top of which is 4 in., while the bottom is $5^1/_2$ in. wide. The open spaces between the retorts are available to the hot gases of combustion, whose heat is transmitted through the retort shells into the coal mass within. This manner of transmitting and conducting the heat to the coal is a well-known essential feature of the indirect method. A retort unit consists of twelve retorts which are structurally connected in order to facilitate handling. It is of course evident that units may consist of other suitable group arrangements. Each retort unit is supported upon and transported by a steel carriage or truck.

In this method the ordinary retort is not used. Instead, an oven about 150 ft. long is employed as a chamber for both the retort units and their supporting trucks. A track is provided which permits the direct transportation of the retort unit by means of their supporting trucks into the oven. A receiving chamber about 10 ft. long is provided at one end of the oven for the reception of one truck and its retort unit. This receiving chamber can be shut off by a sliding partition from the main portion of the oven. After the receiving chamber has been loaded with one truck containing one retort unit, the outer door of the chamber is closed, and the sliding partition between the chamber and the main oven is opened. The car or truck is then connected with the train of cars which is already located in the oven proper. The temperature which is maintained in the oven proper does not, at any time, exceed 932 deg. fahr. The retort units and their contents are subjected to the continuous temperature of the oven proper. The progress of the train of cars through the oven is slow because a time period of from 10 to 12 hr. is required to complete the process of distillation. From the front end of the train, a car is discharged into a discharge chamber as soon as the work of distillation has been completed. The operation—the forward movement of cars, and the discharge of cars from the discharge chamber—is continuous.

Upon leaving the discharge chamber, each retort unit is lifted from its supporting truck and the char contents of the retorts are automatically deposited upon the truck platforms. Steel brushes are used to sweep the char from the truck platform into a hopper which is situated below the truck.

The char is conveyed upon a belt from the hopper to the storage bin. During its forward progress on the belt, the char is cooled. The storage bin is located either above the pulverizer or the briqueting plant. The pulverized char is used under the boilers of a comparatively large power plant (6500 kw.). When the briquets are manufactured, they are shipped to dealers.

In the plant just described attempts were made to use pulverized coal in the retorts, but it was found that much trouble ensued because of the adhesion of fluid coal to the sides of the retorts during the process.

Reports of the tests made, of course, show that the yield of tar was higher when finer material was used. Nevertheless, it was determined that coal ranging in size from $^1/_4$ to $^1/_2$ in. insured the most economical handling.

Another experiment was tried which deviated from the usual procedure of condensing the gases for their tar and tar-water products. Instead, the gas, after cleaning and scrubbing, and with a heating value of from 550 to 800 B.t.u. per cu. ft., was piped to the local gas works for distribution to consumers. In this case the gas of combustion in the retort oven was obtained from separate gas producers. This gas had a heating value of about 110 to 125 B.t.u. per cu. ft.

Conclusion

The writer is of the opinion that the fuel economy of a power plant will be raised by distilling coal, using the low-temperature process, and producing gas of a high heating value whenever such a power plant can be connected with a gas works. The char should be used in pulverized form under the boilers. Where superheated steam instead of gas from gas producers is used in the distillation of the coal, a great benefit can be derived from the heat of the char by the dry-quenching of this material, the heat to be utilized under a separate boiler for raising low-pressure steam or for superheating the steam used for the process of distillation.

It is not within the province of this paper to compare the different systems of distillation, except in so far as to point out that, for the lignite problem, low-temperature distillation, with externally heated retorts, seems to be the most advantageous. The reasons for this are that it yields the highest quantity of char, containing about 10 to 15 per cent of volatiles, and produces

the greatest amount of tar. But compared with the system of internally heated retorts or high-temperature distillation of fuels, the yield of gas of high heating value will be low.

Because extensive experience with distillation of low-grade fuels is lacking in this country, safe conclusions can be drawn from the results achieved in Europe, particularly in Germany. From this evidence it is inferred that the success of low-temperature distillation lies along the line of briqueting the char, thus facilitating its handling and shipping to the tributary country lying within the radius of low cost of transportation, within which it is possible to meet competition with other fuels. It is certain that housewives will approve the use of this fuel for cooking and heating purposes. For industrial purposes the briquet may be used, but if the distance from the carbonizing plant is not too great, the char could be shipped and used as fuel after pulverization at the boiler plant. Even the railroads may use the briquets with excellent results and with the assurance of obtaining smokeless combustion.

If gases of high heating value can be used, the whole process will be simplified, but if it is impossible to use them directly, they should be condensed and the tar and tar water separated. The tar, if clean and practically dust free, will find a ready market in the East.

The separation of light and heavy oils from the tar is not recommended, because they are comparatively plentiful and inexpensive in the United States. This condition, very probably, will prevail in America for many decades.

Since the farmers in the lignite states can make excellent use of ammonium sulphates, it is advisable to separate this pr ct from the tar water.

A low-temperature distillation plant of the Lurgi system is under construction at Lehigh, North Dakota, and is expected to be set in operation during September, 1928. All interested in the development of the use of lignite in the form of char briquets and its by-products hope that the process of low-temperature distillation has solved the problem of fuel supply for the Northwest in a feasible and practical manner crowned with commercial success.

[The above-mentioned Lurgi plant has been in operation since the middle of January, 1929, and it is reported that the operation of the mechanical apparatus as well as the economical results are exceeding expectations. Its capacity is only 100 tons char briquets per 24 hours.—AUTHOR'S NOTE.]

Discussion

EUGENE MCAULIFFE.[2] There are two things that I think the low-temperature carbonization of lignites will bring about. In the first place, any process that is not economical and financially successful is doomed to ultimate failure. If we could take out a material portion of the moisture content of lignite and other low-grade coals at the mine, reducing the transportation expense, a material saving would be created, and that would represent a substantial contribution toward financial success. Then comes that other problem—perhaps it is a collateral problem, but still directly related—the matter of attempting to obtain a better load factor for the mines that produce this low-grade material. Perhaps the worst neglected situation that exists in the coal-mining industry is the fact our load factor runs from 17 to 20 per cent. A tremendous capital investment is standing idle the major portion of the time, and that situation is accentuated by the fact that it costs more to maintain a coal mine idle than it does any other sort of factory. The forces of nature, mine water, the decay of mine timber, and things of that sort all make for heavy expense. If we could increase the return in tons of coal from our untreated timber, our pumpage, and ventilation expense, and things of that sort, we would effect a material economy in the cost of production. Where it takes seven or eight years to work out a certain area, the place must be retimbered several times, making the cost much greater. So those two things—the matter of reduction of transportation expense and the better load factor—that could be brought to the low-grade producing mines by making use of this process, thus reducing the idle period, together with storage facilities, and that would admit of putting back this temporary unmarketable situation to a time when the coal was marketable, seem to me two very compelling factors leading toward the success of the process.

I would like to ask the author what is the present situation with respect to low carbonization. We have a bituminous mine in the State of Washington, and the coal that we have is quite fit for locomotive fuel although it runs about 26 per cent moisture. There is a wide seasonal spread between our minimum and maximum demand as we are dependent wholly on the railroad fuel demand, which is very low during the summer, and then in the fall when the business picks up we have to reach out and assemble casual labor; and so I have thought that perhaps there was a possibility of carbonizing our coal during the off-peak demand period and storing it so that we might take it up in the fall and burn it during the heavy demand. The Northern Pacific and Santa Fe railroads have almost overturned all our past theories of locomotive fuel use by developing a new method of burning coal, and that is by using a small grate opening; they are using table grates with half-inch openings, providing from 13 to 17 per cent air openings, where they used to consider it an absolute necessity to provide not less than 35 per cent. That makes it possible to burn very fine coal successfully in a locomotive and with a very high rate of combustion. Could the author give me any light on that point?

AUTHOR'S CLOSURE

The difficulties of which Mr. McAuliffe speaks can be overcome by the use of low-temperature distillation, in which low-grade fuels of high moisture content are carbonized economically. The char, the result of this process, having the size of pea coal, with a moisture of about 5 per cent and a B.t.u. value of from 12,500 to 13,500, can be easily stored. It can be used on chain grates under stationary boilers or on locomotives with a special grate, but it is preferable to use this fuel in pulverized form. If this process is adapted for the mine mentioned, the load factor can be increased wonderfully, because the economical feature of carbonizing is a continuous process. Of course in this case the char has to be stored in summer time, to be shipped and used for the winter loads. The shipping expenses are also reduced because no freight has to be paid for water as in the case of lignite with 35 to 40 per cent moisture content.

Another method of use of low-grade fuel, if consumed quickly and freshly as it comes from the mine, is the adaptation of a special grate as has been developed by the Northern Pacific Railway on the locomotives of the Montana district. The fuel is semi-bituminous, almost a lignite, with a mixture content of about 23 per cent and a heating value of about 7600 B.t.u. The grates have openings of $^3/_8$ to $^7/_{16}$ in. and are from 16 to 18 per cent of the total grate area. This has been carried out successfully as compared with former methods. In Europe and in one stationary plant in North Dakota step grates are used. The low-grade fuel is partly gasified, and the gas combines in the combustion chamber with the fuel. Although a great improvement over the old methods, it is only a step forward. The only economical way of using low-grade fuels with high moisture content is by reduction of the carbonization process, whereby also valuable by-products are obtained.

Effect of Alloying Elements Upon the Stability of Steel at Elevated Temperatures

By A. E. WHITE[1] and C. L. CLARK,[2] ANN ARBOR, MICH.

ALLOY STEELS during the past few years have made rapid strides in an entirely new field—in the construction of metallic parts which are to withstand stresses at elevated temperatures. It is true that plain carbon steels have been used because of their relative cheapness and ease of fabrication. Yet because of their recognized limitations their place will be taken in an ever-increasing degree by alloy steels. Owing, however, to the large number of alloy steels available there is often considerable confusion as to just what alloy steel is best suited for the problem at hand. It was for the purpose of furnishing information regarding the effect of various alloying elements upon the steels to which they were added that the work reported in this paper was undertaken.

Stability Characteristics

In order for a metal to be serviceable at elevated temperatures it must be stable at the temperatures to be employed. When a metal is stable, two distinct characteristics are implied:

1 That the metal or alloy is capable of resisting oxidation at the temperatures being considered
2 That the metal or alloy is capable of resisting indefinitely, or at least for the economic life of the piece of which it forms a part, the stresses to which it is to be subjected.

Since this paper is primarily concerned with the second of these two characteristics, the first will be dismissed with a few general statements.

Resistance to Oxidation. A generalization well set forth by Stoughton[3] regarding the effect of alloy additions upon the corrosion-resisting properties of the metals to which they are added is: "When a metal forms a solid solution with other metals, it gives to the alloy some of its own corrosion-resisting properties." Since oxidation may be considered as high-temperature corrosion, the same statement applies to it.

From this, if the resistance to oxidation is to be increased, then some alloying element must be added which is itself resistant under the given conditions and which when added to the steel dissolves in the ferrite. Two corrosion-resistant elements which may be considered in this connection are nickel and chromium. Nickel when added to steel dissolves in the ferrite and so increases the ability of the metal to resist either oxidation or corrosion. Chromium, on the other hand, has a greater affinity for the carbon than the ferrite. Thus if added in small amounts it will combine entirely with the carbon forming carbides, and the resistance to oxidation is not increased unless the steel is subjected to a heat treatment to throw the carbides, at least partially, into solution. If, however, the carbon is sufficiently low or the chromium is added in large enough amounts so that there is more than enough chromium to combine with the carbon, then the remaining chromium will dissolve in the ferrite and the resistance to oxidation is increased without any heat treatment.

As an example of the latter two cases, chromium stainless steels and chromium stainless irons may be considered. The stainless steels, containing approximately 12 per cent chromium and 0.30 per cent carbon, require a heat treatment to give them their oxidation-resisting properties, while the stainless irons, containing approximately 12 per cent chromium and 0.10 per cent carbon, resist oxidation without any previous heat treatment.

Load-Carrying Ability. The experimental work reported in this paper is concerned with the effect of temperature upon the tensile properties of metals and alloys. Before presenting the test results, however, it will be best to consider the entire field from a theoretical standpoint.

Ever since the presentation in 1912 of a paper by Rosenhain[4] concerning the conditions existing at the crystal boundaries, metallurgists have generally accepted the belief that metals consist of two states, a crystalline and an amorphous state. Also, as expressed by Beilby,[5] the crystalline phase or state is "thermally stable but mechanically unstable" and the amorphous phase is "thermally unstable but mechanically stable." This implies that the relative strength of these two phases is not fixed, but may vary according to given conditions.

If it is desired to increase the strength of a metal consisting of two phases of unequal strength, the following ways are open:

1 The addition or formation of some substance which by its presence increases the strength of the weaker phase
2 The addition or formation of some substance which tends to remove the weaker of the two phases.

From this it follows that in order to increase the load-carrying ability of a metal at any temperature it is first necessary to determine which of the two phases is the weaker and then take steps to strengthen or remove this weaker phase.

It is a well-established fact that at atmospheric temperature, fracture of ordinary steels proceeds through the grains and not around them. This is owing to the greater strength of the amorphous boundaries. As the temperature of testing is increased, however, the amorphous phase weakens at a more rapid rate than that of the crystal proper, and a temperature is finally reached where fracture proceeds around the grains and not through them. This temperature Jeffries[6] calls the "equicohesive temperature." In general, under very slow rates of loading, this corresponds to the lowest recrystallization temperature of the alloy when in a severely cold-worked state. Values for recrystallization temperatures reported in the literature vary considerably, but that generally accepted for commercial iron[7] is in the neighborhood of 850 deg. fahr. (454 deg. cent.).

From the foregoing it is evident that before the effect of alloying elements upon the load-carrying ability of metals can be de-

termined it will be necessary to know over what temperature range and for what length of time this stability is desired. That is, for plain carbon steels those elements, the addition of which may cause increased stability up to temperatures in the neighborhood of 850 deg. fahr. (454 deg. cent.), are not necessarily the ones that will have the greatest effect in increasing the load-carrying ability at the higher temperatures.

If stability is desired below the equicohesive temperature, then we advance the following hypothesis:

1 The addition or formation of any element, compound, or constituent which does not enter into solid solution with the matrix, but which by the very nature of its presence interferes with the crystal slippage, will tend to increase the load-carrying ability of the material of which it forms a part

2 The addition or formation of any element, compound, or constituent which tends to increase the amount of amorphous material will increase the load-carrying ability of the material of which it forms a part.

For stability above the equicohesive temperature, our hypothesis follows:

1 The addition or formation of any element, compound, or constituent which tends to decrease the relative proportion of amorphous material to crystalline material will increase the load-carrying ability of the material of which it forms a part

2 The addition or formation of any element, compound, or constituent which strengthens the grain boundaries by interfering with plastic flow will increase the load-carrying ability of the material of which it forms a part.

steels were subjected to short-time tensile tests at temperatures as high as 1500 deg. fahr. (816 deg. cent.) in some cases and to 1250 deg. fahr. (677 deg. cent.) in others. The last five, together with steels G and P′ were tested after various heat treatments only at 1000 deg. fahr. (538 deg. cent.).

It is realized that proportional-limit values as obtained in short-time tensile tests may not be, at temperatures above the equicohesive temperatures at least, a true criterion of a metal's load-carrying ability. Yet it is believed that for temperatures not too far above this point carefully determined proportional limits can be used as a good measure of the metal's ability to resist rupture for periods up to several thousand hours.

For this reason proportional-limit values rather than creep-test results are here presented, because in this way it was possible to investigate a much larger group of alloys. In two cases creep tests were run as a check on the proportional-limit values, and these results also are presented.

The method used for determining the proportional limit values was the same as described in previous papers by the authors.[8,9] On this one property the literature is full of conflicting data. Great care and attention to detail are necessary to get correct values. For example, on one of the manganese steels on which we have had occasion to do considerable work certain investigators have reported proportional-limit values at 1000 deg. fahr. (538 deg. cent.) of approximately 40,000 lb. per sq. in. The best value we have been able to obtain after various heat treatments, one of which is that which is supposed to bring out the best properties, is 15,000 lb. per sq. in. We make no claim that our values on this steel and on the others that will be reported are beyond question. We do contend that the work was carefully performed and that close adherence to those factors which give accuracy were followed. We have confidence, therefore, in our results.

Considering the foregoing principles and the effect of certain alloy additions upon the metallographic structure of the metals to which they are added, it should be possible to predict and explain the influence of the various alloy additions upon the load-carrying ability of the resulting alloy. Also the matter of heat treatment should be given careful consideration, for often the selection of proper heat treatment is equally as important as the selection of the proper alloying element. The alloying elements that will be considered in this paper are nickel, chromium, tungsten, manganese, molybdenum, vanadium, and various combinations of these elements.

Methods of Present Investigation

For the purpose of obtaining the data from which the factors producing stability at elevated temperatures could be determined, short-time tensile tests were conducted on a large number of alloy steels. The chemical composition of these steels is given in Table 1.

With the exception of the last five listed in Table 1, the

Some question arises in high-temperature testing as to just what heat treatment should be applied to the metal before subjecting it to the testing process. It has been shown several times that in all tempering or drawing operations at least two factors must be considered, (1) the temperature employed and (2) the time during which the metal is maintained at that temperature. Therefore, if it is desired to subject the specimens to any sort of a quenching operation, it is necessary to draw them at a sufficiently high temperature so that the time effect at the temperature at which they are to be used will not cause any marked change in structure with corresponding changes in physical properties.

[9] A. E. White and C. L. Clark, "Properties of Ferrous Metals at Elevated Temperatures as Determined by Short-Time Tensile and Expansion Tests," Dept. Eng. Res., Univ. of Mich., reprint No. 3, 1927.

Because of the necessity of following any quenching treatment with such a high degree of tempering, all of the metals reported in this paper on which tests were conducted at temperatures above 1000 deg. fahr. (538 deg. cent.) were subjected to either a normalizing or an annealing treatment. It is felt that these two treatments more nearly represent the working conditions encountered in service.

If, however, the metals are to be used at only relatively high temperatures, such as 1000 deg. fahr. (538 deg. cent.) or possibly

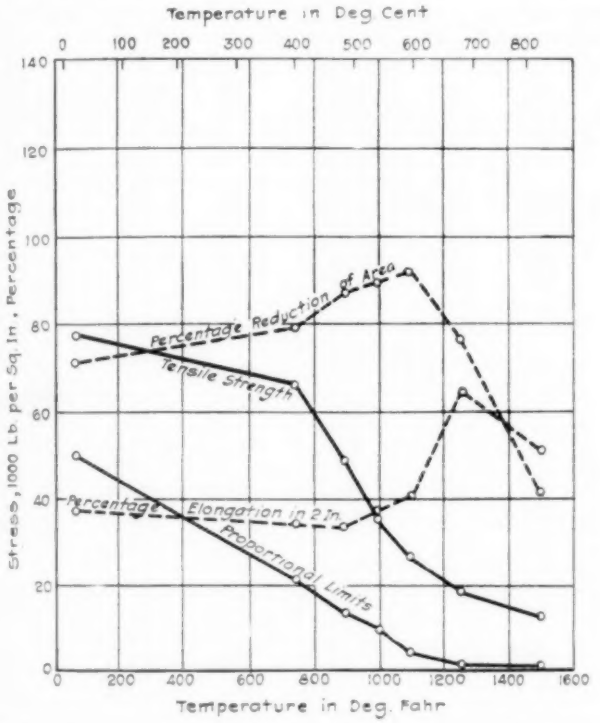

FIG. 1 TENSILE PROPERTIES OF A NICKEL STEEL AT ELEVATED TEMPERATURES

(Chemical composition: C 0.1, Mn 0.43, Si 0.16, S 0.013, P 0.024, Ni 4.95, Cr 0.02. Heat treatment: Normalized at 1500° F., 815°C.)

1100 deg. fahr. (593 deg. cent.), then quenching operations followed by a suitable draw will often result in greatly improved load-carrying properties at these moderate elevated temperatures. With this in view, six selected steels were subjected to various heat treatments and then tested at 1000 deg. fahr. (538 deg. cent.)

RESULTS OF TESTS

Nickel Steels. Nickel dissolves in steel at atmospheric temperature, especially in the ferrite crystals. Since nickel additions produce a marked lowering of the thermal critical range of iron, slowly cooled nickel steels can have various structures, as pearlitic, martensitic, or austenitic, depending on the relative amounts of nickel and carbon present.

With low-carbon nickel steels in the pearlitic zone, one of the effects of the addition of nickel is to reduce grain size. At atmospheric and slightly elevated temperatures this reduced grain size improves the strength of the alloy due to the presence of larger amounts of amorphous material. At elevated temperatures above the equicohesive temperature this reduced grain size results in a weakening of the alloy if the rate of application of the load is very small, due to increasing the amount of the weakest phase (amorphous) present.

Considerable percentages of nickel will produce an alloy with a structure entirely austenitic. Austenite, being a solid solution of carbon or iron carbide in gamma iron, fails to satisfy any of the four principles set forth for producing good load-carrying ability. For this reason one would not expect these steels to exhibit high tensile properties in any part of the temperature range. That this is the case will be shown in connection with the chromium-nickel steels.

The tensile properties at elevated temperatures of two nickel steels in the normalized state are given in Figs. 1 and 2. Tables 2 to 13 give the results for these steels, as well as for all the other steels to be considered. These two steels differ only in carbon content, one containing twice the amount of the other. In both cases the tensile-strength and proportional-limit values fall rapidly after 750 deg. fahr. (399 deg. cent.), which is probably close to the equicohesive temperature range, showing that the metal possesses little load-carrying ability above this temperature.

From the foregoing it can be concluded that plain nickel steels in the normalized state do not offer possibilities of having high load-carrying ability at temperatures much above 750 deg. fahr. (399 deg. cent.). Neither should various heat treatments be

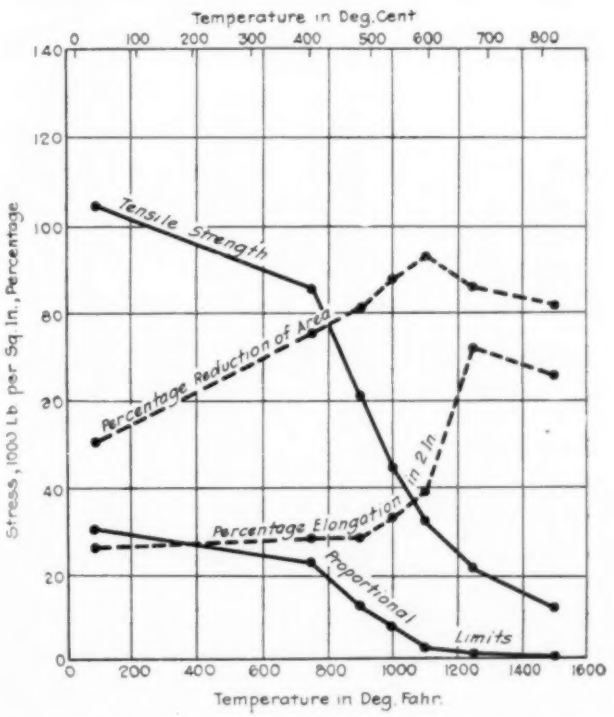

FIG. 2 TENSILE PROPERTIES OF A NICKEL STEEL AT ELEVATED TEMPERATURES

(Chemical composition: C 0.23, Mn 0.57, Si 0.23, S 0.028, P 0.04, Ni 4.95. Heat treatment: Normalized at 1500°F., 815° C.)

expected to greatly increase the stability of low-nickel steels at temperatures in the neighborhood of 1000 deg. fahr. (538 deg. cent.). That such is the case is shown in Figs. 3 to 5. It is true that the steel tested also contains some molybdenum, but the nickel is the predominating alloying element. As the quenching temperature is raised from 1450 deg. to 1650 deg. fahr. (788 deg. to 899 deg. cent.) a slight increase in hardness is obtained, but, as shown in Photomicrographs 1 to 6, this can be acounted for by refinement in grain size. The hardness, as determined by the Rockwell machine, shows a decrease as the quenching temperature is raised from 1650 deg. to 1750 deg. fahr. (899 deg. to 954 deg. cent.). From the photomicrographs this is again what should be expected, as the grain size increases as the temperature is raised above 1650 deg. fahr. (899 deg. cent.).

Considering the proportional-limit values obtained at 1000 deg. fahr. (538 deg. cent.) on this steel after various heat treatments, they are found to vary from 7500 lb. to 15,000 lb. per sq. in. As should be expected, the treatment producing the finest structure, quenching from 1650 deg. fahr. (899 deg. cent.), gives the lowest proportional-limit value. The highest values were obtained after quenching from 1750 deg. fahr. (954 deg. cent.) and also after normalizing from this same temperature. It should be observed that the specimens were in all cases drawn at 1200 deg. fahr. (649 deg. cent.) before being subjected to the tensile tests.

carbides that are deposited within the crystal will interfere with the process of crystalline slippage, and for that reason materially increase the stability of the alloy at all temperatures below the equicohesive temperature. The carbides which are precipitated at the grain boundaries will interfere with the plastic flow of this material, and so increase the load-carrying ability of the metal above the equicohesive temperature. Therefore steels which contain chromium in sufficient amounts manifest a much greater load-carrying stability at all temperatures than plain carbon steels or nickel steels.

Likewise, compositions which produce the free carbides show greater strength in the alloys in which they are found than compositions which throw the carbides into solid solution, as evidenced by the superior results of 8 per cent chromium, 8 per cent tungsten steel (Fig. 6) over and above those of two alloys, one containing 20 per cent chromium and 8 per cent nickel (Fig. 7) and the other 8 per cent of chromium and 20 per cent of nickel (Fig. 8). To be sure, in the first case 8 per cent tungsten is present and in the other two relatively large percentages of nickel, but the structure of the first steel shows free carbides while the last two are austenitic—solid-solution alloys.

Chromium-Nickel Steels. The addition of both chromium and nickel to a steel should give an alloy having properties which are a combination of those mentioned in the foregoing two cases. Nickel dissolving mainly in the iron will increase the resistance to oxidation of the alloy, while the chromium, being a former of carbides, will tend to increase the load-carrying ability of the alloy. Since nickel additions will produce a marked lowering of the thermal critical range of the iron, the same varieties of structure obtained in the case of straight nickel steels are again possible.

Short-time tensile tests were conducted on four chromium-nickel steels, the results of which are shown graphically in Figs. 7 to 10. The steels presented in Figs. 9 and 10 contain small enough amounts of the alloying elements so that in the annealed condition their structures are pearlitic. Those represented by Figs. 7 and 8, however, contain such large amounts of both chromium and nickel that even in the annealed state they are austenitic.

In a later section it will be shown that not only is the presence of free carbides necessary for the securing of the best load-carrying ability, but the size of these particles as regulated by heat treatment is equally important.

First considering the two lower alloy-containing steels of this group (Figs. 9 and 10), the carbon and nickel contents are nearly identical, while the chromium content of the first is approximately one-half that of the second. From what has been said, the second steel should show the highest proportional-limit and tensile-strength values throughout the temperature range considered. An examination of the figures will show that such is the case.

The results obtained with the two austenitic steels of this group show that the proportional-limit values for both steels throughout the entire temperature range are low. Neither are the tensile-strength values in most cases high. From the conditions presented when discussing the nickel steels, this is what was

expected; that is, low load-carrying ability throughout the entire temperature range. An interesting result in connection with these two steels is that even though the carbon, nickel, and chromium contents were varied considerably, the test results obtained in the two cases were nearly identical.

A comparison of the properties obtained with these four steels shows that if the best results, in regard to load-carrying ability at moderately elevated temperatures, are to be obtained, then the amounts of alloying elements added must not be sufficiently large to cause the steels to become austenitic.

Tungsten Steels. Tungsten combines with the carbon rather than with the iron when added to steel. Since it is similar in this respect to chromium, the tungsten steels should be expected to have load-carrying properties comparable to those of the chromium steels.

The effect of tungsten upon the properties of steel at high temperatures is shown in Fig. 6. It is true that this particular alloy also contains about 8 per cent chromium, but if these results be compared to those from Silcrome (Fig. 11), an alloy containing about the same amount of carbon and from 8 to 9 per cent chromium, then the effect of tungsten can be determined. It is true that Silcrome also contains from 3 to 4 per cent silicon, but this element, being similar to nickel in that it dissolves in the ferrite, does not greatly affect the load-carrying properties. A comparison of the results obtained with these two steels will show the tungsten-bearing steel to have the superior properties, especially at the higher temperatures.

Chromium-Tungsten Steels.[10] Chromium tungsten steels, owing to the presence of two carbide-forming elements, should exhibit good load-carrying properties at temperatures both above and below the equicohesive temperature. One steel of this class (Fig. 6), the results of which have already been discussed, was subjected to tests at temperatures up to 1500 deg. fahr. (816 deg. cent.). This same steel, in addition to two other steels of this group but differing from the first in that they contain much lower percentages of the alloying elements, were tested at 1000 deg. fahr. (538 deg. cent.) in various heat-treated conditions. The results obtained are presented in Figs. 12 to 19.

The steels containing the lower percentages of chromium and tungsten will first be considered. The variation in hardness with heat treatment of steel R is given in Fig. 12. As would be expected for steels of this class, the hardness can be varied considerably by proper heat treatment. In this case the hardness, as determined on both the Rockwell and Brinell machines, increases steadily as the quenching temperature is raised from 1400 deg. to 1800 deg. fahr. (760 deg. to 982 deg. cent.). This can readily be explained by the partial solution of the excess carbides and perhaps also by some refinement of grain size. Both normalizing and annealing treatments produce lower hardness values, a fact to be expected. The structures of this steel after the different heat treatments are shown in Photomicrographs 7 to 22, while

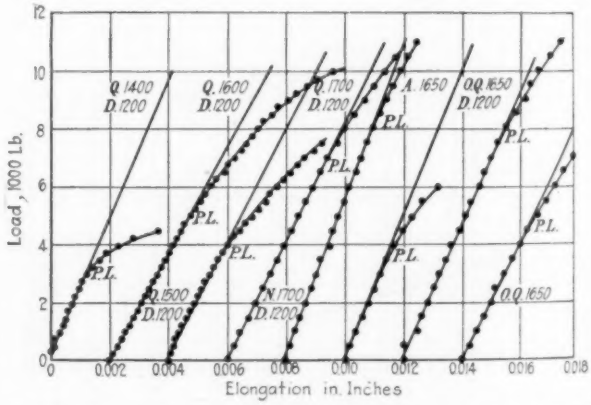

FIG. 14 STRESS-STRAIN CURVES OF 0.6% C, 1.43% CR, 2.19% W STEEL AT 1000°F., 538°C.

(Q., quenched in water; O. Q., quenched in oil; D., drawn; A., annealed; N., normalized.)

those of steels Ra and V (both low-chromium-tungsten steels) are shown in Photomicrographs 23 to 28.

As was the case with the hardness values, the proportional limit and tensile strength for steel R (Fig. 13) also increase rapidly as the quenching temperature is raised. Normalizing from 1200 deg. fahr. (927 deg. cent.) and quenching in oil from 1650 deg. fahr. (899 deg. cent.) gave the highest proportional-limit and tensile-strength values. There are two possible explanations as to why these treatments should give higher values than those obtained by water quenching, say, from 1700 deg. fahr. (927 deg. cent.). Either quenching in water from this high temperature

[10] The authors are indebted to Mr. Malcolm for calling their attention to the good load-carrying properties at elevated temperatures of chrome-tungsten steels of the "V" type.

produced quenching cracks invisible to the eye, an assumption supported by the fact that the specimen quenched in water from 1800 deg. fahr. (982 deg. cent.) was badly cracked, or else there is a critical size of both carbide particle and crystal giving the maximum strength values.

The proportional-limit results presented in Fig. 13 show that a rather large variation can be obtained depending upon the heat treatment. For example, the lowest value shown is approximately 15,000 lb. per sq. in., while with proper heat treatment this can be raised to 37,500 lb. per sq. in.

It will again be observed that all the quenched and normalized specimens with one exception were first drawn at 1200 deg. fahr. (649 deg. cent.) before being subjected to the high-temperature tensile test. The one exception was oil-quenched from 1650 deg. fahr. (899 deg. cent.) and then tested without a previous draw except that obtained in the testing furnace at 1000 deg. fahr. (538 deg. cent.). Both the proportional-limit and tensile-strength values in this particular case were lower than those obtained with the steel subjected to the same treatment but drawn at 1200 deg. fahr. (649 deg. cent.). This may be explained on the assumption that the residual stresses in the undrawn sample are of sufficient magnitude to lower the strength values.

Steels Ra and V (see Table 1) were tested at 1000 deg. fahr. (538 deg. cent.) in two heat-treated states. These steels were both subjected to the same treatments, and it is interesting to note that the steel with the lower chromium content gave the highest proportional-limit values, as shown in Fig. 15. This does not necessarily imply, however, that the same relationship would hold for all heat treatments, and it may be that this particular treatment is more favorable to the lower-chromium-carrying steel in that it produces the size of grain and carbide particle best suited to give maximum tensile properties. That this is probably the case is shown by the fact that when the quenching or normalizing temperature of the steel R, very similar to steel Ra, is raised, then the tensile properties approach very near to those shown by steel V at the lower quenching temperature.

Next considering the alloy containing higher proportions of both chromium and tungsten, Fig. 17 shows that even a greater increase in hardness values can be obtained than was the case with the first steels of this group. The hardness increases rapidly with quenching temperature, attaining a maximum value of 57 Rockwell C hardness for the specimen quenched from 2250 deg. fahr. (1232 deg. cent.). Again, this increased hardness can be

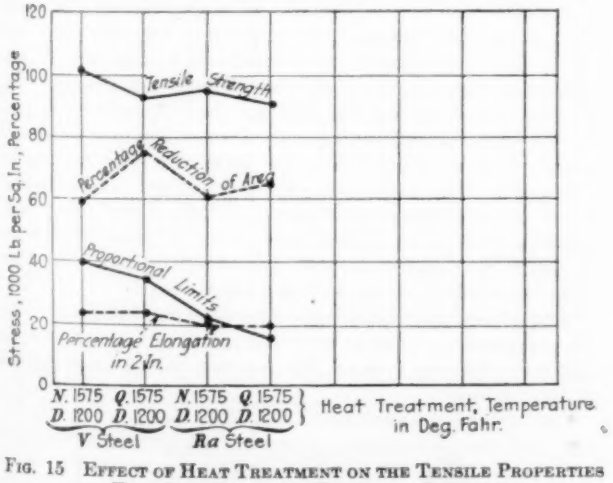

FIG. 15 EFFECT OF HEAT TREATMENT ON THE TENSILE PROPERTIES OF TWO LOW-CHROMIUM-TUNGSTEN STEELS AT 1000°F., 538°C.

accounted for on the basis of the partial solution of the excess carbides. The metallographic structures corresponding to the various heat treatments are shown in Photomicrographs 29 to 33. These pictures show a decrease in the size of the carbide particles as the quenching temperature is raised.

The variation in tensile properties with heat treatment is even more marked than in the case of the hardness values. The proportional-limit values vary from 17,500 lb. to 100,000 lb. per

sq. in. As far as the authors are aware, this latter value is one of the highest proportional-limit values ever reported at this temperature. With this same treatment, however, the ductibility of the metal, as shown by the reduction-of-area and percentage-elongation values, is very slight. Some of the other less drastic treatments, such as either quenching or normalizing from 1700 deg. fahr. (927 deg. cent.), give proportional-limit values almost as startling, being in the neighborhood of 50,000 lb. per sq. in. This is also a higher value than the authors have as yet seen reported.

The tensile-strength values are also remarkably high for this temperature. In the case of the specimen normalized from 1800 deg. fahr. (982 deg. cent.) and in the undrawn condition, the tensile strength could not be obtained as the proportional limit of the holders was reached before the load corresponding to the tensile strength of the specimen. All that can be said for the tensile strength in this case is that it lies above 140,000 lb. per sq. in., as it was at this stress that the holders began to give noticeably.

As was the case with one of the first steels of this group, two specimens with the same previous treatment (except that one was drawn and the other was not) were tested. In this case the specimen which had not been drawn except at 1000 deg. fahr. (538 deg. cent.) gave a higher proportional-limit value than the one previously drawn at 1200 deg. fahr. (649 deg. cent.). Although this appears contrary to the results obtained with the first steel, such may not be the case. In the first instance steels in the quenched condition were being considered, while in the latter the specimens were in the normalized state. If the same type of steel is considered in these two states, that in the normalized condition must be more stable than the one in the quenched condition, owing to the less drastic way in which its structure was obtained. Thus, even though the normalized steel was tested at the same temperatures at which it was drawn, its structure is possibly sufficiently stable to resist the action of the stress applied and the time.

In order to determine whether or not these proportional-limit values would be used as a criterion of the metal's load-carrying ability, a specimen after being normalized from a temperature of 1700 deg. fahr. (927 deg. cent.) was subjected to a load of 35,000 lb. per sq. in., and this load was maintained constant for 600 hr. The results of this test are shown in Fig. 20.

The results show that even after 600 hr. the elongation was only slightly over 0.002 in. If the test had been maintained longer, the metal might possibly have continued to have crept, but with no doubt at probably a slower rate than shown during the first 600 hr. Since the rate of creep is so small, it is evident that the metal would be able to withstand this stress for a considerable time.

Manganese Steels. Manganese is similar to both chromium and nickel in that when added to steel it unites with the carbon, forming double carbides, and also dissolves in the ferrite. The separation of free carbides is not obtained unless both the carbon and manganese are present in relatively large amounts. For this reason the addition of this element should increase the load-carrying ability of metals at elevated temperatures, but not to such a degree as chromium or tungsten.

The short-time tensile properties of various carbon-manganese steels at elevated temperatures are given in Figs. 21 to 24. For the purpose of comparison, the properties of a plain carbon steel containing the usual percentage of manganese is included. On the basis of proportional-limit findings, the 1.55 per cent manganese, 0.44 per cent carbon steel is the outstanding member of this group. This steel also shows the maximum reduction-of-area values over a large part of the temperature range. The maximum tensile-strength values were obtained with the 2.06 per cent manganese, 0.44 per cent carbon steel. None of these steels shows as high values, however, as were obtained with some of the other steels, especially in the higher temperature ranges.

The 1.55 per cent manganese, 0.44 per cent carbon steel was also subjected to different heat treatments and tested at 1000 deg. fahr. (538 deg. cent.). The results obtained are presented in Figs. 25 to 28.

The hardness values shown in Fig. 25 do not show much variation with heat treatment. Increasing the quenching temperature from 1450 deg. to 1550 deg. fahr. (788 deg. to 843 deg. cent.) slightly raises the hardness as shown by both the Rockwell and Brinell hardness numbers. This is undoubtedly due to grain refinement and some solution of the carbides. As the quenching temperature is further increased up to 1750 deg. fahr. (954 deg. cent.), the hardness, especially as obtained on the Brinell machine, falls off due to increase in grain size. The specimen normalized from 1750 deg. fahr. (954 deg. cent.) gives lower hardness values than the one subjected to this same treatment from 1550 deg. fahr. (843 deg. cent.). Again, this can be explained on the

basis of grain size. The lower values shown by the specimens subjected to the double-quenching treatment are evidently due to the higher drawing temperatures employed. The metallographic structures obtained with the various heat treatments are shown in Photomicrographs 34 to 40.

Neither do the tensile properties of this steel, shown in Fig. 26, vary to any great degree with heat treatment. As was the case with the hardness values, the proportional-limit and tensile-strength values increase as the quenching temperature is raised from 1450 deg. to 1550 deg. fahr. (788 deg. to 843 deg. cent.) and then decrease as the quenching temperature is increased further. In the case of the tensile tests, however, the highest proportional-limit values were obtained from the specimen normalized from 1550 deg. fahr. (843 deg. cent.) and the one subjected to the double-quenching treatment. The higher drawing temperatures

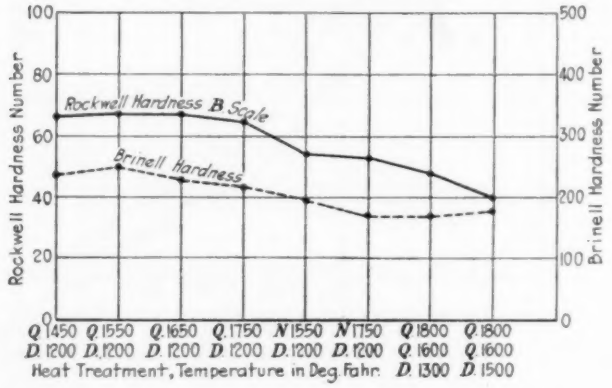

FIG. 25 EFFECT OF HEAT TREATMENT ON THE HARDNESS OF 0.41% C, 1.43% MN STEEL
(Q., quenched in water; D., drawn; N., normalized.)

(Q., quenched in water; D., drawn; N., normalized.)

were used in the steels subjected to the double-quenching treatments because for the lower draws no definite proportional-limit values could be obtained. In view of the fact that the other measurable factors obtained from the specimens with the lower draws were similar to those obtained with the 1300 deg. fahr. (704 deg. cent.) draw, we feel justified in the conclusions that the proportional-limit values for the lower draws would not be appreciably above those for the higher draws.

Certain investigators[11] have claimed much higher proportional-limit values for manganese steels of this type at 1000 deg. fahr. (538 deg. cent.) or temperatures in that neighborhood after being subjected to the double-quenching treatment shown in the figures. Since the highest values the authors were able to obtain are only in the neighborhood of 12,500 lb. per sq. in., it was decided to submit this steel to a creep test in order to determine which values were the more nearly correct. Accordingly, the specimen, after being given the preferred heat treatment recommended by those who reported the higher proportional-limit values, was subjected to a load of 10,000 lb. per sq. in., a value of the same order of magnitude as the proportional-limit value of the authors, but only about 25 per cent of the one reported by other investigators, and tested at 1000 deg. fahr. (538 deg. cent.).

The results of this long-time test are given in Fig. 28. It will be observed that the creep proceeds uniformly and rather rapidly for nearly 300 hr. and then the rate increases, the increased rate continuing up to rupture, which occurred at 435 hr. One of the outstanding facts about this test is the high degree of elongation obtained, 59 per cent. This is considerably more than is usually obtained in long-time tests.

The effect of heat treatment upon the tensile properties at 1000 deg. fahr. (538 deg. cent.) of another manganese steel was also investigated. This steel in addition to the manganese also contained some chromium. The results are given in Figs. 29 to 31.

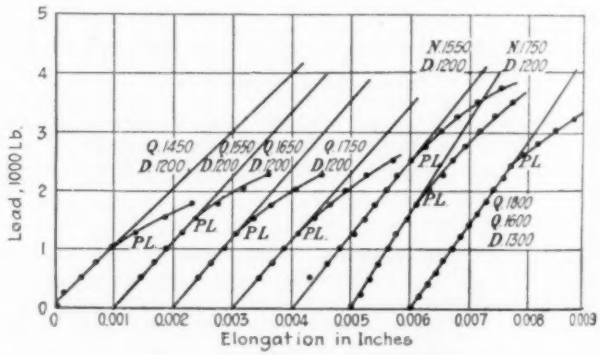

FIG. 27 STRESS-STRAIN CURVES OF 0.41% C, 1.43% MN STEEL AT 1000°F., 538°C.
(Q., quenched in water; D., drawn; N., normalized; P. L., proportional limits.)

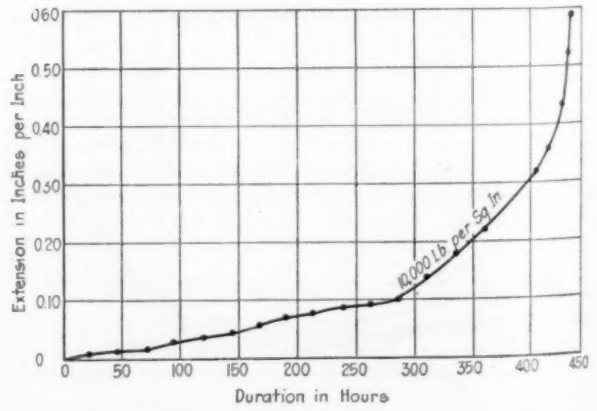

FIG. 28 FLOW OF HEAT-TREATED 0.44% C, 1.55% MN STEEL AT 1000°F., 538°C.
(Heat treatment: 8 hr. 1800°F., water-quenched; 1/2-hr. 1600°, water-quenched; drawn at 1000°F.)

The hardness values obtained with this steel differ from those of the straight-carbon manganese steel in that after increasing with quenching temperature up to 1600 deg. fahr. (871 deg. cent.)

[11] V. Krivobok, B. Larsens, W. Skinkle, and W. Masters, "Some Characteristics of Low-Carbon-Manganese Steel," Tech. Publ. No. 24, A.I.M.E., 30 pp., 1927.

they do not decrease but remain constant as the quenching temperature is further raised to 1800 deg. fahr. (982 deg. cent.). This is no doubt due to the partial solution of the chromium carbides, offsetting the increased grain size. This also explains why the specimen normalized from 1550 deg. fahr. (843 deg. cent.) exhibited lower values than the specimens normalized from 1750 deg. fahr. (954 deg. cent.). The structures corresponding to the various heat treatments are shown in Photomicrographs 41 to 45.

Heat treatment failed to materially increase the proportional-limit values of this steel. The specimens quenched at all temperatures above 1500 deg. fahr. (816 deg. cent.) were badly cracked in the quenching operation, and accordingly were useless for tensile-testing purposes. The maximum proportional-limit value obtained was approximately 14,000 lb. per sq. in., and this was obtained with the specimen normalized from 1550 deg. fahr. (843 deg. cent.).

Molybdenum and Vanadium Steels. Molybdenum and vanadium in that they combine with the carbon to form carbides when added to steel are both similar to chromium and so should, like chromium, increase the load-carrying ability of the alloys to which they are added. They both differ from chromium in that smaller percentages of these elements are required to produce the same change as in the case of the chromium alloys.

Vanadium in that it is a grain refiner is similar to nickel. In this respect it will, like nickel, increase the load-carrying ability at temperatures below the equicohesive temperature, but for temperatures above will have the opposite effect. It is also claimed that vanadium is beneficial in that it reduces intercrystalline brittleness, a condition often encountered in heat-resisting alloys.

No tests were conducted on steels containing only vanadium as the alloying element, but the low-chromium-tungsten steel considered in a previous section contained an appreciable amount of this element.

Likewise, no tests were conducted on steels containing only molybdenum as the alloying element. The effect of heat treatment on the tensile properties at 1000 deg. fahr. (538 deg. cent.) of a nickel-molybdenum steel was investigated, and these results were also given in a previous section.

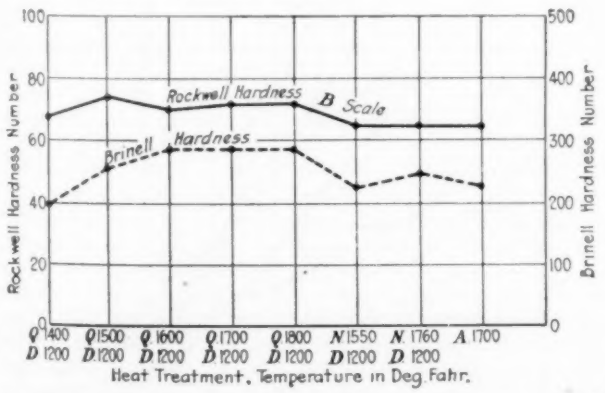

FIG. 29 EFFECT OF HEAT TREATMENT ON THE HARDNESS OF 0.49% C, 1.21% MN, 0.33% CR STEEL

(Q., quenched in water; D., drawn; A., annealed; N., normalized.)

Chromium-Aluminum Steel. The effect of heat treatment upon the tensile properties at 1000 deg. fahr. (538 deg. cent.) of a chromium-aluminum steel was also investigated. The aluminum, dissolving mainly in the iron, was not expected to greatly affect the load-carrying ability, but it was desired to determine the joint action of both chromium and aluminum on the high-temperature properties of steel. The results obtained are shown in Figs. 32 to 34.

The structures corresponding to the various heat treatments are given in Photomicrographs 46 to 54. The pictures portray some interesting conditions. For instance, the samples quenched either in oil or water from 1650 deg. fahr. (899 deg. cent.) are

(Q., quenched in water; D., drawn; A., annealed; N., normalized; P. L., proportional limits.)

completely surrounded with a ring of polyhedral grains of metal resembling either ferrite or austenite. The specimen water-quenched from 1700 deg. fahr. (927 deg. cent.), as well as the one annealed from the same temperature, contains a large amount of this same constituent, while the specimen normalized from this temperature consists entirely of it. That this constituent is relatively hard is shown by the hardness value obtained from the normalized specimen.

As would be expected from the photomicrographs, the hardness of this alloy can be varied considerably, depending upon the heat treatment. The increased hardness can be accounted for on the assumption that either the chromium carbides or else complex compounds of chromium, aluminum, and carbon are either partially or wholly dissolved in the ferrite as the quenching temperature is raised. In the case of the normalized specimen all

the carbon and chromium seem to have disappeared, and must be in solution in the polyhedral crystals shown.

As in the case of the hardness values, the tensile strength varies considerably depending upon the treatment, but the proportional limits remain nearly constant regardless of the treatment. The maximum proportional-limit values were obtained by oil-quenching from 1550 deg. fahr. (843 deg. cent.) or water-quenching from 1550 deg. fahr. (843 deg. cent.), or 1750 deg. fahr. (954 deg. cent.). The minimum value was obtained by oil-quenching from 165 deg. fahr. (899 deg. cent.).

Conclusions

This paper has endeavored to throw additional light on, and to furnish further data with respect to, the properties of metals at

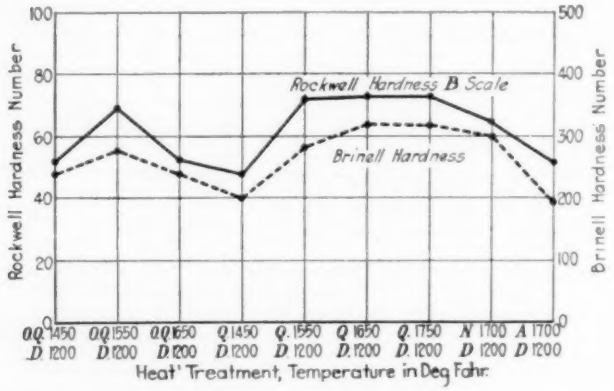

Fig. 32 Effect of Heat Treatment on the Hardness of 0.5% C, 1.6% Cr, 1% Al Steel

(Q., quenched in water; O. Q., quenched in oil; D., drawn; A., annealed; N., normalized.)

elevated temperatures. It has done this by (1) advancing a theory or hypothesis accounting for the stability of the various types of steels at elevated temperatures, and (2) by giving specific data on various types of alloy steels, showing (*a*) the effect of elevated temperatures on various types of steels when in an annealed or normalized state, and (*b*) the effect of heat treatments which would presumably bring out the best possible proportional-limit values on various types of steels when tested at a temperature of 1000 deg. fahr. (538 deg. cent.).

The hypothesis advanced to account for the influence of the different alloying elements on steels when at elevated temperatures is set forth in two parts, one dealing with the conditions below the equicohesive temperature and the other dealing with conditions when above this temperature. The hypothesis follows.

Heat treatment: All steels normalized or annealed.)

Below the Equicohesive Temperature.

1 The addition or formation of any element, compound, or constituent which does not enter into solid solution with the

matrix, but which by the very nature of its presence interferes with the crystal slippage, will tend to increase the load-carrying ability of the material of which it forms a part.

2 The addition or formation of any element, compound, or constituent which tends to increase the amount of amorphous material will increase the load-carrying ability of the material of which it forms a part.

Above the Equicohesive Temperature.

1 The addition or formation of any element, compound, or constituent which tends to decrease the relative proportion of amorphous material to crystalline material will increase the load-carrying ability of the material of which it forms a part.

2 The addition or formation of any element, compound, or constituent which strengthens the grain boundaries by interfering with plastic flow will increase the load-carrying ability of the material of which it forms a part.

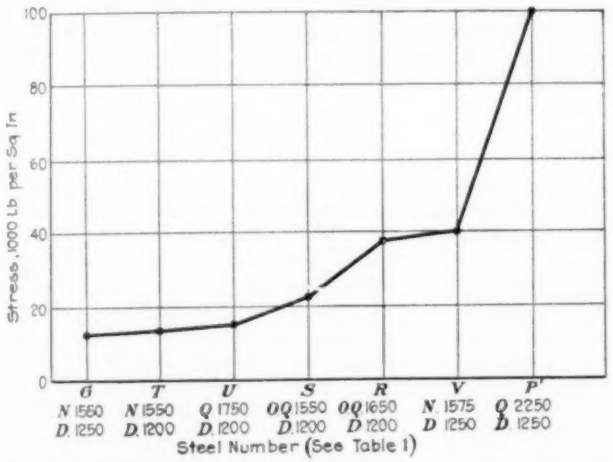

FIG. 36 MAXIMUM PROPORTIONAL-LIMIT VALUES OBTAINED AT 1000°F., 538°C, WITH VARIOUS SELECTED STEELS

Two views are held by those using materials at elevated temperature. One is that all such materials should be used in the annealed or normalized state. The other is that, under certain conditions and with certain types of uses, materials may be employed which have been subjected to heat treatments that bring out the highest possible short-time characteristics at elevated temperatures. All will agree that the greatest stability is in material in the normalized or annealed condition. For that reason a very considerable amount of work done in this laboratory has been on materials in one or the other of these two conditions. In Fig. 35 are given the proportional-limit values at various elevated temperatures from steels which were initially in a normalized or annealed condition. Though the values at atmospheric temperatures are given, for the purposes considered only those values at 750 deg. fahr. (399 deg. cent.) or higher should be considered. As a matter of fact, the best criterion for the stability characteristics of these alloy steels will be secured by studying the values at 1000 deg. fahr. (538 deg. cent.) and higher. With such an analysis, the steel designated as P' and containing 7.93 per cent chromium and 7.70 per cent tungsten stands out above all of the other steels.

In Fig. 36 are given the highest proportional limits at 1000 deg. fahr. (538 deg. cent.) that it is possible to secure on various alloy steels which had been subjected to such a treatment as would bring out the highest possible proportional-limit value. The manganese steel of which the authors made favorable mention in a previous paper does not possess as high proportional-limit values as any of the other steels which were subjected to this study. Every possible effort was made to obtain as high a proportional limit as possible for this steel, but the authors were not able to obtain values in excess of 12,500 lb. per sq. in. Particular attention is directed to the steel designated as P', which contains 7.93 per cent chromium and 7.70 per cent tungsten. By quenching this steel from 2250 deg. fahr. (1232 deg. cent.) a proportional limit of 100,000 lb. was obtained. So far as the authors are aware, this is the highest proportional limit which has as yet been recorded at this temperature. On the steel designated as R, which is similar to the V steel (a type recommended by one of the largest valve-manufacturing companies), 1.43 per cent chromium and 2.19 per cent tungsten, a proportional limit at 1000 deg. fahr. (538 deg. cent.) of 37,500 lb. was obtained. Because of the lower chromium and tungsten values this should prove to be both a cheaper and a more readily workable steel. Therefore steel of this type is recommended when moderately high-temperature values are desired, although for the higher temperatures a steel of the P' type should manifest the maximum stability characteristics.

Discussion

L. W. SPRING.[12] With reference to the 8 per cent tungsten-8 per cent chromium steel mentioned, we have flow tests under way which show it to stand high among the alloys in the matter of flow resistance. Previous tests to determine retention of hardness when heated for a long time showed that this chrome-tungsten alloy with 0.57 per cent carbon, quenching from 2100 deg. fahr. and held continuously at 900 deg. temperature for 300 hours, advanced in hardness from 590 Brinell to 630 Brinell. Brinelling this piece every week, we found that after a total of 2000 hours it had retained its hardness of 630 Brinell, after which it gradually fell off, until after a total of 2900 hours at 900 deg. the hardness was 510 Brinell, at which time the test was discontinued. The 0.30 per cent carbon alloy with this tungsten and chromium had much the same general characteristics, but, as expected, it does not hold its hardness so long. The foregoing results were far better than most of the alloys tested, the 0.57 per cent carbon alloy described being second only to quenched high-speed steel of 17 per cent tungsten, 4 per cent chromium, and 0.60 per cent carbon. Other alloys tested were 13 per cent chromium–0.12 per cent carbon stainless iron, 13 per cent chromium–2 per cent tungsten steel containing 1 per cent molybdenum and 0.54 per cent carbon, 13 per cent chromium–4 per cent tungsten, 17 per cent chromium–1 per cent carbon alloy, 8 per cent chromium–2 per cent tungsten and 3 per cent silicon, none of which held their hardness as well as the 8 per cent tungsten–8 per cent chromium or the high-speed steel. Duplicate tests holding the temperature continuously at 750 deg. instead of 900 deg. showed all of these alloys capable of retaining their hardness more or less indefinitely.
